Computed tomography imaging in the context of transcatheter aortic valve implantation (TAVI) / transcatheter aortic valve replacement (TAVR): An expert consensus document of the Society of Cardiovascular Computed Tomography

1. Preamble/introduction

Since the publication of the first expert consensus document on computed tomography imaging before transcatheter aortic valve implantation (TAVI)/transcatheter aortic valve replacement (TAVR) by the Society of Cardiovascular Computed Tomography (SCCT) in 2012, there has been tremendous advancement in the field. Significant technological advancements and a wealth of trial data have led to deep integration of TAVI/TAVR and CT imaging into clinical practice. The indications for TAVI/TAVR as the treatment strategy for patients with symptomatic severe aortic stenosis (AS) has expanded from those who are ineligible for surgery or high risk surgical candidates to also now include those at intermediate risk for conventional surgical valve replacement.

Advances in non-invasive imaging have supported growth and maturation of the field. Clinical outcomes have improved based on the thoughtful integration of advanced non-invasive imaging into patient selection, treatment planning, device selection, and device positioning. While computed tomography (CT) was initially used primarily for the anatomical information of the aortic root, followed by a commonly non-ECG synchronized CTA data acquisition of the aorto/ilio/femoral vasculature for assessment of the access vasculature. Ideally, both acquisitions are combined in a comprehensive scanning protocol with a single contrast administration. The sequence of patient preparation and the relevant principles of CT data acquisition will be explained in brief below.

2.1. Scan strategy and scan coverage

In general, two different approaches are used to combine the ECG-synchronized data set of the aortic root structures and the non-ECG-synchronized computed tomography angiography (CTA) of the aorto/ilio/femoral vasculature into one comprehensive acquisition protocol:

1) Cardiac ECG-synchronized data set of the aortic root and heart followed by a non-ECG-synchronized CTA of the thorax, abdomen, and pelvis. Although this approach can result in repeat data acquisition of the aortic root and cardiac structures, the time-intensive ECG-synchronized data acquisition is kept to a minimum, allowing for a reduction of the overall contrast dose. Furthermore, limiting the ECG-synchronized data acquisition decreases the radiation dose-intensive portion of the examination, despite parts of the scan range possibly being covered twice. The ECG-synchronized data set should at least cover the aortic root, but can include the entire heart.

2) ECG-synchronized data acquisition of the thorax followed by a non-ECG-synchronized CTA of the abdomen and pelvis. A disadvantage of this approach is the higher radiation dose, and the relatively long acquisition time required for the entire thorax with potential need for larger contrast dose and risk of breathing artifacts.

The scanner hardware employed may further dictate which of these approaches is employed.
2.2. ECG-synchronized CTA of the aortic root and heart - acquisition technique

The selected acquisition mode as well as exposure settings should account for dynamic changes of aortic root geometry and dimensions throughout the cardiac cycle. Given that aortic root dimensions are commonly larger in systole,\textsuperscript{10,13} and that most sizing algorithms for transcatheter heart valves are based on systolic dimensions, systolic scan coverage is recommended. However, diastolic information may be valuable for evaluation of aortic valve morphology and rarely, the largest dimensions of the annulus may occur in diastole in the setting of reversed dynamism in sepsal hypertrophy.\textsuperscript{11-13} For that reason, image acquisition covering the entire cardiac cycle should be considered. This wider phase of acquisition offering systolic and diastolic data may be particularly useful if systolic reconstructions are degraded by artifact. Scan coverage should at least include the aortic root but coverage of the entire heart is beneficial.

For CT systems with limited detector coverage, i.e. systems that cannot cover the entire aortic root within one rotation, retrospective ECG-gating allows coverage of the entire cardiac cycle, while offering most flexibility regarding data salvage by means of ECG-editing. Dose-modulation may be used to mitigate the high radiation exposure, with peak tube current applied during at least systole. However, tube current outside of the peak acquisition window should be maintained to such a level as to allow for characterization of the aortic annulus and valve. Prospective ECG-triggering may constitute an alternative. However, this technique is more susceptible to step-artifacts in the setting of increased heart rate variability (e.g. premature contractions, atrial fibrillation) with the risk of rendering images inadequate for quantitative analysis, and does not allow for image salvage by means of ECG-editing. If employed, the acquisition window should be kept wide to cover at least systole.

For systems with whole-heart coverage (i.e. 16cm detector coverage), an ECG-gated one beat acquisition should be employed. Peak tube current should be applied at least during systole, with consideration for coverage of the entire cardiac cycle. Recommended acquisition mode for employed scanner systems are listed in Table 1.

Other acquisition settings, in particular tube voltage and tube current settings should follow institutional policies and preferences but should allow for acquisition of image data with sufficiently low image noise to ensure fully diagnostic image quality in thin-slice reconstructions. Most scanner systems require a brief intermission between the ECG-synchronized and non-synchronized data acquisition to reposition the table and adjust scan settings. This needs to be accounted for by the contrast administration protocol in order to allow for sufficient contrast attenuation of the aorto/ilio/femoral vasculature.

2.4. Radiation parameters and considerations

Acquisition parameters should employ the ‘As low as reasonably achievable’ (ALARA) principle.\textsuperscript{9} According to recommendations on radiation protection in cardiovascular CT by the Society of Cardiovascular Computed Tomography (SCCT), a tube potential of 100 kV should be considered for patients weighing ≤ 90 kg or with a body mass index (BMI) ≤ 30 kg/m\textsuperscript{2}; whereas a tube potential of 120 kV is usually indicated for patients weighing > 90 kg and with a BMI > 30 kg/m\textsuperscript{2}.\textsuperscript{9} Tube current should be adjusted, based on individual patient’s size, to the lowest setting that guarantees acceptable image quality.\textsuperscript{7} Expected increase in image noise with lower tube current can be mitigated with the use of iterative image reconstruction. The majority of commercially available scanner systems provide software algorithms to automatically adjust exposure parameters to the patient’s body habitus within defined boundaries.

To date, patients being treated with TAVI/TAVR have predominantly been septuagenarians and octogenarians with the mean age of patients receiving TAVI/TAVR being 79.8–83.6 years in high and intermediate risk trials, 79.1 years in the all comer NOTION trial and 80.1 years in the low risk OBSERVANT registry with mean age not expected to drop below 75 years of age in low risk cohorts.\textsuperscript{6,15,17} As a result the primary concern for the imaging protocol should be to ensure diagnostic quality images, and to minimize the need for repeat CTA and repeat contrast administration. In case of younger patients, the most effective mode for reducing radiation dose is to minimize the scan volume performed using ECG-synchronization as well as limiting the peak dose coverage when using dose modulation. Prospectively triggered acquisitions focusing on systole can be considered a reasonable alternative particularly in patients with lower and regular heart rates.

2.5. Contrast administration

Intravenous contrast administration is required for assessment of the aortic root anatomy and peripheral vasculature. In particular accurate identification of the annular plane and contour, as well as accurate evaluation of the access route requires sufficient contrast enhancement. Optimal images require high intra-arterial opacification, and attenuation values should exceed 250 Hounsfield units.\textsuperscript{9}

Use of dual head injector and antecubital IV access is recommended.

For a more comprehensive evaluation the scan range can be extended cephalad to fully include the subclavian arteries for assessment of this alternative access route.\textsuperscript{15} Most commonly, this CTA is performed employing a helical, non-ECG synchronized data acquisition immediately following the ECG-synchronized data set of the aortic root. Other acquisition settings, in particular tube voltage and tube current settings should follow institutional policies and preferences, but should allow for acquisition of image data with sufficiently low image noise to ensure fully diagnostic image quality in thin-slice reconstructions. Most scanner systems require a brief intermission between the ECG-synchronized and non-synchronized data acquisition to reposition the table and adjust scan settings. This needs to be accounted for by the contrast administration protocol in order to allow for sufficient contrast attenuation of the aorto/ilio/femoral vasculature.
and should be considered according to institutional protocols. In patients with impaired kidney function total amount of contrast should be reduced to a minimum while still ensuring sufficient contrast attenuation. This can be achieved using lower flow rates as low as 3 ml/sec., low tube potential (down to 80kVp), multiphasic contrast injection protocols and diligent optimization of the scanning protocol and timing. Prospective high pitch imaging is an alternative useful adjunct to low contrast dose whilst maintaining image quality.

### 2.6. Patient preparation

Patients should be instructed to maintain an adequate fluid intake prior to the examination. In patients with eGFR ≥30mL/min/1.73 m², even in the presence of concomitant risk factors, a regime of no prophylaxis has been shown to be non-inferior to IV hydration for the prevention of acute kidney injury. In cases with severe renal impairment, cautious pre-scan intravenous hydration may be beneficial and should be considered according to institutional protocols.

For administration of iodinated contrast, at least a 20-gauge intravenous access should be placed, preferably in an antecubital vein. Although elevated heart rates may negatively affect image quality, in particular when using single-source systems, it is not recommended to perform routine heart rate control with beta blockade, given the risk of potential side effects in patients with severe aortic stenosis. Administration of sublingual nitrates in patients with significant AS is contraindicated.

### 2.7. Non-contrast cardiac CT

Non-contrast evaluation of the aortic root is not an essential component of the TAVI/TAVR work-up, but may have utility in the setting of uncertain AS severity where the aortic valve calcium score is known to correlate well with aortic stenosis severity. This is of most use in suspected low-flow low-gradient AS in those with either a preserved or reduced ejection fraction with no flow reserve on dobutamine stress echocardiography. In this situation, the calcium score of the valve can be used to adjudicate the presence or absence of severe aortic stenosis. CT acquisition for the assessment of aortic valve calcification should be performed using the same acquisition parameters used for assessment of the coronary artery calcium score although further studies are underway to determine thresholds for post-contrast CT scans. The valvular calcification is then contoured utilizing standard coronary artery calcium scoring software, with contours applied around the valvular calcification, ensuring the exclusion of aortic wall, left ventricular outflow tract (LVOT) or coronary calcification. Sex specific thresholds are utilized, with an Agatston score of ≥3000 in men and ≥1600 in women making severe aortic stenosis very likely, while an Agatston score of < 1600 in men and < 800 in women makes it highly unlikely. Non-contrast cardiac CT should not be used for annular sizing due to the inability to identify the cusp hinge points and thus the inability to accurately and reproducibly define the annular plane.

### 2.8. Reconstruction technique

ECG-synchronized CT data should be reconstructed as an axial, thinsliced multiphasic data set, also referred to as ‘cine’, ‘functional’ or ‘4D-CT’. Multiphasic data sets should be reconstructed with < 1mm slice thickness using a small reconstruction field of view encompassing only the cardiac structures and a 512 × 512 matrix in order to optimize spatial resolution. Prior to image reconstruction, the ECG-tracing should be manually reviewed to ensure correct R-peak identification by the scanning system, with manual correction if required. When using retrospective ECG-gating, ECG-editing should be considered to reduce artifacts in the setting of increased heart rate variability, e.g. in premature contractions or atrial fibrillation. For relative image reconstruction, reconstruction interval should be spaced at ≤10% intervals across the acquired portion of the cardiac cycle. Alternatively, if available on the employed scanning system, multiphasic data sets can be reconstructed using absolute image reconstruction at 50msec increments, which result in superior image quality in patients with increased heart rate variability such as in atrial fibrillation.

The non-ECG synchronized CTA of the aorto/ilio/femoral vasculature should be reconstructed as an axial data set with ±1.5 mm slice thickness using a small reconstruction field of view encompassing only the cardiac structures and a 512 × 512 matrix in order to optimize spatial resolution. Prior to image reconstruction, the ECG-tracing should be manually reviewed to ensure correct R-peak identification by the scanning system, with manual correction if required. When using retrospective ECG-gating, ECG-editing should be considered to reduce artifacts in the setting of increased heart rate variability, e.g. in premature contractions or atrial fibrillation. For relative image reconstruction, reconstruction interval should be spaced at ≤10% intervals across the acquired portion of the cardiac cycle. Alternatively, if available on the employed scanning system, multiphasic data sets can be reconstructed using absolute image reconstruction at 50msec increments, which result in superior image quality in patients with increased heart rate variability such as in atrial fibrillation.
thickness in a contiguous or overlapping fashion, using a large field of view and either filtered back projection or iterative reconstruction.

3. Aortic root: anatomical definitions and assessment

Precise understanding and assessment of the anatomy of the aortic valvular complex is crucial to achieve optimal sizing of transcatheter heart valves (THV) as well as to identify patients at increased anatomical risk for adverse events such as coronary artery occlusion. The aortic root is an extension of the left ventricular outflow tract, extending from the basal attachment of the aortic valve cusps within the LVOT to their peripheral attachment at the level of the sinotubular junction. Its components are the sinuses of Valsalva, the fibrous interleaflet triangles and the valvular cusps themselves.\textsuperscript{30,31}

3.1. Aortic annulus: definitions and measurement techniques

For the purpose of anatomical sizing in the context of TAVI/TAVR, the aortic annulus is defined as the luminal contour within a virtual plane aligned with the most basal attachment points of the three aortic valve cusps (sometimes referred to as the ‘basal hinge points’). Quantitative assessment requires the accurate identification of each of these three points in turn to create a plane that transects all three. Identification and positioning of the annular plane can be performed:

1. Manually, using standard multiplanar reformats, the technique for which is shown in Fig. 1.
2. Using a software-based facilitating workflow with manual identification of the basal hinge points by placing marker points with subsequent positioning of the plane by the software.

While facilitated or semi-automated workflows may be used, the interpreter analyzing the imaging must confirm the accuracy of the generated annular plane and perform manual corrections if required. For a summary of recommendations please see Table 5.

For quantification of annular dimensions, various measurement tools are available across software platforms (Fig. 2):

1. Cubic spline interpolation: Manually placed segmentation points which are automatically connected by a cubic spline interpolation.
2. Polygon: Manually placed segmentation points which are automatically connected by straight lines.
3. Attenuation/Hounsfield unit based contour detection.
4. Freehand contour: The annular contour is traced manually with the cursor.

All techniques commonly provide the annular area in either [mm\(^2\)] or [cm\(^2\)]. Cubic spline interpolation commonly provide also the annular perimeter in [mm]. Polygon tools may underestimate the annular perimeter when compared to cubic spline interpolation, given the straight line connection of the segmentation points. Attenuation/ Hounsfield unit based contour detection as well as freehand contour techniques may, depending on the software platform, result in jagged contours, artificially increasing the reported perimeter. For this reason, smoothing algorithms may be used to create a rather spline-like contour. Perimeter values should only be reported when using these measurement tools, if the contour is smoothed.

Most contouring tools provide short and long axis dimensions in [mm] which are automatically derived by software algorithms, although methodology differ between platforms (e.g. perpendicular versus non-perpendicular orientation; intersection centric versus eccentric). Alternative, manual caliper measurements can be performed. Overall, short and long axis dimensions inform on the eccentricity of the annular cross-sectional dimensions. Importantly, manual caliper measurements should not be used to assess overall annular dimensions instead of contouring tools.

Independent of the measurement technique used, the annular contour should be drawn along the blood-pool tissue interface, carefully avoiding presence of any tissue within the contour and avoiding any contrast outside of the contour. In case of annular calcification, irrespective of crescent or protruding distribution, the contour should be drawn in a harmonic fashion as if no calcium is present, as this aids in measurement standardization.

3.2. Annular dynamism & phase selection

During systole, conformational changes with decrease in ellipticity as well as stretch of the annular contour commonly result in a larger annular area and perimeter as compared to diastole (Fig. 3).\textsuperscript{16,32} This annular dynamism has significant implications for sizing with the potential for unintended undersizing if sizing is based on diastolic assessment.\textsuperscript{12,33}

Annular measurements should be performed using the ECG-synchronized, ideally multiphasic dataset. Identifying the reconstruction phase with largest annular dimensions is important given the implications for device sizing. The annular anatomy should be reviewed throughout the available portion of the cardiac cycle and the phase yielding the largest dimensions with adequate image quality should be visually identified. Importantly, changes in the orientation of the annular plane throughout the cardiac cycle may require adjustment of the imaging plane. Care should be taken to identify a reconstruction phase with adequate image quality, ie. sharp depiction of the annular contour. Reconstruction phases with inadequate depiction of the annular contour, ie. blur or double contours, should be avoided.

3.3. Image quality

Reliable quantification of aortic annular and aortic root dimensions requires adequate image quality defined by sharp depiction of the annular contour given sufficient contrast attenuation, noise preposition as well as absence of motion artifacts, double contours, or stair step artifacts. Image quality can be rated using a subjective, qualitative grading scale as good, fair and poor (non-diagnostic) (Table 4).

3.4. Landing zone calcium

The device landing zone comprises the valve cusps, aortic annulus and LVOT.\textsuperscript{34,35} It has been demonstrated that the presence of severe calcification of the LVOT and aortic valve is associated with increased risk of paravalvular regurgitation particularly when calcium protrudes into the LVOT.\textsuperscript{36-40} In clinical practice, the description of annular (within annular plane) and sub-annular (upper 4–5mm of the LVOT where device gets into contact) calcification is almost exclusively performed in a subjective, qualitative fashion graded as none, mild, moderate, severe based on the circumferential extent, the depth of extension inferiorly into the LVOT and the thickness of the calcification projecting radially into the LVOT (Fig. 4). Annular and sub-annular calcification should be described as crescent/flat/adherent or protruding as well as its relation to the aortic cusps. The location of calcification within the LVOT varies significantly across severe aortic stenosis patients. The region below the non-coronary and the left coronary cusps, including the intervalvular fibrosa, is most frequently affected. Large protruding nodules of calcification may increase the risk of annular rupture particularly with balloon expandable valves and should thus be specifically mentioned in the report.\textsuperscript{12} Finally, the device landing zone is in close spatial relationship with the conduction system which may be compressed and damaged, causing atrioventricular block and need for pacemaker implantation especially in the
**Step & Description** | **Multiplanar reformats**
--- | ---
**Step 1:** Start out with multi-planar images in default axial, sagittal, and coronal orientation; center cross-hairs onto the aortic valve.

**Step 2:** Align the cross-hairs in the sagittal and coronal views with the long axis of the aortic root; the resulting double oblique transverse view will depict the aortic valve en face.

**Step 3:** Move the double oblique transverse plane up and down to identify the lowest insertion point of the right coronary cusp which is usually located at about 1 o’clock. Position the center of the cross-hairs exactly at the most basal insertion point of the right coronary cusp (white arrow head).

**Step 4:** Rotate the cross-hairs counter-clock-wise without moving up and down while maintaining its center position so that the formerly coronal view (here red cross-hair) transects the lowest insertion point of the non-coronary cusp, which is located at approximately 8 o’clock (white arrow head).

**Step 5:** The formerly coronal, now double-oblique view will show the lowest insertion point both of the right coronary cusp and the non-coronary cusp (white arrow heads). In this view, rotate the (here orange) cross-hair indicating the double-oblique transverse view to transect exactly through the most basal insertion point of the non-coronary cusps. Once this is achieved, the transverse double oblique plane will contain two of the three lowest cusp insertion points.

**Step 6:** In the formerly sagittal view, rotate (without moving it) the cross-hair of the transverse double oblique plane (here orange) until the lowest insertion point of the left coronary cusp just barely appears in the double oblique transverse view (white arrow head). Now, the formerly axial plane is exactly aligned with the lowest cusp insertion points of all three aortic cusps and represents both the orientation as well as the level of the annular plane.

**Step 7:** Measurements of aortic annulus dimensions should be performed in the annular plane by means of a contouring tool.

---

**Fig. 1.** Identifying the annular plane in aortic valves with tricuspid morphology.
context of severe calcification of the subannular device landing zone, with this effect amplified in the presence of pre-existent right bundle branch block.\textsuperscript{41,42} Unusual findings with regard to these variables should be included in the report.

### 3.5. Valve morphology: definition and measurement techniques

Bicuspid aortic valves (BAV) are found in up to 6\% of patients presenting for TAVI/TAVR, and are associated with lower device success rates and higher rates of paravalvular regurgitation, but similar outcomes.\textsuperscript{43,44} Numerous classifications of BAV morphology exist including that of Sievers and Schmidtke\textsuperscript{45} (which essentially focuses on the number of raphes (0, 1 or 2 for the respective types). More recently, a TAVI/TAVR-directed simplified BAV classification has been proposed. It distinguishes BAV morphology regarding (a) number of commissures (two vs. three) and (b) presence or absence of a raphe, yielding 3 broad morphologies: (1) tricommissural, in clinical routine often referred to as ‘functional’ or ‘acquired’ BAV (not part of Sievers classification); (2)

Fig. 3. Dynamic changes of the aortic annulus throughout the cardiac cycle. Example with common anatomy and regular dynamism (upper row), demonstrating larger dimensions in systole than diastole, in parts due to bulging of the aortomitral continuity (dashed yellow line) towards the left atrium in systole and flattening in diastole. The lower row shows an example of septal hypertrophy with smaller annular dimensions in systole than diastole, in part due bulging of the basal septum (dashed blue line) into the annulus during systole. (For interpretation of the references to colour in this figure legend, the reader is referred to the Web version of this article.)
bicommissural raphe-type (equivalent to Sievers Type 1); and (3) bicommissural non raphe-type (equivalent to Sievers Type 0) (Fig. 5). Ascending aortic dilation and aneurysms are less common in ‘tricommisural’ BAV than ‘bicommissural’ BAV. Within ‘bicommissural’ BAV, the non-raphe type BAV typically exhibits larger sinus diameters despite smaller anuli. For bicommissural raphe-type BAV, raphe characteristics may also be described qualitatively and quantitatively including raphe length and raphe calcium. Valve morphology should be systematically characterized and reported in all pre-TAVI/TAVR CT reports. Further, the degree of raphe calcification should be reported, e.g. using a qualitative scale (mild, moderate, severe), as severe raphe calcification may relate to higher likelihood of paravalvular regurgitation.

Defining the annulus may be a challenge in BAV, particularly in Sievers Type 0 BAVs where there are only two hinge points to define the annular plane. The technique used for tricuspid aortic valves therefore frequently needs to be adjusted as detailed in Fig. 6. The annulus size should be measured and reported in the same fashion for BAV as for tricuspid aortic valves. The ascending aorta should also be examined in BAV due to the association between BAV and aortopathy.

### 3.6. Coronary ostial height and Sinus of Valsalva assessment

Coronary occlusion is a feared complication of TAVI/TAVR which, while relatively rare with an incidence of 0.66%, is associated with a poor clinical outcome with a reported 30 day mortality of up to 40.9%. CT is well established as the pre-procedural imaging gold standard for the determination of the risk of coronary occlusion. Low coronary ostial height (< 12mm) from the annulus and sinus of Valsalva mean diameter < 30 mm connote an increased risk of coronary occlusion. However, it should be noted that there is no absolute threshold at which the procedure should be considered contra-indicated, given the relatively low specificity of these measurements, and thus coronary ostial height should not be considered as an isolated measure of risk of occlusion. Rather, the derived values for coronary height and sinus of Valsalva width should be interpreted in the context of annular dimensions, overall root dimensions and the anticipated THV size.

To ensure reproducibility the coronary ostial height should be measured in a perpendicular fashion to the annular plane using an electronic caliper tool from the annular plane to the lower edge of the coronary artery ostium, yielding a value in [mm] (Fig. 7). Sinus of Valsalva diameter should be measured in parallel to the annular plane using three caliper measurements in [mm]. For symmetric sinus of Valsalva anatomies, the three values can be averaged (Fig. 7). There is no recommendation as to whether these measurements are to be performed in systole or diastole. The SOV diameter and coronary artery heights should be included in the report.

### 3.7. Sinotubular junction

Sinotubular (STJ) diameter and height are relevant to identify anatomies in which the anticipated THV may potentially get into contact with the STJ. In particular when using balloon-expandable devices in low STJ height anatomies, STJ diameter should be compared to the anticipated THV size in order to identify anatomies with smaller STJ diameter than THV diameter, which would be indicative of increased risk for STJ injury.

The STJ height should be measured in a perpendicular fashion to the annular plane using an electronic caliper tool from the annular plane to the lowest edge of the STJ, yielding a value in [mm] (Fig. 7). STJ diameter should be measured using a caliper tool on an imaging plane aligned with the STJ (Fig. 7).

3.8. Ascending aorta

The ascending aorta should be assessed for the presence of aortopathy. Ascending aortic dimensions should be assessed on double-oblique multiplanar reformat in [mm] (Fig. 7).

3.9. Optimal projection curve

Ideally, TAVI/TVAR is performed with fluoroscopic angulations providing a coplanar view of the aortic annulus without parallax. CT can be used to identify these patient-specific ‘optimal’ C-arm angulations. Use of these CT-derived angulations allows optimization of initial pre-deployment fluoroscopic angulation, reducing the need for repeat pre-deployment root shots thereby reducing radiation exposure, contrast usage and procedural time. Optimal C-arm angulations should be reported as degrees [°] LAO or RAO with the corresponding values for cranial or caudal angulation. Dependent on institutional preferences, typically views are either centered on the right coronary cusp, or use predefined LAO angulation (e.g LAO 10°), or are optimized for visualization of the left main stem. When identified projections result in cranial or caudal angulation > 25°, alternate angulations should be provided, given the physical restraints of the C-arms. However, it is essential to recognize that CT predicted angulations are only valid if the patient’s chest is positioned in a similar fashion on the CT table as during the procedure. Please refer to Table 6 for a summary of recommendations.

3.10. Sizing considerations

CT is the non-invasive imaging gold standard for annular sizing and THV selection. In clinical practice, balloon expandable devices are largely sized on the basis of annular area, with self-expandable devices relying on perimeter. The reasons for this are partly historical but also reflect different risk profiles of these devices and the geometric implications of sizing with the different variables. Sizing based on manually assessed short and long axis diameters have been shown to be less reproducible, and can be considered obsolete.

3.10.1. Oversizing

The term ‘oversizing’ has been introduced over the last 6 years to help describe when a THV is deployed that is larger than the native annulus. The term ‘oversizing’ is a generic term as oversizing can be calculated based on any measurement of the annulus. In routine, oversizing is calculated as a percentage [%], as follows

Oversizing [%] = (THV nominal measurement/ annular measurement − 1) x 100

It is important to recognize, that the percentage oversizing calculated is strongly dependent on the annular measurement used, with very different implication of oversizing area than oversizing perimeter or perimeter derived diameter. Given the formula of a circle where area = π*radius² and circumference = π*diameter, the area increases exponentially while perimeter increases proportionally with increasing diameter. The percentage area oversizing is approximately 2 fold greater than the percentage perimeter when dealing with a perfect
circle but the implications are even greater than expected owing to the non-circular geometry of the annulus. Both annular area and perimeter are clinically acceptable, but it is imperative that the imager and implanting physician appreciate the differences and are aware of the parameter being used for device sizing of specific devices. Further, the optimal threshold for oversizing is also device specific. Thus routine reporting of oversizing is not required, however familiarity of the concept is beneficial for subsequent discussion in Heart Team meetings.

### 3.10.2. Modification of sizing based on root calcification

CT not only provides information regarding annular size, but also provides important ancillary information that is helpful in guiding sizing and THV selection. Annular and sub-annular calcification, particularly when protruding into the lumen, can result in increased risk of both annular rupture and paravalvular regurgitation. Protruding landing zone calcification below the non-coronary cusp has been shown to be most closely-associated with annular injury, with this effect amplified when combined with aggressive annular oversizing. Presence, location and characteristics of subannular calcification should thus be integrated into all pre-TAVI/TAVR CT scan reports as described in the ‘landing zone calcium’ section.

### 3.10.3. Annular rupture

Annular rupture is an infrequent adverse event but is associated with a high mortality if it occurs. Presence, location and characteristics of subannular calcification should thus be integrated into all pre-TAVI/TAVR CT scan reports as described in the ‘landing zone calcium’ section.

<th>Step &amp; Description</th>
<th>Multi-planar reformats</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>Step 1:</strong> Start out with multi-planar images in default axial, sagittal, and coronal orientation; center cross-hairs onto the aortic valve</td>
<td><img src="image1.png" alt="Multi-planar reformats" /></td>
</tr>
<tr>
<td><strong>Step 2:</strong> Align the cross-hairs in the sagittal and coronal views with the long axis of the aortic root; the resulting double oblique transverse view will depict the aortic valve en face.</td>
<td><img src="image2.png" alt="Multi-planar reformats" /></td>
</tr>
<tr>
<td><strong>Step 3:</strong> Move the double oblique transverse plane up and down to identify the lowest insertion point of the more anterior/lateral cusp. Position the center of the cross-hairs exactly at the most basal insertion point (white arrow head).</td>
<td><img src="image3.png" alt="Multi-planar reformats" /></td>
</tr>
<tr>
<td><strong>Step 4:</strong> Rotate the cross-hairs counter-clock-wise without moving up and down while maintaining its center position so that the formerly coronal view (here red cross-hair) transects the lowest insertion point of the medial/posterior cusp (white arrow head).</td>
<td><img src="image4.png" alt="Multi-planar reformats" /></td>
</tr>
<tr>
<td><strong>Step 5:</strong> The formerly coronal, now double-oblique view will show the lowest insertion points of both cusps (white arrows heads). In this view, rotate the (here orange) cross-hair indicating the double-oblique transverse view to transect exactly through the most basal insertion point of the medial/posterior cusp. Once this is achieved, the transverse double oblique plane will contain the most basal cusp insertion points of both cusps.</td>
<td><img src="image5.png" alt="Multi-planar reformats" /></td>
</tr>
<tr>
<td><strong>Step 6:</strong> Move the center of the cross-hairs to the center of the lumen (yellow arrow) without changing the orientation and position of the formerly coronal, now double-oblique view (red cross-hair). This is best done by scrolling through the formerly sagittal, now double oblique view.</td>
<td><img src="image6.png" alt="Multi-planar reformats" /></td>
</tr>
<tr>
<td><strong>Step 7:</strong> In the formerly sagittal, now double oblique view, rotate the cross-hair of the transverse double oblique plane (here orange) while maintaining alignment with the most basal insertion points (arrow heads) until the smallest cross-sectional area is achieved on the transverse double oblique plane. Over- and under-angulation results in overestimation of the annular cross-sectional area (dashed lines).</td>

balloon-expandable valves, significant prosthesis oversizing, and prior radiation therapy. In addition, the presence of moderate/severe sub-annular calcification, particularly below the non-coronary cusp on pre-procedural CTA, is associated with a significantly increased risk for annular rupture.44 In addition, the depth of calcification within the LVOT is also important, as calcification immediately below the annular plane connotes a higher risk than calcification lower within the LVOT. Protruding nodules of calcification are considered to connote higher risk than flat or mural calcification. The risk of aortic annulus rupture increases with the degree of oversizing of the prosthesis (particularly with > 20% oversizing) and with the extent of calcification of the upper part of the LVOT (within 2 mm below the annulus plane) particularly when immediately below the non-coronary cusp.34,58

3.10.4. Atrio-ventricular conduction block

An increased depth of implantation is the most frequently identified predictor of LBBB and self-expandable prostheses.32–45 Reduced implant depth during TAVI/TAVR has been shown to significantly decrease mortality and permanent pacemaker insertion rate.35 In addition, shorter length of the semi-membranous septum has been reported to be associated with higher risk of conduction disturbance post TAVI/TAVR, with a length of less than approx. 8 mm predictive of high-degree AV-block, particularly when combined with a deep implant depth, or the presence of pre-existent right bundle branch block.46,47 The length of the semi-membranous septum can be measured in the coronal plane, at the longest point between the annular plane and the muscular septum.48 However, routine assessment of semi-membranous septum length has not seen widespread adoption into clinical routine.

4. Vascular access

4.1. Overview

Vascular complications are independently associated with increased morbidity and mortality after TAVI/TAVR, however the rates of complications have fallen with improved pre-procedural screening with major vascular complications currently occurring in 4.5% of procedures.48,60 Access sheath sizes have reduced in size, however this simply shifts the threshold at which trans-femoral access can be achieved, rather than negating the importance of identification and quantification of vascular disease and dimensions.50 Given the continuous evolution of delivery systems, no reference is made to current devices and vessel diameter requirements. Please refer to Table 7 for a summary of recommendations.

Analysis of iliofemoral vessel size, calcification, and tortuosity is required to determine if trans-femoral access can be achieved or whether an alternative access route is required.71,72 Due to its ability to accurately quantify all these aspects, CT provides greater predictive value for vascular complications than invasive angiography.73

Risk factors for vascular complications are an external sheath diameter that exceeds the minimal artery diameter, moderate or severe calcification, and vessel tortuosity.74–76 While early reports described an increased risk at a sheath:diameter ratio ≥ 1.05, more recent work on modern access devices which are typically smaller with an increasing prevalence of expanding sheath designs, suggests a more liberal threshold of ≥ 1.12 can be safely used.77

4.2. Quantification of luminal dimensions

The minimal diameter of the vasculature between the aortic valve and the right and left common femoral artery should be reported. This can be performed either manually on multiplanar reformats using a double-oblique technique, or using semi-automatic post-processing using centerline placement and curved multiplanar reformats. When the latter is used, manual verification of the center line should be performed to ensure accurate vessel tracking, and appropriate intraluminal location of the centerline. When using either technique, attention should be paid to the potential for calcium blooming artifact, and appropriate windowing used to correct for this where necessary. It

should also be ensured that all measurements are performed perpendicularly to the long axis of the vessel at the location of the maximum stenosis. Transverse source images allow no more than a preliminary assessment of vessel size.

4.3. Calcification

Extend and distribution of calcifications of the iliofemoral vasculature should be assessed and reported. To describe the severity, a subjective, semi-quantitative grading scale can be used: none, mild (spotty), moderate (coalescing), severe (bulky, protruding, horse-shoe, circumferential). Care should be taken to identify circumferential or near-circumferential (horse-shoe) calcification particularly in areas of tortuosity or bifurcations, as these prevent vessel expansion when the sheath and valve pass through.

4.4. Tortuosity

Tortuosity of vascular structures can be assessed on transverse source images, but evaluation is facilitated using a volume rendered display from multiple viewing angles, such as anterior-posterior and RAO or LAO projections. In the absence of calcification, iliofemoral arterial tortuosity is not necessarily a contraindication for femoral access, as tortuous vessel segments usually straightened with sheath insertion. However, when calcified, tortuous segments carry a substantial risk of access failure and the operator should be advised about this situation.

4.5. Access site

Careful interrogation of the common femoral artery puncture site is important to ensure that there is no focal stenosis nor calcifications anteriorly that may interfere with the arterial puncture or deployment of arterial closure devices. Also, the anatomy should be reviewed for the presence of a high femoral artery bifurcation. Relevant findings should be reported, ideally with detailed location in relation to fluoroscopically identifiable anatomical landmarks, such as the level of the femoral head (e.g. lower third).

4.6. Aorta

For transfemoral access, the thoracic and abdominal aorta should be assessed for the presences of relevant pathologies. In particular, the presence of ascending aortic aneurysm and the degree of ascending aortic calcification should be noted – the latter relevant for potential cross-clamping. Further relevant pathologies include abnormal elongation and kinking, dissections, aneurysms, and exophytic plaque.

4.7. Alternate access

If transfemoral access is not feasible, depending on local practice, subclavian and/or carotid arteries can be reported using the same techniques and reporting parameters of the iliofemoral vessels. Due to more favorable angulation, an left-sided approach is preferred for subclavian access. Finally, if a transcaval approach is to be considered, the presence, size and level of calcification free windows of the aortic wall adjacent to the inferior vena cava should be reported. Additionally the report should also include a clear description of all vascular pathologies including aneurysms, dissection, and occlusions.

5. Coronary arteries

In the setting of good image quality, modest motion artifact in particular, coronary CTA can rule out significant coronary stenosis with high negative predictive value. However confident assessment of coronary stenosis severity on TAVI/TAVR scans is challenging, particularly due to a high prevalence of coronary calcification and higher heart rates resulting in motion artifact. Beta-blockade must be used with caution and nitroglycerin is contra-indicated, with the absence of these associated with reduced diagnostic accuracy. Independent from the assessment for CAD, the presence and course of anomalous coronary arteries, easily interpreted, should be reported.

6. Incidental non-cardiac non-vascular findings

With growing evidence and increasing clinical adoption, TAVI/TAVR is increasingly being performed in younger patients with lower risk profiles. This increases the relevance of incidental findings on CT as the life expectancy of patients undergoing TAVI/TAVR will be longer than in the past. All imaging obtained should be reviewed carefully for incidental findings. This is best performed by trained radiologists, either as a combined or separate report according to local practices. The clinical recommendations and downstream management of incidental findings on pre-TAVI/TAVR CT will vary according to the risk profile.
and life expectancy of the patients as well as local clinical practice. Please refer to Table 7 for a summary of recommendations.

7. Post-TAVI/TAVR CT

Echocardiography is the test for evaluation of transcatheter heart valve function and durability.\textsuperscript{87,88} CT enables post-implant imaging of transcatheter heart valves (geometry, position, leaflets),\textsuperscript{89–98} There is however, no consensus regarding the clinical need to perform routine cardiac CT in TAVI/TAVR recipients. Cardiac CT is an important adjunctive modality to echocardiography in patients where there is concern for valve thrombosis, infective endocarditis, or structural degeneration.\textsuperscript{24,99} Hypoattenuated leaflet thickening (HALT) (Figs. 8 and 9) and restricted leaflet motion (also referred to as HAM (hypoattenuation affecting motion)) determined by CT often indicate leaflet thrombus formation.\textsuperscript{7,8,100–102} When echocardiography is indeterminate, CTA can be useful for adjudication of leaflet thrombus. When imaging in the post TAVI/TAVR setting for the assessment of HALT, full cardiac cycle imaging is recommended to maximize image quality and to permit assessment of leaflet motion. IV contrast administration and timing should be performed as per the routine TAVI/TAVR workup, although a smaller contrast dose is required due to the lack of need for peripheral vasculature imaging. Leaflet thickening should be described based on location, extent in length and overall thickness. Importantly, HALT takes a meniscal shape when viewed on a long-axis MPR at the center of the cusp (Figs. 8 and 9). In regard to extent of HALT along the curvilinear leaflet, as subjective grading scale can be employed as outlined in Fig. 8.

Restricted motion should be reported as present or absent. Restricted valve motion without thickening on CTA is rare and should be reported with great caution, to avoid the risk of unnecessary treatment.\textsuperscript{100,102,103}

8. Valve-in-valve implantation

8.1. Overview

Valve in valve (VIV) implantation of THVs into failing bioprosthetic valves has evolved as a treatment alternative with high technical success rates and promising patient outcomes.\textsuperscript{104} Broadly, bioprosthetic valves can be categorized as stented surgical (rigid scaffold), stentless surgical (no rigid scaffold), and transcatheter heart valves.

The Valve-in-Valve International Data (VIVID) Registry has shown that coronary occlusion is more common in VIV than TAVI/TAVR in native aortic stenosis, with occlusion reported in 2.3% of VIV compared with 0.66% in native valve TAVI/TAVR.\textsuperscript{48,105} Factors related to the observed higher frequency are canted position of the stented surgical bioprosthesis within the aortic root and small root dimensions, the latter in particular in patients with stentless surgical valves. Pre-procedural CT plays a limited role in THV sizing, but a key role in the discrimination of patient specific risk for coronary occlusion. Vascular access should be reported as for TAVI/TAVR in native aortic valves (see Vascular Access section). Please refer to Table 8 for a summary of recommendations.
8.2. Assessment for risk of coronary artery obstruction

Implantation of a THV within a stented surgical valve is technically different from TAVR in native aortic valves, as the stented bioprosthetic valves provides the scaffold for THV anchorage. The THV displaces the bioprosthetic leaflets into an open position with the THV frame and overlying bioprosthetic leaflets forming a ‘covered’ cylinder. The anatomical orientation of the cylinder is being dictated by the orientation of the surgical valve. Frequently, the surgical valve is implanted in a canted fashion in regard to the long axis of the aortic root, with the potential for close proximity of the bioprosthetic leaflets/THV to the coronary ostia and subsequent risk of coronary obstruction despite a large aortic root. Conceivably, the distortion is not adequately described by the coronary artery height and sinus of Valsalva width. To account for this anatomical distortion, the concept of predicting the distance from the anticipated, expanded THV frame to the coronary artery orifice, also referred to as the THV to coronary ostia (VTC) distance was introduced. This concept was validated in a recent VIVID multicenter analysis, which demonstrated the VTC to be the only independent predictor of coronary obstruction, with a VTC of less than 4mm indicating an increased risk of coronary artery obstruction.

It is recommended that the VTC is assessed for the right coronary artery and the left main coronary artery, if the posts extend to or above the level of the orifices (Fig. 10). If the coronary arteries originate above the posts, obviously no VTC is required.

The VTC can be assessed using either a multiplanar reformat (MPR) capable of producing a circular region of interest (ROI), or an advanced post-processing platform capable of simulating a virtual cylinder with a defined diameter and height. The MPRs should be carefully aligned with the orientation of the surgical valve. The ROI is drawn at the level of the coronary artery orifice and the distance from the ROI to the orifices is assessed with a caliper tool and reported in [mm]. For this reason, VTC assessment should not be confined to the level of the ostium but additional measurements should be employed above the ostium to identify the risk of potential sealing.

Sinus of Valsalva (SOV) width and coronary ostia height can also be measured but the VTC has been shown to provide incremental risk discrimination as the other measurements do not take into account the SHV tilting/canting. VTC distances < 4mm should be highlighted as being at high risk of procedure related coronary obstruction.

Implantation of a THV within a stentless surgical valve is biomechanically similar to TAVR in native stenosis due to the absence of a

Fig. 11. Pre-procedural assessment of virtual THV to coronary artery distance in patients undergoing transcather valve-in-valve procedure. The example shown here features a stented valve with a non-planar basal sewing ring. Steps 3 to 6 account for identifying alignment with the three most basal points. In case of a planar basal ring, these steps can be omitted.

<table>
<thead>
<tr>
<th>Step &amp; Description</th>
<th>Multiplanar reformats</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>Step 1:</strong> Start out with multiplanar images in default axial, sagittal, and coronal orientation; center cross hairs onto the aortic valve.</td>
<td><img src="image1.png" alt="Image" /> <img src="image2.png" alt="Image" /> <img src="image3.png" alt="Image" /></td>
</tr>
<tr>
<td><strong>Step 2:</strong> Align the cross-hairs in the sagittal and coronal views with the long axis of the aortic root; the resulting double oblique transverse view will depict the aortic valve prosthesis en face. Steps 3 to 6 apply to valves with a non-planar sewing ring. For valve with a planar sewing ring align the transverse view to match the orientation of the sewing ring.</td>
<td><img src="image4.png" alt="Image" /> <img src="image5.png" alt="Image" /> <img src="image6.png" alt="Image" /></td>
</tr>
<tr>
<td><strong>Step 3:</strong> Move the double oblique transverse plane up and down to identify the lowest insertion point of the sewing ring at the former right coronary cusp which is usually located at about 1 o’clock. Position the center of the cross-hairs exactly at the most basal point of the sewing ring (white arrow).</td>
<td><img src="image7.png" alt="Image" /> <img src="image8.png" alt="Image" /> <img src="image9.png" alt="Image" /></td>
</tr>
<tr>
<td><strong>Step 4:</strong> Rotate the cross-hairs counterclockwise without moving up and down while maintaining its center position so that the formerly coronal view (here red cross-hair) transects the lowest point of the sewing ring at the former non-coronary cusp, which is located at approximately 8 o’clock (white arrow).</td>
<td><img src="image10.png" alt="Image" /> <img src="image11.png" alt="Image" /> <img src="image12.png" alt="Image" /></td>
</tr>
<tr>
<td><strong>Step 5:</strong> The formerly coronal, now double-oblique view will show the most basal points of the sewing ring in the position of the former right and non-coronary cusp (white arrow). In this view, rotate the (here orange) cross-hair indicating the double-oblique transverse view to transect exactly through the most basal point of the sewing ring at the former non-coronary cusps. Once this is achieved, the transverse double oblique plane will contain two of the three lowest sewing ring points.</td>
<td><img src="image13.png" alt="Image" /> <img src="image14.png" alt="Image" /> <img src="image15.png" alt="Image" /></td>
</tr>
<tr>
<td><strong>Step 6:</strong> In the formerly sagittal view, rotate (without moving it) the cross-hair of the transverse double oblique plane (orange) until the lowest point of the sewing ring in the left coronary cusp position just barely appears in the double oblique transverse view (arrow). Now, the formerly axial plane is exactly aligned with the three lowest points of the sewing ring.</td>
<td><img src="image16.png" alt="Image" /> <img src="image17.png" alt="Image" /> <img src="image18.png" alt="Image" /></td>
</tr>
<tr>
<td><strong>Step 7:</strong> Move the cross-hairs to the center of the sewing. Maintain the centered position in Step 8.</td>
<td><img src="image19.png" alt="Image" /> <img src="image20.png" alt="Image" /> <img src="image21.png" alt="Image" /></td>
</tr>
<tr>
<td><strong>Step 8:</strong> Move the position of the transverse double-oblique image to the level of the left main orifice. Draw a circular region of interest with THV-specific diameter (purple circle) to simulate the anticipated THV. The center of the region of interest should reflect the center of the sewing ring/center of cross hairs. Measure the distance from the region of interest to the left main orifice. Note: Also assess if there is close proximity above the orifice towards the STS.</td>
<td><img src="image22.png" alt="Image" /> <img src="image23.png" alt="Image" /> <img src="image24.png" alt="Image" /></td>
</tr>
</tbody>
</table>

Repeat step 8 for the right coronary artery.
rigid scaffold. However, stentless surgical valves are often employed in small root anatomies. This, in combination with anatomical distortion increases the risk of coronary obstruction. Stentless surgical valve cases should be interpreted similar to native aortic stenosis cases regarding risk of coronary occlusion, with the sinus dimensions and coronary heights measured and reported as described earlier.

8.3. THV sizing

If unknown, the size of a SAVR can be estimated from measuring the internal area of the basal SAVR ring on the CT reconstructions and cross-referencing with published reference charts.107,108 However, reference charts are currently limited to two publications and do not reflect the complete complement of available SAVRs, with different measurement techniques used in both of these. When using reference charts careful adherence to the measurement technique employed in the respective papers is required to allow for accurate estimation of the valve size.

8.4. Requirements for CT data acquisition and reconstruction

As anatomical information of both the aortic root and aorto/ilio/femoral vasculature is required pre-VIV, the requirements for CT data acquisition and reconstruction are similar to those for planning of TAVR in native aortic valve. The contrast-enhanced, ECG-synchronized cardiac CT acquisition should cover at least the aortic root. In stented surgical valves, the lack of dynamism due to the rigid bioprosthetic heart valve scaffold requires only a single ECG-synchronized frame. However, acquisition and reconstruction of the entire cardiac cycle allows for additional CT data which may be beneficial in case of motion or misregistration artifacts. Of note, in the setting of stented surgical valves with radiopaque scaffold, a non-contrast CT dataset may be sufficient for assessment of coronary obstruction risk, as coronary artery orifices can be identified based on surrounding epicardial fatty tissue. In patients with stentless surgical valves, acquisition protocols for native aortic stenosis should be employed, and contrast enhancement is required.

9. Reporting

All measurements of the aortic root and access route should to be stored as screenshots in the picture archiving and communication system (PACS) for future review and reference. Screenshots should ideally include MPR reference images with cross-hairs displayed, which allows to comprehend the orientation and location of the imaging plane on which the measurement was taken. Pertinent components of a comprehensive report are listed in Table 9.

10. Summary

CT imaging plays an important role in procedural planning for TAVI/TAVR and should be a fully integrated component of any TAVI/TAVR program. The use of CT in TAVI/TAVR is multifaceted and should include appropriate image acquisition and reconstruction as well as the comprehensive assessment the aortic root and vascular access. Importantly, the individuals responsible for the interpretation of the CT examination should be part of the Heart team to ensure appropriate incorporation of the data from the CTA into the patient selection.
process and procedure planning.
