INSAR Mission Statement
To promote the highest quality autism research.

INSAR’S VALUES

BUILDING IDENTITY
Promote INSAR as the globally recognized and inclusive society for autism researchers

DIVERSE AND GLOBAL
Represent and serve a diverse and global community.

INTERDISCIPLINARY AND TRANSLATIONAL
Cultivate interdisciplinary and translational research, public-private partnerships, and relationships with industry.

NEXT GENERATION
Foster opportunities for leadership and career development for a diverse next generation of autism researchers.

PARTNERSHIPS
Foster understanding, communication, and collaboration between autism researchers and people affected by autism.

RESEARCH TO PRACTICE
Disseminate scientific knowledge to inform research priorities, policy, practice, and public understanding.

SETTING THE BAR
Increase the quality, diversity, and relevance of research promoted through annual meetings, journal, educational, and other year-round activities.

## KEYNOTE — INVITED, KEYNOTE SPEAKERS, AWARDS

### 101 - Autism: One Name for a Wide Spectrum
**Keynote Speaker: Wendy Chung**

*(Keynote)* Autism: One Name for a Wide Spectrum  
**W. K. Chung**, Department of Pediatrics, Columbia University, New York, NY

Autism represents a wide spectrum of manifestations that differ between individuals and along the life course. Developing the evidence necessary to identify ways to support individuals with autism requires greater homogeneity of subsets of individuals with autism and tailoring of supports to the individuals. SPARK and Simons Searchlight are large cohorts of individuals with autism and genetic neurodevelopmental conditions, respectively. These studies are connecting participants with researchers to more efficiently and effectively understand autism, the brain, and human behavior and to identify the molecular basis for these differences.

### 103 - Adapting and Innovating: A Model of Care for Low Resource Settings
**Keynote Speaker: Gauri Divan**

*(Keynote)* Adapting and Innovating: A Model of Care for Low Resource Settings  
**G. Divan**, Child Development Group, Sangath, New Delhi, India

This lecture will describe the journey taken by Sangath, a not-for profit in India, to realize the goal of universal health care for young children with autism in low-resource settings that have limited specialty services. Sangath started as a child development centre in Goa, a western state of India, designing its services as a traditional multi-disciplinary team based on high-income country models of ideal care. The early experiences of clinicians and families pushed the team to consider how they could enhance the coverage of evidence-based interventions in the context of the many barriers to these centre based models of care. Sangath then embarked on a journey to understand these barriers of access by iteratively adapting, expanding and evaluating a multi-component parent-mediated communication intervention which could be delivered in community settings by non-specialist providers. This body of work has set the stage for a major initiative to scale-up the intervention in the entire region, guided by the principles of universal health coverage for young children with autism.

### 104 - Plenary Roundtable Discussion: Precision Health for Neurodiverse Communities
**Panel Chair: T. Bourgeron, Institut Pasteur, Paris, France**

**Panelists:**  
Emily Jones, Centre for Brain and Cognitive Development, Birkbeck University of London, London, United Kingdom  
M. Doherty, Autistic Doctors International, Navan, Ireland  
V. K. Jaswal, University of Virginia, Charlottesville, VA  
J. A. Eccles, Brighton and Sussex Medical School, Brighton, United Kingdom

*(Keynote)* Precision Health for Neurodiverse Communities  

Over the past decade, two approaches have substantially influenced autism research – the neurodiversity paradigm and precision medicine/precision healthcare. Whereas some view these two approaches as opposite ends, others embrace them as inherently synergistic due to their shared focus on the diversity among autistic people, and the need to tailor support to individual characteristics, needs and preferences. The goal of this Roundtable discussion is to explore what neurodiversity approaches and precision healthcare approaches have in common for panelists, where they differ, the challenges of either approach, and how they could be addressed.
We welcome five panelists who directly work on aspects of precision health and/or within a neurodiversity affirmative framework, bring first and/or second person lived experience to the table, and together cover a broad spectrum of interests and support needs from infants and young children over minimally-verbal autistic individuals to eloquent autistic self-advocates. Prof Thomas Bourgeron is a geneticist at the Institut Pasteur, Paris, who first linked a rare mutation in a single gene with common forms of autism. He leads a new consortium aimed at co-designing genetic research with autistic people. Prof Emily Jones is a cognitive developmental neuroscientist at Birkbeck University, London. She uses multi-modal approaches to improve early detection and identify appropriate targets for intervention. Dr Mary Doherty is an autistic physician and mother to autistic children, as well as founder of the peer support and self-advocacy group Autistic Doctors Internationally. Both Profs Bourgeron and Jones are Principle Investigators of AIMS-2-TRIALS, which is currently the largest consortium dedicated to the development of precision medicine for autism in the world. Dr Doherty serves as one of the group’s Autism-Representatives. Prof Vikram Jaswal is a psychologist at Virginia University with a research focus on communication in non-speaking and minimally-speaking autistics, and a family member of a non-speaking autistic person. Dr Jessica Eccles is a Senior Clinical Academic Psychiatrist at Brighton and Sussex Medical school. She is part of a neurodiverse research team focused on brain-body interactions.

The Roundtable will discuss how neurodiversity and precision medicine frameworks ensure that different autistic people’s needs are heard and included in decisions. It will probe panelists directly working on precision healthcare to what extent insights or challenges from the neurodiversity paradigm and/or movement have impacted their own research. Conversely, it asks panelists about priorities from different neurodivergent communities and how they have been (or could be) picked up by researchers. The format of the roundtable invites one panelist to initially respond to a topic and then gives other panelists the possibility to respond. We acknowledge that the views of panelists are examples only that cannot represent all perspectives. Instead, it is hoped that this Roundtable on one of the most timely topics in current autism research will inspire more dialogues and discussion among INSAR delegates.

KEYNOTE — INVITED, KEYNOTE SPEAKERS, AWARDS

105 - Ageing with Autism: Facts, Fallacies and Future Directions
Keynote Speaker: Patricia Howlin

(Keynote) Ageing with Autism: Facts, Fallacies and Future Directions
P. Howlin, King's College London, London, United Kingdom

Although, until relatively recently, there were very few studies involving autistic adults, especially older adults, the last decade or so has witnessed an upsurge in adult autism research. Most of this research has focussed on the difficulties many autistic adults experience in the transition from adolescence into early-to-mid adulthood, and on the lack of support networks to help them achieve their goals in life. In the present talk I will review recent studies of outcome in adulthood, involving both longitudinal and cross-sectional cohorts in Europe, UK and Australia. I will focus particularly on trajectories from mid to later adulthood with respect to social functioning, mental health and quality of life.

However, it is important to recognise that much of this work has been conducted from a “neurotypical” perspective, with judgements of what constitutes a “good” outcome based on criteria that are not endorsed by many autistic adults themselves. Indeed, some of the subjective, qualitative data we have collected present a rather different picture of adult lives compared with the “objective” results from quantitative studies.

Thus, as well as attempting to summarise the advances that have been made in understanding the experiences of autistic people as they move through adulthood, I will try to address ways in which research in this area needs to be improved in order to meet the very differing needs and expectations of all in the wider autism community.

Adult Outcome: Medical, Cognitive, Behavioral

PANEL DISCUSSION — ADULT OUTCOME: MEDICAL, COGNITIVE, BEHAVIORAL

219 - Autistic Ageing: Cognitive Changes, Self-Perceptions, and Medication Profiles

Panel Chair: Carolien Torenvliet, Universiteit van Amsterdam, Amsterdam, Netherlands

Discussant: Francesca Happe, Social, Genetic and Developmental Psychiatry Centre, Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, UNITED KINGDOM

Research on ageing in autism is scarce, yet given the increased awareness of autism in middle, and late adulthood, and the uncertainties associated with ageing itself, it seems crucial to gain insights on the late life development of physical, mental, and cognitive health of
autistic people. Therefore, this panel highlights new findings on ageing in autism. Autistic people might be at risk for age-related disease, as research by Klein et al. (talk 1) indicate high rates (30%) of positive dementia screening, and elevated symptom endorsement in autistic adults. This might be moderated by medication use, as findings from O’Nions et al. (talk 2) suggest increased prescription rates for mental health medication in autistic adults, especially at older age. However, cognitive findings are contradictory, as self-report data by Charlton et al. (talk 3) show high rates of prospective, and retrospective memory difficulties in (older) autistic adults, yet longitudinal data by Torenvliet et al. (talk 4) suggests that cognitive performance does not deteriorate more rapidly in autistic than non-autistic adults. Most likely, age-related changes in autism are heterogeneous, with large individual differences. By contrasting different data sources, our panel aims to unravel if and why ageing in autism may be particularly burdensome.

### 219.001 (Panel Discussion) Self-Reported Cognitive Decline Among Middle and Older Age Autistic Adults

**Background:** Very little is known about autistic adults as they age. Early evidence suggests a potentially high risk for dementia and atypical cognitive decline in autistic middle and older age adults. Research in the general population indicates that self-reported cognitive decline may predict future dementia earlier than performance-based measures. Nevertheless, self-report dementia screeners have not been used to date in autism research.

**Objectives:** We aimed to: 1) describe the rates and profiles of self-reported cognitive decline, 2) examine associations of age, sex designated at birth, and autistic traits with self-reported cognitive decline, and 3) document the psychometrics of one self-report measure of cognitive decline (i.e., the AD8; Galvin et al., 2007) in a sample of autistic adults.

**Methods:** Participants included 210 middle and older age autistic adults (mean age=55.63, range=42-81 years, 58% female; Table 1) recruited through SPARK Research Match. Participants completed self-report on the following: a dementia screener (AD8), autistic traits (AQ28; Hoekstra et al., 2011), and current memory problems (PRMQ; Smith et al., 2000). We examined whether age, sex, or autistic traits were related to screening positive vs. negative for likely cognitive decline on the AD8 (higher-threshold cutoff ≥2; recommended self-report cutoff ≥1). Cronbach’s alpha and Pearson’s correlations were used to examine AD8 reliability and convergent validity (PRMQ), respectively.

**Results:** We found high rates of cognitive decline with 30% and 49% of the sample screening positive using a higher-threshold cutoff (≥2 items endorsed) and the conventional self-report cutoff (≥1 items endorsed), respectively. The patterning of AD8 symptom endorsement observed in the autistic adults paralleled that observed in a population-based sample in the USA (See Figure 1; Passler et al., 2021). For example, declining interest in leisure activities and everyday problems with thinking, memory, and judgment were the most commonly endorsed symptoms, while forgetting the month or year was the least common symptom in both groups. However, the rate of symptom endorsement was elevated in autistic adults (30%) compared to the population-based sample (23%). There was evidence that autistic individuals designated female at birth may be more vulnerable to cognitive decline with 54% of females and 40% of males screening positive when a cutoff of ≥1 was used (X²(1, N=210)=3.62; p=.057). Reports of cognitive decline did not vary by age (r=-.02, p=.73), with younger and older adults equally reporting cognitive decline. Modestly elevated autistic traits were found in those screening positive vs. negative for cognitive decline (cutoff ≥1: t(207)=1.65, p=.05, d=.23; cutoff ≥2: t(207)=3.12, p=.001, d=.47). Finally, the psychometrics of the dementia screener were good (Cronbach’s alpha=.84), including convergent validity with an independent measure of current memory problems (r=.49, p<.001).

**Conclusions:** Overall, findings showed high rates (30%) of self-reported cognitive decline among middle and older age autistic adults. The symptom pattern mirrors the general population, but autistic adults showed higher rates of symptom endorsement. These results could signal an emerging public health crisis in autistic adults as they age, and support the potential utility of self-report measures for early screening for cognitive decline in this population.

### 219.002 (Panel Discussion) Age Differences in Mental Health Prescribing to Autistic People: A Matched UK Cohort Study

**Background:** Autistic people have more mental health diagnoses and receive more psychotropic medications than non-autistic people. However, it is not clear how psychotropic prescribing differs related to age, sex, and co-occurring intellectual disability within the autistic population in the UK, and whether prescribing trends follow those seen in the non-autistic population.
Objectives: The aim of this study was to investigate in a large, representative national sample, the rates of psychotropic prescribing in 2018 across different age-bands in UK autistic males and females with and without intellectual disability (ID) to explore prescribing differences within the autistic population, and to see whether prescribing in autistic people follows population-level trends. Looking at data from 2000 to 2018, we also aimed to explore if prescribing in autistic people is motivated by similar presenting concerns compared to the general population, stratifying results by age.

Methods: A retrospective matched cohort study of prospectively collected anonymised UK primary care data from the IQVIA medical research database (IMRD). Data for 2018 were available for 9,601 autistic people without ID and 46,028 matched comparison people; plus 1,772 autistic people with ID and 8,990 matched comparison people. Data between 2000-2018 were available for 21,450 autistic people without ID and 101,077 matched comparison people, plus 5,032 autistic people with ID and 24,803 matched comparison people.

Results: Distinct patterns of prescribing related to age were observed in autistic people with and without ID. Whilst younger autistic people tend to receive stimulants and melatonin, few older autistic people received these medications. Instead, they received more antipsychotics, hypnotics other than melatonin, anxiolitics, anti-epileptics, and antidepressants. The greatest difference for autistic over 50s vs. their matched non-autistic comparison groups during 2018 was for antipsychotics, which were prescribed to autistic males without ID 9 times as often, autistic females without ID 13 times as often, autistic males with ID 23 times as often, and autistic females with ID 38 times as often vs. their matched comparison groups. Autistic people were more likely to receive medication without a common mental health indicator in their records (e.g. antipsychotics without a record of severe mental illness (SMI)). Between 2000 and 2018, autistic adults aged 50+ without ID who did not have an SMI record were 39 times as likely, and autistic adults aged 50+ with ID 136 times as likely to receive antipsychotics in a given year vs. people in their respective comparison groups without SMI.

Conclusions: The findings suggest substantial age-related differences in prescribing among autistic people. Much higher use of antipsychotics in older autistic vs. comparison people, particularly in those with ID, could reflect over-prescribing. Some diagnosed older autistic people may also have more complex mental health needs, and/or atypical presentations of mental health challenges, leading to differences in diagnostic coding. These findings should be viewed in the light of evidence that at least nine out of 10 UK autistic over-50s are undiagnosed: those diagnosed likely have more complex needs than autistic people on average.

219.003 (Panel Discussion) Self-Reported Prospective and Retrospective Memory Among Middle Aged and Older Autistic and Non-Autistic People

Background: Research often demonstrates poorer memory among autistic adults compared to non-autistic comparison groups. Difficulties have been observed in retrospective (recalling information, RM) and prospective (remembering to perform a future action, PM) memory. However, few studies have explored these abilities in middle-aged or older autistic people, or have considered individuals’ self-perceived memory difficulties. Although performance on both PM and RM tasks declines with older age (in the general population), age-effects are not commonly observed on self-report measures. On self-rated memory measures, people may compare their own memory functioning to similar age peers, therefore reducing age-associations.

Objectives: Explore self-rated RM and PM abilities in middle-aged and older autistic people, including age-effects, and compare these abilities to an age and education matched non-autistic comparison group.

Methods: 350 autistic adults (58% assigned female at birth) aged 40-83 years, were recruited via Simons Foundation Powering Autism Research (SPARK) research match. To provide a comparison group, a publicly available dataset was leveraged from a study run in collaboration with the British Broadcasting Corporation (BBC), including 408,938 participants. BBC data were filtered and a sample of 350 people matched as closely as possible on age, birth-sex and education level was retained. In both samples, individuals completed the Prospective and Retrospective Memory Questionnaire (PRMQ) which includes memory questions about PM-vs-RM (memory type), cued-vs-uncued memory (cue), and short-vs-long delay (delay).

Results: An ANOVA examined differences between the SPARK (autistic) and BBC (non-autistic) groups, and effects of conditions (memory type, cue, delay) as well as their interactions. A main effect of group was observed with the autistic group reporting more memory difficulties than the non-autistic group (F=29.22, p<.001). Significant main effects were also observed for memory type (F=357.19, p<.001, more PM difficulties), cue (F=360.38, p<.001, more uncued difficulties) and delay (F=213.78, p<.001, more short delay difficulties). No interactions between group and memory type, cue or delay were observed.

A significant correlation was observed between age and total PRMQ score, for the autistic group (r=-0.18, p<.001) but not the non-autistic group (r=0.015, p=.78). Separate correlational analyses were run for each memory type. Autistic people reported significantly more prospective (r=-0.18, p<.001) and retrospective (r=-0.16, p<.001) memory problems with older age; whereas no age associations were observed for non-autistic people (prospective memory, r=0.017, p=.76; retrospective memory, r=0.047, p=.38). Differences in correlations were statistically significant (prospective: z=-2.17, p=.03; retrospective: z=-2.75, p=.006).
Conclusions: Autistic middle-aged and older people reported more memory difficulties than non-autistic people of similar age and education level. No significant interactions were observed between group and any of the memory-related conditions. Among autistic people poorer RM and PM was associated with older age, whereas age-effects were not observed among non-autistic people. Self-reported memory difficulties are important as they are often associated with poorer performance on cognitive tests and everyday difficulties. Results suggest that autistic people may be at increased risk for memory problems as they age, compared to non-autistic people. Further studies are required to explore the association between self-reported memory and performance on memory tasks among autistic older people.

219.004 (Panel Discussion) Cognitive Ageing in Adults with Autism
C. Torenvliet, A. P. Groenman, T. A. Radhoe, J. Agealink van Rentergem, W. J. van der Putten and H. M. Geurts, (1)Universiteit van Amsterdam, Amsterdam, Netherlands, (2)University of Amsterdam, Amsterdam, Netherlands, (3)Leo Kannerhuis, Amsterdam, Netherlands, (4)Leo Kannerhuis, Parnassia Group, Amsterdam, Netherlands

Background: Cognitive data on ageing in autism is scarce, and studies are often underpowered. Our previous cross-sectional work, however, does not indicate evidence for differential age-related cognitive effects in autism, in two large independent samples (n\textsuperscript{total}=204, n\textsuperscript{total no autism}=204). However, as this study used cross-sectional cognitive performance data, findings might be clouded by cohort effects. Furthermore, individuals could have used different strategies to come to the same test scores. To gain further insight in cognitive ageing in autism we need well-powered longitudinal studies, and/or more detailed studies on cognitive ageing in autism.

Objectives: We conducted a series of studies in which we investigated cognitive ageing in a large sample of autistic and non-autistic adults between 24 and 85 years.

Methods: Multilevel analyses were conducted to compare 128 autistic adults to 112 non-autistic adults over two to three timepoints (average time interval: 3.5 years). Participants were tested on a wide range of cognitive tasks (k=15) measuring verbal memory, visual (working) memory, prospective memory, theory of mind, fluency, response speed, inhibition, planning, and switching. Using a new Bayesian method, we compared models with- and without a group difference (autism/no autism) in age-related decline. Furthermore, we are currently collecting data (n=100) by which we aim to investigate cognitive strategies in younger, and older (autistic) adults. These comparisons might give us more detailed insights in how autistic people approach cognitive tasks, whether this is different at older age, and if age-related effects are different compared to non-autistic people.

Results: Our longitudinal results indicate that the used task battery was sensitive in detecting both cross-sectional age-related effects, and/or longitudinal changes across our sample, with worse performance at older age and/or later timepoints (Figure 1, left panels). However, in line with our cross-sectional results, age-related cognitive decline was not significantly different between those with- and without autism (p’s > .233, see Figure 1, right panel). Bayesian analyses confirmed that evidence was mostly in favor of a model that specified no differences in age-related decline between those with- and without autism (BF\textsubscript{01’s} > 28). Next to these results, at INSAR 2023, we will present our data on cognitive strategies, providing further insight on whether the underlying cognitive strategies are also similar between those- with and without autism, or that individuals with autism may come to the same cognitive test scores by using different approaches.

Conclusions: These data suggest that, at group level, autistic individuals do not seem particularly vulnerable for cognitive decline. However, based on the known heterogeneity in autism, it may be likely that some autistic adults are more vulnerable for accelerated cognitive decline than others. Detailed information on which cognitive strategies are used, might enable us to further theorize on if, and how cognitive differences in autism arise, and whether this is likely to result in either risks or resilience regarding cognitive ageing.

PANEL DISCUSSION — ADULT OUTCOME: MEDICAL, COGNITIVE, BEHAVIORAL
228 - Obstetric Care and Pregnancy Experiences Among Autistic People

Panel Chair: Jessica Rast, A.J. Drexel Autism Institute, Drexel University, Philadelphia, PA
Discussant: Dena Gassner, Social Work, Towson University, West Hempstead, NY

Pregnancy and childbirth carry a multitude of biological and social changes associated with short and long-term health and well-being. For autistic people, pregnancy can bring increased sensory hypersensitivity, feelings of low self-advocacy in obstetric care, and mental health exacerbations. Early evidence also suggests autistic pregnant people may be at higher risk of pregnancy complications, including pre-eclampsia and preterm birth. However, the obstetric profiles of autistic people remain largely understudied. This panel will explore autism and pregnancy across multiple countries, healthcare settings, and research methods. The first two presentations will consider pregnancy among autistic people in the United States, including one analysis of a sample with Medicaid public insurance and a second analysis among a sample with a mix of private and public health insurance. The third presentation will discuss pregnancy outcomes among autistic and non-autistic people in Sweden. The fourth presentation will focus on a qualitative analysis of perinatal mental health in autistic people in
Background: Previous studies have shown that women with disabilities are at increased risk of experiencing certain negative pregnancy outcomes, including preterm birth and low birthweight, and receive a relative lack of preconception care. However, very little is known about the experiences of autistic women during pregnancy. What little is known about reproductive health in autistic women suggest they have reduced access to preventive care. Further, autistic people generally have higher rates of co-occurring mental and physical health conditions than their peers without autism that may place autistic women at increased risk for adverse pregnancy and delivery outcomes.

Objectives: The purpose of this study was to examine the pregnancy experiences of autistic women in Sweden, including health service use, maternal health conditions during pregnancy, and delivery outcomes.

Methods: We used the Swedish Medical Birth Register to identify all pregnancies in Sweden between 2014 and 2020. Autistic women were identified by pre-existing diagnosis of autism (N=4420) 1987-2021 in the National Patient Register. We included a comparison group of women without autism (N=791,800). We examined presence of certain health conditions during pregnancy and delivery outcomes by group. We will expand the analysis to include further obstetric outcomes, and additionally investigate discrepancies in antenatal care and methods of delivery, if accepted. We will also explore stratification by intellectual disability.

Results: Autistic women were more likely than non-autistic women to have certain health conditions during pregnancy that put them and their fetus at increased risk for adverse outcomes, including diabetes (1.7% versus 0.9%) and obesity (24.6% versus 14.7%). They were also more likely to have preeclampsia (4.8% versus 3.1%) and gestational diabetes (2.8% versus 2.3%).

There were a few differences in delivery outcomes as well. Autistic women were more likely to have premature delivery (before 37 weeks) (7.7% versus 5.4%). Small for gestational age births were similar across groups although slightly higher in autistic women (2.7% versus 2.3%), and Apgar scores below seven at five minutes were slightly common in autistic women (2.4% versus 1.4%).

Conclusions: Findings suggest that autistic women who become pregnant had increased rates of several characteristics and health conditions that may place their pregnancy at higher risk; they were more likely to have diagnoses of pregnancy-related health conditions; and they had a higher rate of premature delivery. Autistic women may need better care before and during pregnancy, including access to contraceptive care, to reduce risk and increase maternal and fetal health.

Background: The literature examining pregnancy experiences among autistic people is small. However, it suggests that autistic people may be at higher risk of gestational complications, such as pre-eclampsia and pre-term birth compared to non-autistic peers. Further, autistic people have reported traumatic experiences in healthcare overall, including obstetric care. There is a paucity of descriptive epidemiology on pregnancy in autistic people in the United States, including characterization of their prenatal care utilization and obstetric risks.

Objectives: To describe obstetric care utilization and obstetric health outcomes in a sample of pregnant autistic people in the US.

Methods: Our study took place at Kaiser Permanente Northern California (KPNC), a large, integrated healthcare delivery system. Among KPNC members with a clinician-documented diagnosis of autism, we identified all pregnancies with outcomes that occurred between January 2011 and July 2022. From electronic health records, we additionally extracted information on sociodemographic factors, health diagnoses during pregnancy, birth outcomes, and quality indicators of obstetric care utilization, including timing of the first prenatal care appointment and routine prenatal screenings. Perinatal depression was assessed through a combination of a) clinical diagnosis of depression in the two years preceding the pregnancy through the first 12 months of the postpartum period and b) scores indicative of moderate/severe depression symptoms on the PHQ-9, a validated screener for depression that is regularly administered throughout prenatal and postpartum care.
Results: Between 2011-2022, there were 161 pregnancies among 121 autistic individuals. The average age of pregnancy onset was 25.6 years (standard deviation: 6.0 years). The sample was 59% White, non-Hispanic; 19% Hispanic; 12% Black; 5% Asian; and 6% multiracial or another race/ethnicity. Most pregnant individuals had private health insurance (71%). Gestational complications were relatively common, with 23% of pregnant individuals receiving a diagnosis of gestational hypertension, followed by 10% pre-eclampsia, and 10% gestational diabetes. 32% of pregnant individuals had a diagnosis of depression in the two years before pregnancy onset. During pregnancy, the prevalence of depression increased to 65%. In the 12 months postpartum, the prevalence of depression was 39%.

Among these pregnancies, 91 (57%) ended in live birth, 47 (29%) ended in therapeutic abortion, and 23 (14%) ended in spontaneous abortion, ectopic pregnancy, or stillbirth. Among those delivering a live birth, 10% reported perinatal smoking, 16% initiated prenatal care after the first trimester, and 31% had delayed or missed screenings for gestational diabetes. The prevalence of preterm birth and low birthweight was 12% and 4% respectively.

Conclusions: The rate of perinatal smoking, delayed initiation of prenatal care, pre-eclampsia, gestational hypertension, and perinatal depression appear to be higher in this autistic sample than what has been reported in the general pregnant population of California. These results, while preliminary, suggest that the obstetric needs of autistic people, including the accessibility of prenatal care and support services for perinatal mental health, warrant more attention. Analyses will be updated in a larger sample of pregnancies occurring between 1997 and 2022 at KPNC and compared to a sample of non-autistic people with pregnancies during the same time period.

228.003  (Panel Discussion) Maternal Health Outcomes Among Autistic Birthing People
L. Shee and S. Tao, (1)A.J. Drexel Autism Institute, Philadelphia, PA, (2)Drexel University, Philadelphia, PA

Background: Identifying the experiences of birthing people is a critical component to understanding service gaps and improving maternal health outcomes. However, population-level information is needed to support the growing population of autistic individuals aging into childbearing years. A limited but expanding research base primarily utilizing qualitative methods has identified that suboptimal experiences are reported by autistic birthing people. Research using national registry data from Sweden found that autistic individuals who gave birth were more likely to be younger and to experience a range of adverse health outcomes across pregnancy, childbirth, and postpartum periods, including preeclampsia, preterm birth, and cesarean delivery, than their peers. Further efforts are urgently needed, especially among diverse populations, to identify if and how these findings are observed in other countries to help drive care improvements.

In the US, Medicaid insures more than half of births and is the largest behavioral health insurer in the nation, indicating that there are prime opportunities to identify and study the needs of autistic birthing people. Medicaid presents a unique opportunity to examine the experiences of a diverse group of autistic birthing people, large data sources are needed to examine population-level health outcomes in tandem with documenting and understanding the systems that provide their prenatal, childbirth and postpartum care. To refine and build services to support the needs of autistic birthing people, large data sources are needed to examine population-level health outcomes in tandem with documenting and understanding the lived experiences of this group. Medicaid presents a unique opportunity to examine the experiences of a diverse group of autistic birthing people to drive future research to support their needs.

Conclusions: Services and supports to meet the needs of autistic birthing people is an under researched area, to the detriment of the systems that provide their prenatal, childbirth and postpartum care. To refine and build services to support the needs of autistic birthing people, large data sources are needed to examine population-level health outcomes in tandem with documenting and understanding the lived experiences of this group. Medicaid presents a unique opportunity to examine the experiences of a diverse group of autistic birthing people to drive future research to support their needs.

228.004  (Panel Discussion) Autism and Prenatal Depression: Factors Influencing the Decision to Disclose Prenatal Depression to Healthcare Professionals
S. Hampton, E. M. Weir, P. C. Allison, S. Baron-Cohen, and R. Holt, (1)Department of Health Sciences, University of York, York, UNITED KINGDOM, (2)Autism Research Centre, Department of Psychiatry, Autism Research Centre - University of Cambridge, Cambridge, United Kingdom, (3)Autism Research Centre, Department of Psychiatry, University of Cambridge, Cambridge, United Kingdom

Objectives: This study examines the characteristics and health outcomes of autistic birthing people in a national sample of Medicaid-enrolled individuals.

Methods: National (US) Medicaid claims for 2016 for all enrolled autistic individuals aged 14 to 50 and similarly aged cohorts of individuals with intellectual disability (ID) and a random sample of Medicaid enrollees were constructed. Diagnoses of autism and ID were identified using validated algorithms from the Chronic Condition Warehouse (CCW) which have also been used in the majority of autism research to date. Childbirth was identified using a random protocol for claims data. Totals of 8,370 autistic birthing people, 30,900 birthing people with ID, and 383,068 other birthing Medicaid enrollees were identified.

Results: Autistic birthing people had the youngest age of first observed birth (mean age=21.87, SD 5.88 years) of the three groups (ID mean age=24.6, SD=6.87; other enrollees mean age=25.3, SD=6.3). More than one in four (28.8%) autistic birthing people were Black, compared to 35.9% of the ID group and 22.9% of the other enrollee group. Almost one-third of autistic birthing people were eligible due to poverty (29.3%), which was lower in the ID group (19.1%). Most autistic birthing people lived in urban areas (69.5%), although this was also common among birthing people with ID (71.6%) and other Medicaid enrollees (72.4%). With recently acquired data through 2019, longitudinal data will be updated across these characteristics, including medical conditions and co-occurring mental health diagnoses.

Conclusions: Services and supports to meet the needs of autistic birthing people is an under researched area, to the detriment of the systems that provide their prenatal, childbirth and postpartum care. To refine and build services to support the needs of autistic birthing people, large data sources are needed to examine population-level health outcomes in tandem with documenting and understanding the lived experiences of this group. Medicaid presents a unique opportunity to examine the experiences of a diverse group of autistic birthing people to drive future research to support their needs.
Background: Prenatal depression is an important public health concern due to its serious impact on both mother and child. There is growing evidence that autistic people are substantially more likely than non-autistic people to experience prenatal depression. As such, ensuring that autistic people have access to mental health support during pregnancy is vital. However, some autistic people report being reluctant to disclose personal information, such as their autism diagnosis, to professionals. There is no research exploring whether autistic people feel able to disclose prenatal depression to professionals and seek the support they require.

Objectives: This study aimed to explore the factors influencing autistic and non-autistic people’s decision whether to disclose prenatal depression to healthcare professionals.

Methods: An anonymous online survey was completed by 42 non-autistic respondents (mean age 37.99 years; SD = 8.78) and 91 autistic respondents (mean age 40.31 years; SD = 8.12). All respondents experienced depression during their most recent pregnancy. The autistic and non-autistic groups did not significantly differ on age, gender (100% of non-autistic and 91% of autistic participants identified as women), ethnicity (90% of non-autistic and 92% of autistic participants identified as white), education level (79% of non-autistic and 71% of autistic participants were university educated) or parity (69% of non-autistic and 75% of autistic participants were multiparous). Respondents were predominantly UK-based (60% of non-autistic and 50% of autistic participants). Respondents provided a qualitative response describing what influenced their decision about whether to disclose their prenatal depression to a professional. Responses were analysed using content analysis. The first two authors independently devised themes and subthemes arising from the responses, meeting regularly to reach consensus. Counts for each theme per group were calculated.

Results: For both groups, four themes comprising ten subthemes emerged: Awareness; Decision to disclose influenced by support needs; Experience of healthcare; Stigma and vulnerability (Figure 1; Table 1). Disclosure was sometimes influenced by respondents’ level of awareness of their symptoms, with some believing that what they were experiencing was typical for pregnancy and therefore not requiring professional attention. Some respondents were motivated to disclose to obtain support and help minimise the impact of depression on themselves and their family, especially when symptoms were severe. Others, however, felt they were able to cope without support. Another influential factor, particularly among the autistic group, was respondents’ experiences with professionals, with some respondents lacking trust in professionals. Some respondents who disclosed felt their disclosure was dismissed and did not lead to adequate support. Respondents sometimes reported reluctance to disclose due to fear of judgement, with some, particularly autistic respondents, fearing that their child may be taken away if they disclosed.

Conclusions: This study indicates several barriers to disclosing prenatal depression. It is crucial that pregnant people feel able to disclose, in order to get the support that they need. Building trust between professionals and pregnant patients, as well as promoting awareness of the signs of symptoms of prenatal depression, may help both autistic and non-autistic people feel able to seek support.

ORAL SESSION — ADULT OUTCOME: MEDICAL, COGNITIVE, BEHAVIORAL

302 - Aging in Autism

Moderator: Patricia Howlin, King's College London, London, United Kingdom

302.001 (Oral) Age-Related Physical Health of Older Autistic Adults: A Population-Based Cohort Study
S. Liu, H. Larsson, R. Kaja-Halkola, P. Lichtenstein, A. Butwicka and M. Taylor, (1)Karolinska Institutet, Stockholm, Sweden, (2)School of Medical Sciences, Örebro University, Örebro, Sweden, (3)Department of Medical Epidemiology and Biostatistics, Karolinska Institutet, Stockholm, Sweden, (4)Medical Epidemiology and Biostatistics, Karolinska Institutet, Stockholm, Sweden

Background:
Growing evidence suggests that physical health problems are common in autistic individuals. However, there remains a concerning lack of research among older autistic adults, and little is known about whether intellectual disability (ID) and sex affect their health outcomes.

Objectives:
The objective of this study was to investigate the associations between autism and co-occurring health conditions in older adults and to examine whether ID and sex play roles in these associations.

Methods:
We conducted a cohort study, based on the Swedish population, of individuals born 1932-1967. We excluded individuals who died or emigrated before age 45. We followed all included individuals from age 45 up to Dec 31, 2013 (the end of available follow-up). Diagnoses
of autism (exposure, lifetime presence or absence) and age-related physical conditions and injuries (outcomes) were obtained from the National Patient Register. We prospectively examined 39 physical conditions commonly associated with age, such as cardiovascular and metabolic disorders, chronic obstructive pulmonary disease (COPD), and musculoskeletal disorders. We also examined different types of injury, such as poisoning and falls, which are other critical aspects of physical health in older adults. For each outcome, we evaluated the 25-year cumulative incidence and used Cox models to estimate the relative risks of physical conditions. All analyses were repeated separately by ID and sex.

Results:

Older autistic adults had higher 25-year cumulative incidence and relative risks of a range of physical conditions and injuries. Bodily injury was most common, with a 25-year cumulative incidence of 50-0% (95% CI 47.6-52.4), followed by falls (39.3% [36.7-41.9]), dorsopathies (12.8% [11.2-14.4]), type 2 diabetes (12.3% [10.4-14.1]), artherosclerosis (11.9% [10.2-13.6]) and diseases of oesophagus, stomach and duodenum (10.5% [8.8-12.1]). Conditions with notable elevated risk include heart failure (Hazard Ratio [95% CI]; 1.62 [2.22]), chronic obstructive pulmonary disease (1.90 [1.62-2.23]), osteoarthritis (1.73 [1.27-2.36]), glycose dysregulation (2.98 [2.06-4.32]), iron-deficiency anaemia (3.17 [2.69-3.73]), and self-harm (7.20 [6.34-8.17]). These elevated risks remained regardless of ID or sex.

Conclusions:

Our results reveal that older autistic adults are at substantial risk for age-related physical conditions and injuries. These conditions were also common in autistic individuals with and without ID and of both sexes. These findings highlight that as autistic individuals age, targeted follow-ups and intervention programs are critically needed to ensure they receive timely help.

302.002 (Oral) Functional Neurological Disorders Among Autistic Adults and Their Associations with Demographic Characteristics and Well-Being

Background:

Functional Neurological Disorder (FND) encapsulates a group of neurological conditions (e.g., chronic pain) that create significant impairments to daily functioning while lacking a definitive cause. The pathophysiological mechanisms of FNDs remain largely unknown. Prior studies suggest phenotypic overlap between FND and autism spectrum disorder (ASD), such as atypical sensitivity to sensory stimuli. Despite this symptomatic overlap between the conditions, very few studies have examined the potential relationship between FND and ASD and how the possible co-occurrence of FND and ASD could vary by demographic characteristics and impact well-being.

Objectives:

To examine the co-occurrence of FND and ASD and its relations to demographic characteristics and well-being.

Methods:

Autistic adults (N=533, 307 assigned female at birth; age range: 18-83, mean=43.28) were recruited through Simons Powering Autism Research (SPARK) Research Match to complete a battery of questionnaires. For the current study, measures of interest were demographic information, health history, questionnaires assessing subjective quality of life (WHOQOL-BREF), perceived stress (PSS), and depression (PHQ-9) and anxiety (GAD-7) symptomatology. Two subgroupings of FND were examined: medically unexplained disorders (MU; n=32; e.g., chronic pain) and physical health conditions with elevated psychological aspects (EP; n=23; e.g., migraines). Each of these two FND subgroupings was compared separately to a control group (n=478) of autistic adults with peripheral physical health conditions (e.g., hyperlipidemia). Chi-square analyses, independent samples t-tests, and Analysis of Covariance (ANCOVA) were used to examine group differences in demographics, quality of life, and mental health.

Results:

The FND subgroupings (MU, EP) contained a greater proportion of females and gender diverse individuals than found in the control group (χ2>11.16, p<.007). Additionally, the MU group was on average younger than the control group (t=3.92, p<.001, d=0.61). Even after accounting for autistic traits (AQ-28 score), age, and birth-sex, both of the FND groups reported lower subjective physical health quality of life than the control group (F=10.47, p<.001, ηp2=.02). Additionally, the MU group reported lower subjective psychological health quality of life (F=5.30, p=.02, ηp2=.01) and higher depression symptoms (F=3.75, p=.05, ηp2=.01) than the control group, after controlling for autistic traits, age, and birth-sex. No FND-control group differences in anxiety symptomatology or perceived stress were found.
Conclusions:

FNDs co-occur in a significant minority of autistic adults, with over 10% of the autistic adults in the current sample reporting an FND, a higher rate than found in the general population. FNDs were more common among autistic adults assigned female at birth, which parallels findings from specific forms of FND in the general population. Additionally, FNDs were more common among autistic adults who identify as a gender minority compared to those who are cisgender. Finally, both FND subgroupings were linked to decreased subjective physical health quality of life, and MU was further associated with lower subjective psychological health quality of life. More work is needed to understand the driving forces behind associations between FND and ASD as well as the impact of this co-occurrence on well-being.

302.003 (Oral) Heterogeneity in Autism: Two Replicated, Longitudinally Stable, Externally Valid Subgroups of Autistic Adults

T. A. Radhoe, J. Agelink van Rentergem, C. Torenvliet, A. P. Groenman, W. J. van der Putten and H. M. Geurts

Background: Autism is heterogeneous, which complicates the search for support for autistic people. Recently, we tested whether we can identify subgroups that could be helpful in determining which type of support people might need. Using mainly malleable factors as input we identified two subgroups of autistic adults that differed on external (clinical) validators such as quality of life, psychological difficulties and cognitive failures (preprint: https://psyarxiv.com/hs4bx/). Based on input of older/autistic adults, we named these subgroups: (1) Feelings of High Grip, and (2) Feelings of Low Grip.

Objectives: The goal of the current study is to test whether these previously identified subgroups are (a) stable over time, (b) different on external (clinical) outcomes, and (c) predictive of future outcomes.

Methods: Self-report questionnaire data were collected as part of a larger multistage overlapping cohort study on aging in autism (Geurts et al., 2021). The data for this study (T2) were collected two to five years after T1. We used community detection analyses for subgroup identification, using 14 variables as input: measures of autism, demographic and psychological characteristics. As preregistered (AsPredicted no. 77679), we first see whether we replicate T1 subgroups with an independent exploratory analysis in the T2-data set of N=452 adults (30-90 years, 241 autistic, 211 non-autistic comparisons), and we identify subgroups separately in autistic adults (N=241).

We test the external validity of the subgroups at T2 for quality of life, psychological difficulties and cognitive failures. Lastly, we test the predictive validity by using subgroup membership at T1 as a predictor of three validators measured at T2: quality of life, psychological difficulties and cognitive failures.

Results: Two subgroups were identified when combining data from autistic and non-autistic adults: Subgroup 1 included mainly autistic adults (96%) and Subgroup 2 included mainly non-autistic adults (89%). Within the autism group, we also replicated our previous findings by identifying two major subgroups: Feelings of High Grip (N=109) and Feelings of Low Grip (N=122). We also replicated our external validity findings of T1: the Feelings of Low Grip subgroup reported a lower quality of life, more psychological difficulties and more cognitive failures as compared to the Feelings of High Grip subgroup.

Conclusions: Based on these preliminary findings we conclude that the subgroups that we previously identified are replicable and valid. Furthermore, this characterization provides information on other domains beyond those used to construct them. Before the INSAR 2023 meeting we will assess subgroup membership stability and predictive validity. These final analysis steps can provide supporting evidence for the validity and importance of the autism subgroups, and may inform autistic adults and their loved ones of their future.

302.004 (Oral) Being Connected - the Influence of Social Connectedness on Quality of Life and Mental Health in Midlife and Older Age

G. R. Stewart, R. A. Charlton and F. Happe, (1)University College London, London, United Kingdom, (2)Psychology, Goldsmiths University of London, London, United Kingdom, (3)Social, Genetic and Developmental Psychiatry Centre, Institute of Psychiatry, Psychology and Neuroscience, King’s College London, London, UNITED KINGDOM

Background: Research examining the experiences of autistic children, young people, and adults has often indicated lower quality of life, more mental health problems, and low social connectedness (i.e., social isolation) and loneliness, when compared to non-autistic populations. However, despite older age being a period of health and support need changes, few studies have explored the rates and links between quality of life, mental health, and social connectedness later in midlife and older age.

Objectives: This study examined quantitative differences and associations between quality of life, mental health problems, and the experience of social isolation and loneliness among middle-aged and older autistic adults with an age and sex-matched non-autistic comparison group. This study also explored qualitative responses about participants’ experiences of the factors that influence their quality of life in midlife and older age.

Methods: Using a cross-sectional online survey from the AgeWellAutism study, a total of 428 adults (autistic n = 265) aged 40-93 (mean age = 60.50 years) completed standardised questionnaires related to quality of life, current symptoms of depression and anxiety, and their
experiences of social connectedness and loneliness. Participants also responded to open-ended questions about factors that have influenced their quality of life in midlife and older age. Group differences and associations in quantitative measures were examined. Thematic analysis was conducted on qualitative responses to identify common influences.

**Results:** Those in the autistic group reported having lower quality of life, more mental health problems, and being less socially connected (i.e., more socially isolated) and lonelier than the non-autistic group. While there were no gender differences in quality of life, mental health problems, and the experience of social isolation, women reported being lonelier than men in both the autistic and non-autistic group. A similar pattern of results was found when controlling for age and current symptoms of depression and anxiety. Higher social connectedness, lower feelings of loneliness, and fewer symptoms of mental health problems were associated with better quality of life in both groups. Better social connectedness was a particularly strong predictor for higher quality of life and lower mental health problems in the autistic group. Themes identified in the thematic analysis contextualize these experiences and associations, for example, the importance of having support from friends and family.

**Conclusions:** The findings from the current study suggest that autistic adults may be particularly susceptible to lower quality of life, more mental health problems, and higher rates of social isolation and loneliness in older age. Social connectedness was found to be a particularly important predictor of quality of life and mental health for autistic people. This study highlights the importance of social support in midlife and older age and suggests possible targets for interventions to improve autistic people’s quality of life as they enter older age.

**POSTER SESSION — ADULT OUTCOME: MEDICAL, COGNITIVE, BEHAVIORAL**

**401 - Adult Outcome: Medical, Cognitive, Behavioral I**

**401.001 (Poster) “I Am What I Am:” the Role of Essentialist Beliefs and Neurodivergent Identification on Individuals’ Self-Efficacy.**

*A. V. Lebrón-Cruz* and *A. Orvell*, (1)Yale Child Study Center, New Haven, CT, (2)Psychology, Bryn Mawr College, Bryn Mawr, PA

**Background:**

Essentialism is the belief that members of particular categories (e.g., race, gender) are united by an innate and immutable essence. While such beliefs have been associated with negative outcomes such as stereotyping, discrimination, and prejudice, minority group members can at times use essentialist beliefs to validate their identities and empower themselves.

**Objectives:**

Neurodivergence, a term which describes a range of neurological differences, is a relatively recent social category, and it is unknown to what extent it is essentialized. The purpose of this investigation is to examine whether holding essentialist beliefs about neurodivergence serves a protective function among 319 neurodivergent-identifying individuals. Within the context of this work, those who identify as neurodivergent include people who (a) have mental and/or neurological diagnoses (e.g., Autism), (b) might use the label to highlight the naturalness of their condition, and (c) celebrate and/or express how having a different brain may lead to unique life experiences.

We predict that the relationship between essentialist beliefs and self-efficacy will be stronger for those who identify more strongly with the neurodivergent label.

**Methods:**

We recruited a total of 602 individuals from Facebook and Reddit groups centered around neurodiversity (e.g., r/neurodiversity subreddit), disabilities (e.g., The Invisible Disability Support Group on Facebook), and specific disorders (e.g., r/Dyslexia subreddit). After applying exclusion criteria, we retained a sample of 319 participants.

If participants indicated that they identified as neurodivergent and provided consent, they began the questionnaires. Participants completed the neurodivergent identification measure, essentialism measure, self-efficacy measures (counterbalanced), and stigmatization measure. They were then asked to complete open-ended questions pertaining to their lived experiences, and demographic information.

**Results:**

To investigate whether participants’ degree of essentialist beliefs and neurodivergent identification predicted levels of self-efficacy, we performed a regression analysis using PROCESS Model Macro Model 1 to test for moderation (Hayes, 2013). Essentialist beliefs, neurodivergent identification and their interaction were entered as predictor variables and were mean centered. Stigmatization was entered as a covariate. Additionally, there were two separate measures of Self-efficacy utilized—one focusing on global perceptions of success (Model 1: Chen et al., 2001) and the other focusing on perceptions of coping and problem-solving (Model 2: Schwarzer et al., 1995).
Supporting our main predictions, we found that essentialist beliefs were related to higher self-efficacy; further, this relationship was moderated by individuals’ level of neurodivergent identification, such that people with stronger neurodivergent identification showed a stronger relationship between essentialist beliefs and self-efficacy, across both measures (see Figures 1 and 2).

Conclusions:

These results illuminate how essentialist beliefs may validate and empower a group that is often negatively stereotyped. Additionally, as demonstrated by other literature focusing on essentialist beliefs and treatment outcomes, the results of our study may also have implications for that of Autistic individuals’ treatment. Developing interventions which focus on embracing neurodivergent identity and validating one’s life experiences may be a powerful approach to improving Autistic individuals’ quality of life.

401.002 (Poster) "We Have Excessive Dysphoria, Not Only Gender Dysphoria": A Qualitative Analysis of the Co-Occurrence of Autism/Neurodiversity and Gender Dysphoria in Japan

S. Shimoyama, T. Endo, H. Yokoi and H. Ohta, (1)The University of Tokyo, Tokyo, Japan, (2)Showa University Medical Institute of Developmental Disabilities Research, Tokyo, Japan, (3)Showa University, Tokyo, JAPAN

Background:

Recently, there has been increased attention on a link between Autism/Neurodiversity (A/ND) and Gender Dysphoria (GD). Since the late 1990s, clinical attention has been paid to the co-occurrence of A/ND and GD. De Vries et al. (2010) first reported the prevalence of A/ND in GD individuals was 7.8%, which was 7 to 8 times higher than 1% of the world population (e.g., Lai et al., 2014). After the report, it has been discussed actively whether there is a link between A/ND and GD or not (see Kallitsounaki and Williams, 2022, for a review), and underlying hypotheses for the link (see Van der Miesen et al., for a review). To examine the underlying hypothesis for the A/ND-GD link, exploring these individuals’ experiences is essential, but previous research has little focus on the views of those with A/ND and GD except a few qualitative studies in Europe and North America (e.g., Strang et al., 2018).

Objectives:

This study explores the experiences of Japanese adults with A/ND experiencing GD to examine the underlying hypothesis for the co-occurrence.

Methods:

Sampling:

17 Japanese adults with A/ND experiencing GD were recruited from developmental clinics (n=8), gender clinics (n=7), and a self-help group (n=2).

Sample Characteristics:

- All participants are clinically diagnosed with Autism Spectrum Disorder.
- For GD, participants who were aware of GD were recruited. We did not ask them if they have been diagnosed with GD according to the criteria of DSM-5, in consideration of gender diversity.
- 4 Participants were assigned females and 13 were assigned males at birth.
- Ages ranged from 20 to 49 (Mean=30.8, SD= 9.5)

Data collection:

We asked the participants about their life stories regarding the co-occurrence of A/ND and GD from their early childhood to today in semi-structured interviews. The duration time of each interview was approximately 90 to 120 minutes, and each participant had two or three interviews.

Analysis:

Interview data were analyzed using Grounded Theory (Charmaz, 2020).

Results:
The key finding is that the participants have had not only GD but also other types of excessive dysphoria. For example, they had physical dysphoria due to GD but also due to hypersensitivity. Also, since their childhood, they have been feeling dysphoria again and again by being forced to conform to allistic norms including gender norms. And most participants reported that they have been feeling dysphoria that they cannot explain well. This result indicates the need to explore the underlying hypothesis of the co-occurrence, by considering not only GD, but also cumulative dysphoria from childhood. In other words, GD itself might not have a direct link to A/ND, but the excessive of dysphoria might have a link to A/ND.

Conclusions:

This study provides a new perspective on A/ND-GD co-occurrence that GD itself might not have a direct link to A/ND. Instead, we argue that the underlying hypothesis of the co-occurrence is that autistic people are forced to experience excessive dysphoria, including GD, in their social lives from childhood.

401.003 (Poster) "the World's Really Not Set up for the Neurodivergent Person": Understanding Emotion Dysregulation and Mental Health Needs from the Perspective of Autistic Adults

(1)University of Pittsburgh, Pittsburgh, PA, (2)Department of Psychiatry, University of Pittsburgh Department of Medicine, Pittsburgh, PA, (3)Department of Psychiatry, University of Pittsburgh School of Medicine, Pittsburgh, PA, (4)Department of Psychology, University of Wyoming, Laramie, WY, (5)Penn Center for Mental Health, University of Pennsylvania School of Medicine, Philadelphia, PA, (6)Psychology, The University of Alabama, Tuscaloosa, AL

Background: Emotion dysregulation, difficulty monitoring and modifying emotional reactivity and sustained negative emotion, underlies many co-occurring mental health conditions and suicidality in autism. Autistic individuals are 7 times more likely to have impairing emotion dysregulation than neurotypical peers. Most emotion dysregulation research has focused on youth, and little is known about unique aspects of emotion dysregulation in adulthood.

Objectives: The current study sought to understand autistic adults’ experiences of emotion dysregulation and perceived service needs as a precursor to refining existing evidence-based emotion dysregulation interventions for autistic adults.

Methods: Fifteen autistic adults aged 19-68 (7 men, 7 women, 1 transgender, 33% non-Hispanic Black, 7% Hispanic White, 60% non-Hispanic White, median age of diagnosis = 21) completed a 60-minute semi-structured interview. Participants were asked to share stories of recent instances of emotion dysregulation and provide emotion dysregulation service recommendations. Interviews were transcribed and a grounded theory analytic approach was used for coding and thematic analyses. Three coders, including one autistic adult, generated the initial codebook using a consensus approach. The finalized set of codes was grouped into themes and subthemes. Authors discussed and refined themes until consensus was reached. Autistic adults were involved in all aspects of this project.

Results: Thematic analyses illuminated that episodes of emotion dysregulation were often described in the context of a pervasive lack of control at all levels of social life (individual, interpersonal, systemic). At the individual level, participants described limited emergent awareness and control over emotion dysregulation, which was often a product of and sometimes indistinguishable from sensory overload. Episodes of emotion dysregulation resulted in suicide attempts, self-injury, or aggression in over one third of the sample. At the interpersonal level, every participant described interactions in which they were emotionally dysregulated as a result of being misunderstood by a neurotypical person (e.g., family, friend, colleagues). Many described the injustice that occurred when neurotypical people responded to their dysregulation by threatening serious consequences (e.g., disciplinary action, loss of friendship). At the systemic level, participants most frequently referenced a lack of power in healthcare settings (e.g., psychiatric/medical hospitals, crisis centers, outpatient offices) and workplaces. Participants described unjust responses (e.g., involuntary sedation, removal from services, suspension of dental care, loss of job), and feeling unsafe. Across all levels, most of the sample (80%) described holding a tension between the personal costs of camouflaging and the serious consequences of not camouflaging in order to survive adult life. Autistic adults detailed recommendations for better emotion regulation support, including accommodations and access to safe places and people, connection with other autistic people, fostering self-acceptance, and broader societal education and acceptance of neurodivergence.

Conclusions: This study is the first to unpack autistic adults’ own perception of emotion dysregulation which is described as due to a lack of control at all levels of social life. Future directions will require a holistic systems approach, eliminating injustice in healthcare and employment settings, promoting wider acceptance of neurodivergence in neurotypical society, and supporting autistic adults in cultivating self-acceptance, self-advocacy, and regulation skills.

401.004 (Poster) A "Triple Empathy Problem" May Lead to Adverse Healthcare Outcomes for Autistic Adults: A Qualitative Analysis

S. Shaw, L. Carravallah, M. Johnson, J. D. O’Sullivan, N. Chown, S. D. Neilson and M. Doherty, (1)Brighton & Sussex Medical School, Brighton, United Kingdom, (2)Department of Paediatrics and Human Development, Michigan State University, East Lansing, MI, (3)Guyt Valley Medical Practice, High Peak, United Kingdom, (4)Anaesthesia, Cork University Hospital, Cork, Ireland, (5)London South
Background: Autistic people experience poor physical and mental health compared with non-autistic people, and life expectancy is reduced. Autistic people are more likely to use emergency healthcare and to experience emergency hospital admission, after which inpatient mortality is increased.

Barriers to healthcare are well documented. We have previously shown that these barriers are significantly associated with self-reported adverse health outcomes for both formally diagnosed and self-identified autistic respondents. We reported 80% of autistic respondents experienced difficulty attending primary care, with two thirds describing untreated physical and mental health conditions and one third unable to access treatment for potentially serious or life-threatening conditions. Barriers such as telephone-based appointment booking, difficulty communicating with reception staff and doctors, along with sensory challenges in the waiting room are significantly associated with adverse outcomes.

Objectives: This paper presents the qualitative phase of the study. We aimed to explore in depth the experiences of autistic adults accessing healthcare on an experiential level and to identify target areas for intervention to improve access and outcomes.

Methods: This is a quasi-phenomenological study from an autistic research team including autistic medical doctors, using participatory methods. Data were collected as part of a large, mixed-methods, international survey which began with a community-identified need to develop autism training for healthcare providers. A 52-item self-report survey was distributed online. The quantitative results are previously published and this paper reports the qualitative findings, following a thematic analysis.

Results: Data from 1248 autistic respondents were included. Respondents reported a variety of healthcare barriers and adverse outcomes. Here, we give voice to their stories, in their own words. Themes included: early barriers; communication mismatch; doubt – in oneself and from doctors; helplessness and fear; healthcare avoidance and adverse health outcomes; with overarching themes of epistemic injustice and what we term a “triple empathy problem”.

“"The hardest thing about going to the doctor is making the big step of making yourself vulnerable in order to ask for help but often finding help does not come”

Conclusions: Autistic people face barriers accessing healthcare, followed by difficulties interacting with healthcare providers, which may contribute to known healthcare disparities, including increased morbidity and mortality.

Using our exploratory findings, we produce a model that seeks to understand and explain the reported barriers in the context of the previously known healthcare inequities by exploring the interactions between access barriers and adverse outcomes. We also draw on, and build upon, Damian Milton’s “double empathy problem”, situating this in a medical context, to describe what we term a “triple empathy problem”. The double empathy problem describes the bi-directional difficulty autistic and non-autistic people can have understanding each other. There is a similar phenomenon at play between medical practitioners and lay people, which is further compounded for autistic people, leading to additional healthcare access barriers. This is supported by our finding that autistic respondents with medical backgrounds did not report better experiences with healthcare access. Improved healthcare outcomes for autistic people can be achieved by healthcare providers understanding the autistic experience.

401.005 (Poster) A Metaphorical Analysis of Autistic Meltdowns & Shutdowns

L. F. Lewis¹, K. Crouch², E. DeBole², J. Carbone², A. (. Lodestone³ and M. Houser⁴, (1)College of Nursing & Health Sciences, University of Vermont Nursing Department, Burlington, VT, (2)University of Vermont, Burlington, VT, (3)Wravenwood Studios LLC, Burlington, VT, (4)All Brains Belong VT, Montpelier, VT

Background:

“Meltdowns” and “shutdowns” are common responses to dysregulation among autistic people in the face of social, sensory, or other stressors. While previous literature has described behaviors of autistic children during meltdowns, little is known about how meltdowns and shutdowns are experienced by autistic people themselves. Preliminary qualitative data suggests that these experiences are deeply internalized beyond the externalized reactions visible to outside observers. Figurative language used by autistic people can offer rich insight into what this experience feels like for those living it.

Objectives:
The purpose of this qualitative secondary data analysis was to identify the metaphors autistic individuals used to describe experiences of dysregulation, including meltdowns and shutdowns.

Methods:

This study was conducted by a team of autistic and non-autistic people using a participatory action approach. We used the Pragglejaz Group’s metaphor identification procedure to identify figurative language used to describe meltdowns and shutdowns by autistic individuals. Data were collected in two previous phenomenological studies exploring the lived experiences of meltdowns (n = 32) and shutdowns (n = 26) for autistic adults, collected via online interviews, as well as a mixed methods survey study exploring autistic feedback on a tool to facilitate communication about meltdowns and shutdowns for providers and patients (n = 46). Participants ranged in age from 18 to 69 years (M = 35.3); 55% female-identifying, 24.4% male-identifying, and 20.6% gender divergent; 66.1% formally diagnosed as autistic; 15.5% not formally evaluated but told by a health professional they are likely autistic; 18.4% self-identified; 87% White; seven countries represented, primarily United States (66.1%), Australia (10.5%), United Kingdom (10.5%), and Canada (9.2%). Our corpus of text consisted of 79 typed pages, of which we judged 696 lexical units to be used metaphorically. We sorted these into metaphors used most often by autistic adults to describe their meltdown and shutdown experiences.

Results:

Eight metaphors emerged that participants used most frequently to describe the experience of meltdowns: a bomb exploding; something cracked; trying to escape; slamming my lid; a spammy pop-up; hitting my limit; going off-script; and animalistic survival. Six metaphors characterized the experience of shutdowns: being frozen; the blue screen of death; going inside myself like a snail; not keeping up with the world; running on autopilot; and feeling stuck.

Conclusions:

These metaphors add a new voice for understanding autistic people’s experiences of meltdowns. Findings can offer new ways to relate to an experience that can be difficult to describe, thus bridging the double empathy problem. In addition, though autistic people are often thought to use and understand language literally compared to non-autistic people, our findings add to evidence about how autistic people use figurative speech in naturally occurring written expressive language to describe their experiences. Finally, findings suggest that meltdowns and shutdowns each include internalized components, and distinguishing between types of dysregulation may be irrelevant to understanding the experience.

401.006 (Poster) A Randomized Controlled Trial of PEERS® for Careers: Building the Evidence Base and Breaking Employment Barriers for Autistic Adults

E. A. Laugeson, C. T. Moody, R. S. Factor, J. E. Lerner, E. Denluck and A. Gulsrud; (1)UCLA Semel Institute for Neuroscience and Human Behavior, PEERS lab: UCLA PEERS Clinic, Los Angeles, CA, (2)UCLA Semel Institute for Neuroscience and Human Behavior, University of California Los Angeles, Los Angeles, CA, (3)UCLA Semel Institute for Neuroscience and Human Behavior, UCLA Semel Institute for Neurosciences & Human Behavior, Los Angeles, CA, (4)UCLA Semel Institute for Neuroscience and Human Behavior, UCLA PEERS® Clinic, Los Angeles, CA, (5)School Psychology, University of Oregon, Eugene, OR, (6)UCLA Semel Institute for Neuroscience & Human Behavior, Los Angeles, CA

Background: Autistic adults are more likely to be unemployed or underemployed than their peers, both with and without disabilities (Shattuck et al., 2012; Chen et al., 2012). Beyond employer stigma and lack of knowledge about autism (Scott et al., 2019), autistic adults express multifaceted barriers to finding and keeping employment, including challenges related to professional social communication (Black et al., 2020; Anderson et al., 2021). PEERS® for Careers is a novel employment-focused social skills intervention developed to address this need (Moody et al., 2022). Informed by focus groups with autistic adults and other stakeholders, and using evidence-based methods of social skills instruction (Moody & Laugeson, 2020) including career coaching, the curriculum teaches skills needed to obtain, maintain, and thrive in employment settings (e.g., resume writing, interviewing, conversational skills, workplace culture).

Objectives: The purpose of this study was to conduct the first randomized controlled trial of PEERS® for Careers to test the efficacy of the curriculum and determine the level of support most beneficial for autistic adults.

Methods: Participants included 106 autistic adults (M age=22.9, SD=3.6; M IQ=109.6, SD=12.9; 81% male; 49.1% White) who expressed interest in learning employment-related social skills and seeking employment opportunities. All participants received the 20-week PEERS® for Careers curriculum, with 53 participants randomly assigned to additionally receive a career coach to support practice and application of the PEERS® for Careers skills outside of lessons. No significant differences on demographic or outcome variables emerged between the Coach and No-Coach conditions at baseline. Adults completed questionnaires pre- and post-intervention assessing employment status, employment-related social skills knowledge (Test of Employment Social Skills [TESS]; Moody et al., 2022), and social responsiveness (Social Responsiveness Scale, 2nd Edition Self-Report [SRS-2]; Constantino & Gruber, 2008).
Results: Results revealed significant improvements following PEERS® for Careers in employment-related social skills knowledge (TESS), $p<.001$, feelings of preparedness for employment, $p<.001$, and social responsiveness (SRS-2), $p=.004$. Nonparametric tests also showed a significant increase in engagement in employment-related activities, $p<.001$, as well as in paid employment, $p<.001$, from pre- to post-intervention. Those randomized to receive a career coach were more likely to remain enrolled, $p=.034$, and after the 20-week curriculum, showed significantly greater improvements on both the TESS, $p=.007$, and subjective ratings of preparedness for employment, $p=.033$, than those without a coach. Importantly, among participants who were not engaged in any employment-related activity at baseline ($n=62$), those who received career coaching were significantly more likely than the No-Coach group to gain new employment, internship, or volunteer positions by post-intervention, $p=.025$. Future planned analyses will examine continued benefits of PEERS® for Careers during a 10-week employment/internship phase, which included a re-randomization, and subsequent 10-week follow-up phase.

Conclusions: Overall, findings suggest that PEERS® for Careers is effective in improving employment-related outcomes for autistic adults. Results further indicate that career coaching reduces attrition and produces greater benefit than the curriculum alone. In sum, PEERS® for Careers shows success in supporting autistic job-seekers in achieving their employment goals. To build upon this, we intend to develop employer supports to foster more inclusive workplaces.

401.007 (Poster) Age and College Enrollment As Predictors of Treatment Outcomes Among Autistic Young Adults: The UCLA PEERS® Intervention

Background: Challenges with social communication and interaction are a defining characteristic of autism spectrum disorder (ASD; Lord et al., 2020). Given the importance of social connectedness in the transition into adulthood (Monohan et al., 2021) and the vast heterogeneity within autistic individuals (Masi et al., 2017), there is a need for evidence-based social skills interventions among this population. One of the only such programs for autistic young adults is the UCLA Program for the Education and Enrichment of Relational Skills (PEERS®; Laugeson, 2017). However, there are individual and contextual factors yet to be explored that might influence treatment response; specifically, age and enrollment in postsecondary education may impact access to same-age peers and, relatedly, opportunities for skills practice and application during the intervention.

Objectives: This study examined the influence of age and college enrollment on treatment gains of autistic young adults following PEERS® for Young Adults.

Methods: Participants included 102 young adults (males=74, females=28; $M_{age}=23.03$, $SD=3.94$) and their caregivers who completed the PEERS® program. Participants presented with an historical autism diagnosis or clinically-elevated autism symptoms (i.e., total T-score $\geq 60$ on the Social Responsiveness Scale–Second Edition; SRS-2; Constantino & Gruber, 2012). Participants were classified as “In-College” ($n=56$) or “Not-in-College” ($n=46$) based on baseline demographic questionnaire responses. Treatment outcome was assessed using change scores on the SRS-2, Social Skills Improvement System (SSIS; Gresham & Elliott, 2008), Quality of Socialization Questionnaire (QSQ; Frankel et al., 2010), and Test of Young Adult Social Skills Knowledge (TYASSK; Laugeson et al., 2015).

Results: As a whole, the sample significantly improved on all outcome measures ($p$’s$<.001$). At baseline, the Not-in-College participants were on average older, $p=.001$, and had poorer social responsiveness, $p=.006$, than In-College participants. Through a series of ANCOVAs including our variables of interest, college status and age, and a covariate of baseline social responsiveness, neither age nor college enrollment significantly predicted change in social skills (SSIS), problem behaviors (SSIS), or social skills knowledge (TYASSK). The Not-in-College group exhibited marginally greater pre- to post-intervention improvements on the SRS-2 ($M_{diff}=-8.48$) than the In-College group ($M_{diff}=-5.29$), $F(1,88)=3.70$, $p=.058$, over and above age and baseline social responsiveness, such that between-group differences in social responsiveness became non-significant at post-intervention, $p=.664$. Further, there was a trending, positive association between age and change on the QSQ, such that older participants tended to show greater increases in get-togethers post-treatment, $B=.216$, $F(1,86)=3.06$, $p=.084$, over and above college status and baseline social responsiveness.

Conclusions: Regardless of age and college enrollment status, results reveal that autistic adults exhibit significant improvements in social functioning following the PEERS® for Young Adults intervention. Marginally greater improvements in adults of older age or not currently enrolled in college on treatment outcomes suggest that those without pre-existing, structured access to peers (i.e. academic courses, clubs/extracurriculars) may especially benefit from instruction on how to find, engage, and deepen connections with sources of friends through the PEERS® curriculum. Future studies might explore additional factors influencing treatment presentation and outcomes among autistic adults to create more effective, targeted interventions for this population.
401.008 (Poster) An International Priority Setting Partnership (PSP) to Identify and Prioritise Evidence Gaps at the Intersection of Autism and Addiction Using an Adapted Delphi Methodology

J. Robinson, B. Aslan, S. Chamberlain, C. Torry and J. Sinclair, (1)CLASS, Cambridgeshire and Peterborough NHS Foundation Trust, Cambridge, United Kingdom, (2)Learning Disability and Autism Programme, NHS England, London, United Kingdom, (3)Department of Psychiatry, Clinical and Experimental Sciences, College Keep 4-12 Terminus Terrace, Southampton, Faculty of Medicine, University of Southampton, Southampton, United Kingdom, (4)School of Health and Psychological Sciences, City, University of London, London, United Kingdom, (5)Department of Psychiatry, Faculty of Medicine, University of Southampton, Southampton, United Kingdom

Background: Autism Spectrum Disorder (hereafter autism) is a neurodevelopmental condition affecting 1–2% of people worldwide. It commonly presents with co-occurring physical and mental health conditions, and morbidity and mortality rates are higher than those in the general population. Research is limited, but some evidence suggests that autistic individuals might be more likely to have addictions compared to the general population. The rate of substance use disorder (SUD) in autistic people is up to 36%, yet little is known of the underlying aetiology or effective ways of managing SUD in autistic individuals. For behavioural addictions (e.g., gambling) there is a lack of evidence about the mechanisms and motivations in autistic people.

Objectives: To identify the evidence gaps in relation to three sub-topics: problematic alcohol use, substance use and behavioural addictions in autism and, secondly, to reach consensus on the top ten priorities for research, policy and practice.

Methods: We convened an international Priority Setting Partnership (PSP) of potential stakeholders including experts by experience. The phased process included a structured scoping review to identify gaps in the literature and an online survey of questions respondents had about problematic alcohol use, substance use, gambling and autism. The core project team reviewed the final results and a panel of 22 members participated in a two-stage Delphi process and rated the questions in terms of priority.

Results: The structured scoping reviews showed limited evidence from studies that were contradictory, could not be replicated, were reliant on specific tasks and limited by sample sizes. Overall findings suggested that more research is needed to understand the aetiology, prevention and treatment of addictions in autism.

A total of 78 stakeholders, including clinicians and academics in the fields of addiction and autism, autistic professionals, and autistic individuals with lived experience of addiction, posed 601 unique questions via an online survey. Additional questions were elicited via workshops. After excluding questions on the basis of being out of scope or duplications of other questions a final list of 340 questions was confirmed. These questions were analysed and classified into themes of topic questions to be agreed by stakeholders and the Delphi panel. Two iterative rounds of the Delphi process reduced 38 questions to 14 for rating.

The Delphi process produced consensus ratings for top ten policy priorities for research (3), policy (3) and clinical practice (4).

Conclusions: Results indicate agreement regarding directions for future collaborative cross-disciplinary approaches to tackling this important but marginalised area of addiction.

401.009 (Poster) An Overlooked Mental Health Condition: First Estimates of Prevalence and Clinical Correlates of Misophonia in Cognitively-Able Autistic Adults

Z. J. Williams, D. J. Barrett, C. J. Cascio and T. G. Woynaroski, (1)Medical Scientist Training Program, Vanderbilt University School of Medicine, Nashville, TN, (2)Neuroscience Undergraduate Program, Vanderbilt University, Nashville, TN, (3)Department of Psychiatry and Behavioral Science, Vanderbilt University Medical Center, Nashville, TN, (4)Department of Hearing and Speech Sciences, Vanderbilt University Medical Center, Nashville, TN

Background: Misophonia is a newly-described psychiatric disorder in which individuals have strong negative emotional responses (typically extreme irritation, anger, or disgust) in response to specific “trigger” sounds (e.g., chewing, tapping, and sniffing), resulting in significant distress, pathological avoidance behavior, and impairment in daily life (Swedo et al., 2022). There is a sizable body of evidence to suggest that misophonia, like other forms of decreased sound tolerance, is common in the autistic population (Williams et al., 2021). However, the prevalence of this specific phenotype (as opposed to other forms of sound intolerance such as hyperacusis and phonophobia) and its effects on mental health and well-being remain poorly understood.

Objectives: To describe the prevalence, clinical features, and correlates of suspected misophonia (based on a validated screening tool) in a large sample of cognitively-able autistic adults.

Methods: Independent autistic adults aged 18–80 years (n=936, MAge=37.49 years, 63.0% female sex, 80.1% non-Hispanic White, median age of autism diagnosis=23.2 years) were recruited via Simons Powering Autism Research for Knowledge (SPARK) Research Match (Feliciano et al., 2018), as part of a study of sensory differences in autism (RM0111Woynaroski - DST). Misophonia status was determined using the Duke-Vanderbilt Misophonia Screening Questionnaire (DVMSQ; Williams et al., 2022), and both the DVMSQ and Duke Misophonia Questionnaire (DMQ; Rosenthal et al., 2021) were used to characterize the misophonia phenotype.
**Results:** Approximately one third of autistic adults (n=332; 35.5%) screened positive for misophonia on the DVMSQ. Of this misophonia group, 73.8% (n=245; 26.2% of full sample) endorsed “moderate” or “severe/very severe” misophonia-related impairment on the DMQ impairment subscale. The most commonly endorsed trigger sounds included “people talking in the background (e.g., phone calls in public, many people talking at once)” [77.1%], “people making mouth sounds while eating or drinking (e.g., chewing, crunchy slurping)” [70.8%], and “people making repetitive sounds (e.g., typing, tapping nails on table, pen clicking, writing, construction work, using machinery)” [68.7%]. The most frequent emotional reactions when triggered were extreme annoyance/irritation (mean of 3.65 on 0-4 scale), anger/rage (mean of 2.66), disgust (mean of 2.39), and fear/panic (mean of 2.06), and nearly 70% of the misophonia group endorsed physical responses to triggers. Misophonia was more common in females and individuals who additionally reported other forms of decreased sound tolerance. After controlling for sex, age, and hyperacusis status, DVMSQ misophonia status was associated with higher anxiety (d=0.555, CrI: 0.412, 0.698) and depression (d=0.529, CrI: 0.380, 0.684) symptoms, and after controlling for those variables and current anxiety/depression symptomatology, misophonia status was associated with highertrait anxiety (d=0.315, CrI: 0.182, 0.447), more ADHD symptoms (d=0.304, CrI: 0.170, 0.440), more anger-related symptomatology (d=0.298, CrI: 0.184, 0.413), greater somatic symptom burden (d=0.305, CrI: 0.170, 0.442), and reduced overall quality of life (d=−0.131, CrI: -0.262, -0.002).

**Conclusions:** Misophonia was highly prevalent in the present sample of cognitively-able autistic adults, with over 35% screening positive for the condition. Misophonia status is a significant predictor of many relevant mental health outcomes in autistic individuals, highlighting the need for additional research on this understudied disorder and its role in the well-being of autistic adults.

401.010 (Poster) Looking at Me Anxiety: Gaze Anxiety in Autism

*D. J. Milne*, A. Saliba and N. Sugden, (1)School Of Psychology, Charles Sturt University, North Wagga Wagga, NSW, Australia, (2)School Of Psychology, Charles Sturt University, Bathurst, NSW, Australia

Background: Anxiety is a common co-occurring diagnosis in the autism population. Lack of eye contact is one of the diagnostic criteria of an autism diagnosis. The Gaze Anxiety Rating Scale (GARS; Schneier et al., 2011) has been used in social anxiety research to measure gaze anxiety. In non-autistic research gaze anxiety has a positive relationship with social anxiousness and general anxiety. Previously the Gaze Anxiety Rating Scale has not been used in a large autistic participant group study using diagnosed autistic adults. As there is a large prevalence of social anxiety and general anxiety in the autism population along with potential reduced eye contact behavior, exploring the relationship between social, general and gaze anxiety may aid in understanding anxiety presentations in the autism population.

Objectives: The aim of this study was to determine if the GARS can be used in the autistic adult population to measure gaze anxiety. Further this study investigated the relationship between gaze anxiety and generalised anxiety in an autistic cohort and compared this to a non-autistic cohort.

Methods: An online survey method was used with community-sampled participants diagnosed with autism (n = 133), broadly representative of the Australian autistic population, and a concurrently collected non-autistic control group (n = 129). Gaze anxiety was measured using the GARS, social anxiety was measured by the Liebowitz Social Anxiety Scale-Self Report (LSAS-SR; Liebowitz, 1987), and general anxiety was measured using the DASS-21 (Lovibond & Lovibond, 1995).

Results: The GARS was found to be a reliable measure in an Australian community-based adult autistic cohort. In the autistic cohort, higher levels of anxiety and stress measured by the DASS-21, social anxiety as measured by the LSAS-SR, and gaze anxiety as measured by the GARS, were found when compared to a same time data collected non-autistic cohort. A positive relationship was found between the GARS and, general anxiety and social anxiety measures.

Conclusions: The GARS was found to be a reliable measure of gaze anxiety in the autistic cohort. Measuring gaze anxiety may aid in understanding anxiety presentations in autistic adults. The autistic cohort reported significantly higher levels of social, general and gaze anxiety than the non-autistic control.

401.011 (Poster) Are Parkinsonism Features Stable and Linked to Other Aging-Related Concerns Among Middle Aged and Older Autistic Adults?

Background: Emerging evidence linksparkinsonism (i.e., motoric features associated with Parkinson’s Disease, such as limb stiffness and bradykinesia) with autism during middle and older adulthood. However, research to date has been limited to cross-sectional studies only; no studies have examined whetherparkinsonism features change over time. Additionally, it is unclear if there are links between theseparkinsonism features and other aging-related concerns, such as cognitive decline and falls, among middle and older age autistic adults.

Objectives: Examine change inparkinsonism features over a two-year period and contemporaneously investigate associations between parkinsonism features and both subjective reports of cognitive decline and falls during middle and older adulthood in autism.
Methods: 210 autistic adults (58% female) ranging in age from 43-81 (M=56) years were recruited via Simons Powering Autism Research (SPARK) Research Match and completed a series of online questionnaires two years after their original study participation. The presence of parkinsonism features was evaluated using the Parkinsonism Screening Questionnaire (PSQ) at both Time 1 and Time 2. Subjective cognitive decline was measured using the Eight-item Interview to Differentiate Aging and Dementia (AD8) at Time 2. The presence and number of falls a participant had experienced in the last year were also queried at Time 2. Repeated measures analysis of covariance and a partial correlation, both accounting for the effect of lifetime antipsychotic medication exposure, were used to examine change in parkinsonism features over time and associations between parkinsonism features and subjective reports of cognitive decline at Time 2, respectively. Additionally, independent samples t-tests were used to evaluate whether autistic adults reporting falls also reported greater parkinsonism features at Time 2.

Results: Parkinsonism features demonstrated a small but significant improvement (Time 1: M=3.63, SD=4.02; Time 2 M=2.64, SD=3.53) over the course of two years in this sample of middle and older age autistic adults, even after accounting for antipsychotic exposure ($F=6.04, p=.015$). However, screen positive rates for parkinsonism using the PSQ remained high (28.6%). Partial correlations revealed that increasing parkinsonism features were significantly associated with increased reports of subjective cognitive decline ($r=.32, p<.001$; see Figure 1) even after accounting for antipsychotics exposure. Finally, autistic adults who reported experiencing falls (n=44) rated themselves as having significantly more parkinsonism features than those who did not experience falls ($t=2.00, p=.047$).

Conclusions: On the group level, parkinsonism features modestly decreased over time among middle and older age autistic adults. Despite the decrease in symptoms, screen positive rates for parkinsonism remained high at Time 2 (~29%) and were only slightly lower than screen positive rates documented in an overlapping sample that was nearly twice as large at Time 1 (~33%). Furthermore, increasing parkinsonism features were associated with greater subjective reports of cognitive decline and with a recent history of falls among this group of autistic adults. These findings represent a first step to better understanding the developmental progression of the increased risk for parkinsonism among autistic adults and its links to aging-related concerns.

401.012 (Poster) Arithmetic Performance in Visual and Auditory Modalities in Adults with High-Functioning Autism

Y. Zhang and M. Naumceska, (1)Department of Speech-Language-Hearing Sciences, University of Minnesota - Twin Cities, Minneapolis, MN, (2)70 CVETOVI, Skopje, Macedonia

Background: Individuals with high-functioning autism typically show average mathematical skills despite limitations in verbal communication. Previous brain imaging research indicates that language ability plays an important role in performing exact mental computation. Little is known about the neural mechanisms for numeric processing in individuals with autism. For instance, it is unclear whether using visually presented Arabic numbers would bypass the language-related neural networks and eliminate the language-specific effects in arithmetic performance.

Objectives: The present event-related potential (ERP) study aimed to compare adults with high-functioning autism and age-matched control subjects with a mental addition task in visual and auditory modalities.

Methods: Sixteen monolingual adults with clinical diagnosis of high-functioning autism (or Asperger’s) and sixteen age-matched neurotypical control subjects participated in the study. All subjects were native speakers of English, had normal hearing, and were right-handed. The mental addition task used two-digit numbers. There were two presentation conditions. Each trial in the visual condition started with a tone beep prompt. Then the two Arabic numbers with the “+” sign in between were presented together next, followed by the answer in Arabic number. The auditory condition replaced the question part (not the answer part) with auditory verbal stimuli. There were 120 trials for each condition and each answer. The auditory stimuli were presented at 60 dB sensation level. Inter-stimulus interval was randomized between 1500 ~ 2000 ms. Subjects were required to press button for responses. The EEG data were recorded with a 64-channel EEG system in an acoustically-treated booth. The sampling frequency was 512 Hz, and the bandpass filter was 0.016 - 200 Hz. Trials with peak amplitudes exceeding the range of +/- 50μV were rejected. The data were bandpass filter at 0.5-40 Hz and the epoch window was -100 ~ 1000 ms.

Results: Behavioral data showed no significant differences in response accuracy between the two subject groups and two modalities for mathematical calculation. While the control subjects did not show differences in reaction time between the two modalities, the autism group took significantly longer time in the auditory mode than the visual mode, indicating a verbal working memory influence. Both behavioral and ERP data consistently showed strong effects of congruent and incongruent conditions in the two groups. For all subjects, it took longer reaction time to respond to incongruent condition than congruent condition. Corresponding to the behavioral results, the incongruency effect was reflected by a negative ERP component between 300 and 400 ms followed by a positive component between 400 and 600 ms in the visual mode. Compared with neurotypicals, adults with high-functioning autism showed delayed neural responses for the incongruency effect in both early and late components in the auditory mode. Furthermore, a late negative response was found in the autism group.
Conclusions: The behavioral and ERP results indicate that verbal working memory affects neural processing speed of arithmetic performance in individuals with autism. Further, there appears to be no significant difference from neurotypical peers in their arithmetic performance in the visual mode.

**401.013 (Poster) Measuring Adaptive Behavior in Autistic Adults: Comparison of the Vineland-3 Interview Form and Abas-3 Survey**  
*E. Wilkinson, S. E. Teh, N. Jadav and V. H. Bal*, (1)Graduate School of Applied and Professional Psychology, Rutgers University, Piscataway, NJ, (2)Sunway Medical Centre, Penang, Malaysia, (3)Graduate School of Applied and Professional Psychology, Rutgers University - New Brunswick, Piscataway, NJ

**Background:** Adaptive behavior is a broad set of behaviors important to maintaining independence and community participation. The Vineland Adaptive Behavior Scales (VABS; Sparrow et al., 1984; 2005; 2016) and Adaptive Behavior Assessment System (ABAS; Harrison & Oakland, 2003; 2008; 2015) are frequently used adaptive behavior measures. While the VABS is designed for use from birth-adulthood, the ABAS has separate forms for children and adults, potentially making it more useful for assessing a wider range of adult-relevant skills. Comparisons of the ABAS and VABS in child and adolescent samples (Dupuis et al., 2021; Lopata et al., 2013, Tamm et al., 2022) suggest caution is warranted, as ABAS scores have been found to be inconsistently higher than VABS. To our knowledge, no studies to date have looked at the correspondence between Vineland-3 and ABAS-3 in a sample of autistic adults.

**Objectives:** The current study aimed to directly compare parent-report VABS-3 and ABAS-3 scores in a dataset of autistic adults; comparisons are made within adults with nonverbal IQs (NVIQ) <70 and 70+.

**Methods:** Participants (N=29) were referrals to a specialty adult autism clinic or research projects aimed at characterizing autism in adulthood. Caregivers completed the VABS-3 interview and ABAS-3 survey form. All VABS-3 and ABAS-3 were administered within 11 months, with 79% within 3 months (M=1.46 SD=2.59, range=0-11). Standard scores are reported for comparison to other studies; however, because the ABAS-3 floor goes down to approximately 50 and VABS-3 domain floors go as far down as 20, all analyses were conducted using adjusted VABS-3 scores (VAdj), in which all VABS scores below 50 were assigned a value of 49. Analyses were conducted in the full sample and separately for those with NVIQ <70 (n=11) and 70+ (n=18).

**Results:** VABS-3 Adaptive Behavior Composite (ABC) were significantly lower than the ABAS-3 General Adaptive Composite (GAC) even when using AdjABC (d=-.82; Table 1). There was not a significant difference in classification (<70 vs. 70+) on instruments (p=.07); 72% were similarly classified with 9 falling below 70 and 12 70+ on both instruments. VAdjABC scores were significantly lower than the ABAS-3 GAC for both adults with NVIQ<70 (d=-1.12) and those with NVIQ 70+ (d=-.71; Figure 1). Similarly, VAdj Daily Living Skills were significantly lower than ABAS-3 Practical scores for both groups (d=-1.11; d=-.92, respectively). For adults with NVIQ<70, VAdjCommunication and VAdjSocialization scores were lower than ABAS-3 Conceptual (d=-1.24) and Social domains (d=-1.45), respectively. In contrast, for adults with NVIQ 70+, comparison across instruments revealed smaller, non-significant differences (d=-.25, d=-.37).

**Conclusions:** In this sample of autistic adults, VABS-3 scores were lower than ABAS-3 scores. For those with cognitive impairment (i.e., NVIQ <70), differences were larger, likely reflecting wider variability in skills assessed by VABS-3 resulting in lower basal values. For those NVIQ 70+, closer examination of difference between the Daily Living and Practical domains is needed. Considering the wider-spread use of the VABS in autism research, findings suggest caution in assuming measures can be used interchangeable and highlight a need for further research to inform interpretation across studies.

**401.014 (Poster) Associations between Self-Reported Internalizing and Externalizing Symptoms and Scores on the Social Responsiveness Scale-Second Edition in Two Autistic Adult Samples.**  
*J. E. Ederer, J. E. Siegel, E. Wilkinson, H. Lee and V. H. Bal*, (1)Rutgers Graduate School of Applied and Professional Psychology, Piscataway, NJ, (2)Rutgers University Graduate School of Applied and Professional Psychology, Piscataway, NJ, (3)Graduate School of Applied and Professional Psychology, Rutgers University, Piscataway, NJ, (4)Graduate School of Applied and Professional Psychology, Rutgers University - New Brunswick, Piscataway, NJ

**Background:**

The Social Responsiveness Scale-Second Edition Adult form (SRS-2:Adult) is a self-report screening questionnaire commonly used to quantify severity of autism symptoms (Constantino & Gruber, 2012). Research suggests that scores from the parent-report version are influenced by non-autism-specific factors, warranting caution when used as a measure of autism severity in children (Caprioa-Hall et al., 2021; Havdahl et al., 2016; Cholemkery et al., 2014; Hus et al., 2013). Few studies have considered these factors in autistic adults. South and colleagues (2017) reported strong correlations between the SRS-2:Adult and self-report measures of anxiety. Considering high rates of co-occurring psychological and behavioral conditions in autistic adults (e.g., depression anxiety; ADHD; e.g., Hollocks et al., 2018; Jadav et al., 2022), research is needed to further understand how symptoms associated with co-occurring conditions affect SRS-2:Adult scores.
Objectives:

To examine the influence of non-autism-specific factors which may affect the interpretation of SRS-2:Adult scores.

Methods:

Study 1. 66 participants with both SRS-2 and ASR scores were drawn from a sample of 72 adults with autism diagnoses referred to a specialty adult autism clinic or adult autism research studies (Table 1). Pearson’s correlation analyses were used to assess the relationship between SRS-2 scores and the Internalizing and Externalizing subscales of the ASEBA Adult Self Report (Achenbach et al., 2017). Chi-square analyses were used to explore the association between clinical cut-offs on each instrument.

Study 2. 50 autistic adults with both SRS-2 and ASR scores were drawn from a sample of 66 adults recruited for an online survey of repetitive behaviors were used to internally replicate findings from Study 1 (Table 1).

Results:

Study 1. SRS-2 T-Scores were positively correlated with Internalizing ($r=0.48, p<.001$) and Externalizing ($r=0.30, p=0.015$) ASR scales. SRS-2:ASR Internalizing correlations were significant for both males ($r=0.54, p=0.002$) and females ($r=0.48, p=0.005$), while Externalizing was associated for females ($r=0.43, p=0.014$) but not males ($r=0.04, p=0.841$). Overall sensitivity of the SRS-2:Adult was 80.6%. SRS-2 classification was marginally associated with ASR-Externalizing classification ($X^2(1)=3.51; p=0.061$), but not the ASR-Internalizing scale ($X^2(1)=3.74; p=0.390$, Table 2).

Study 2. SRS-2 T-Scores were positively correlated with Internalizing ($r=0.63, p<.001$) and Externalizing ($r=0.34, p=0.016$) ASR scales. SRS-2:ASR Internalizing associations were observed for males ($r=0.68, p=0.021$) and females ($r=0.63, p<0.001$), whereas Externalizing were marginal (females: $r=0.31, p=0.052$) or nonsignificant (males: $r=0.42, p=0.201$). Sensitivity of the SRS-2:Adult was 82.4%. SRS-2 classification was associated with ASR-Externalizing ($X^2(1)=4.86; p<0.001$), and ASR-Internalizing classification ($X^2(1)=13.02; p<0.001$, Table 2).

Conclusions:

Consistent with child studies of parent-reported SRS, self-reported SRS-2:Adult scores and ASR scales for internalizing and externalizing scales were correlated. Although the SRS-2:Adult accurately classified 80-82% of participants, analyses suggested the instrument’s sensitivity differed depending on levels of externalizing behaviors. Taken together, preliminary results highlight a need to use multiple measures to characterize adult autism samples in order to inform interpretation of self-report measures intended to capture autism-related behaviors. Additional multivariate analyses will be conducted to explore factors affecting SRS-2:Adult scores, including gender and the relative contribution of different diagnostic scales (i.e., Depressive, Anxiety, ADHD), as well as co-occurring clinical diagnoses.

401.015 (Poster) Autism Spectrum Disorders, a Meta-Analysis of Executive Function: Un Update of 40 Years of Research

E. A. Demetriou, A. Lampit and A. J. Guastella, (1)University of Sydney, Camperdown, NSW, Australia, (2)University of Melbourne, Melbourne, VIC, Australia, (3)Brain and Mind Centre and Children's Hospital Westmead, Sydney, NSW, Australia

Background:

Evidence of executive function (EF) difficulties in autism spectrum conditions (ASC) across development remains mixed, establishing its role is critical for guiding diagnosis and interventions.

Objectives:

The primary objective of this study was to provide an update of the previous meta-analysis reported in 2017 on EF performance in ASC compared to peers without ASC.

Methods:

The PRISMA-P guidelines were followed in developing the protocol which was registered with PROSPERO (CRD42021274347). The Embase, Medline and PsychINFO databases were searched to identify peer-reviewed studies published since July 2016 which were added to the studies reviewed in the original meta-analysis (1980 up to end of June 2016). The random effects model was selected, and a number of moderator analyses are planned. The primary outcome measure was Hedges’ $g$ effect size for EF and moderator factors.
Results:

Results will be reported according to the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines. The preliminary analysis identified an additional 123 studies that met eligibility criteria for the review. The total number of study participants was 26899 (N, ASC=13252, non ASC=13647). Preliminary results identified a moderate overall effect size for reduced EF (Hedges’ g=0.58, 95% confidence interval (CI) 0.51–0.65). This was attenuated when behavioural ratings were excluded from the overall analysis (Hedges’ g=0.50, 95% confidence interval (CI) 0.44–0.56).

Conclusions:

The findings confirm the broad EF difficulties identified in the original meta-analysis with implications for future support and remediation programmes.

401.016 (Poster) Autism and Aging: Genetic Genomic Perspectives

D. Geschwind, Semel Institute, University of California, Los Angeles, Los Angeles, CA

Background:

Autism Spectrum Disorder (ASD) is a neuropsychiatric syndrome with high heritability (70-80%), whose phenotypic and genetic heterogeneity have challenged efforts to identify causal genetic factors. Nevertheless, the last decade and a half of genetic studies in ASD has yielded substantial advances in our knowledge of its genetic architecture, which is consistent with a significant effect of polygenic risk, as well as substantial contributions from rare de novo variation, including identification of over 200 high confidence risk genes. How these different genes impact specific clinical features is poorly understood, including how they impact disease trajectory over time, especially as it relates to aging.

Objectives:

Proposes a novel conceptual framework that examines the overlapping genetic and genomic architecture between ASD and neurodegenerative disorders of late life.

Methods:

This presentation integrates the literature, applies bio-informatic analysis of existing data, including new methylation data.

Results:

Despite the genetic and clinical heterogeneity in ASD, we have found that there is a shared molecular neuropathology in post-mortem brain from the majority of children and adults diagnosed with ASD. This includes a genetically driven down-regulation of synaptic signaling genes, including vesicle transport, mitochondrial energetics and activity dependent genes, concomitant with an up-regulation of neural immune signaling, including microglia and astrocytes. Remarkably, several of these pathways overlap with those changing in multiple neurodegenerative disorders, such as the down-regulation of neuronal energetics and the specific up-regulation of microglia and immune/inflammatory pathways. Whether these changes in ASD brain reflect accelerated aging or increased susceptibility, to disorders of aging are not yet known. But, these are critical to ascertain, given emerging clinical data on potentially increased risk for aging disorders involving mitochondrial dysfunction, such as Parkinson’s Disease. Moreover, ASD associated pathways based on known mutations include ubiquitination and protein homeostasis, which are also impacted in aging. The recent identification of the epigenetic clock, which is a highly accurate predictor of biological age based on DNA methylation, provides the opportunity to understand whether ASD broadly, or specific genetically defined forms, show advanced biological aging, data that we are currently analyzing and expect to present at IMFAR.

Conclusions:

Research in aging in ASD is at its very early stages. Advances in genomics allow us to examine whether aging trajectories are altered in ASD and how genetic factors impact aging in autism.

401.017 (Poster) Autism at 30: Daily Activities, Future Goals, and Normative Outcomes for Autistic Adults

H. Singer1, E. B. Clarke2 and C. Lord3, (1)UCLA CART (Center for Autism Research and Treatment), Los Angeles, CA, (2)CART, UCLA, Los Angeles, CA, (3)UCLA Semel Institute for Neuroscience and Human Behavior, Los Angeles, CA
**Background:** Though most research on autism spectrum disorder (ASD) focuses exclusively on childhood, autism is a lifelong condition. While research on the transition to adulthood for adults with ASD and other developmental conditions like intellectual disability (ID) has surged in recent decades, research exploring “established adulthood,” defined as the stage from ages 30-45, remains sparse. Further, current literature tends towards deficits-based perspectives rather than exploring strengths of autistic participants’ lives. As such, it is unknown what happens to autistic adults with and without co-occurring ID in the decade after reaching adulthood.

**Objectives:**

1) Examine features of daily life for autistic adults in their early thirties and characterize their future hopes and goals.

2) Identify differences of participants’ daily lives and goals across intellectual ability (with and without ID).

**Methods:** 157 individuals (M_age=32.13 years, SD=0.12) from a longitudinal cohort studying autism were included, 67 without ID (verbal IQ ≥70) and 90 with ID (verbal IQ < 69). Participants were consecutive referrals to developmental clinics identified between ages 2-3 and followed for three decades. The sample was 19% Black, 18% female, 59% rural, and 44% had a parent not college educated. Standardized cognitive measures assessed IQ when participants were 18 years. Between ages 25-32, participants completed interviews and questionnaires about residence, employment and relationship history, generative activities, and desires for the future. For participants without ID, self- and caregiver-report data on future goals was analyzed. For participants with ID, caregiver-report data was analyzed.

**Results:** At age 32, 46.7% of participants resided with caregivers (51.7% with ID, 40.3% without ID). By age 32, 73.1% of participants without ID had been employed at least part-time and 52.2% full-time; 19.1% of participants with ID had been employed part-time. For participants without ID, 46.2% graduated from university, and 49% had been in a romantic relationship by age 32.

On average, participants engaged in a median of 2 independent enriching activities (with ID $m=2.21$, without ID $m=3.07$). Social activities were less common, particularly for participants with ID (Figure 1).

Adults without ID and their caregivers frequently reported goals of having children and partners (Figure 2). Across all participants, self-improvement goals were frequently identified: learning to cook, groom, drive, budget, and/or other practical goals for independence. Most goals for participants with ID mentioned developing life skills, gaining autonomy, and finding a supportive home and caregiver(s) for later life.

**Conclusions:** Regardless of diagnosis or ability, fundamental questions of how to live a fulfilling life are universal. This study attempts to expand traditional deficits-based approaches to meaningfully characterize activities and other strengths within this often-overlooked age group.

Further, these findings suggest the importance of distinguishing the differing needs of autistic adults with and without ID in certain contexts. These include employment expectations and interpersonal-based goals. In other contexts, like residing with caregivers and goals for greater independence, the lives and wishes of autistic adults across intellectual ability are similar. To our knowledge, this study is among the first to investigate such goals.

401.018 (Poster) Autism, Adulthood and Employment Challenges: The Double Empathy Problem Applied to Perceptions of an Autistic Employee in the Workplace

**K. A. Szechy and L. A. O'Donnell, Social Work, Wayne State University, Detroit, MI**

**Background:** High unemployment rates are found among adults on the autism spectrum. Problems with social functioning in the workplace can be significant barriers to employment success. Traditionally, Theory of Mind (ToM) deficits have been proposed as the underlying cause of social difficulties for autistic individuals. Alternatively, the Double Empathy Problem (DEP) posits that the source of these social challenges lies not within ToM deficits, but in the potentially problematic interactions between autistic and non-autistic persons. Evidence for the DEP demonstrates that individuals within the autistic community have high quality social rapport and communication with each other, however, non-autistic individuals are more likely to misperceive the behaviors of autistic persons.

**Objectives:** Of the extant data regarding the DEP, there are no known studies using measurement methodology from the ToM literature, and also applying the DEP to autistic social interactions in the workplace. This study proposes to compare autistic and non-autistic participants’ ability to accurately interpret the behaviors of an autistic employee at work, using similar methodology to Happé’s strange stories ToM measure.

**Methods:** A sample of 255 participants (173 non-autistic, 82 autistic) read a vignette of a hypothetical autistic employee having difficulty coping in the workplace. Participants were not told that the character in the vignette was autistic. Participants then completed open-ended survey questions regarding their interpretation of the employee’s behavior. Participants also completed measures of autism traits and autism
knowledge, as well as questions about their general experience with autistic persons. Two independent raters blind scored the ToM responses of each participant.

Results: A significantly greater proportion of autistic participants accurately interpreted the behavior of the autistic character (ToM score = 2) in the vignette, compared to non-autistic participants (\(z = 8.65, p = .003\)). Logistic regression analysis that accounted for demographics and experience with autism, indicated being autistic (\(OR = 3.23, p = .008\)) and having increased autism knowledge (\(OR = 1.12, p < .001\)) as significant predictors of more accurate ToM scores.

Conclusions: Results from this study contribute to the growing field of evidence that supports the DEP, shifting the paradigm of autistic social functioning and interventions away from proposed autistic social deficits towards addressing problems in the autistic/non-autistic social interaction. Autistic persons in the workplace experience misunderstanding, stigma, social isolation, and employment failures. They also bear the burden of responsibility for trying to understand and cope in the non-autistic world of employment. Results of this study point to the responsibility of the non-autistic community to develop knowledge and understanding of the thoughts, feelings, and intentions of their autistic colleagues in the workplace. From the perspective of the DEP, helpful interventions would include instituting workplace autism education, acceptance, support, and accommodations. These interventions could help remove the barriers for autistic adults to obtaining and retaining employment, thus significantly impacting their adult functioning and quality of life.

401.019 (Poster) Autism-Related Language Preferences of French-Speaking Autistic Adults: An Online Survey

P. Geelhand, F. Papastamou, M. Belenger, E. Clin, L. J. Hickman, C. T. Keating and S. Sowden, (1)ACTE — Center of research in Linguistics — ULB Neuroscience Institute, Université libre de Bruxelles, Brussels, Belgium, (2)Université libre de Bruxelles, Bruxelles, Belgium, (3)ACTE, Université libre de Bruxelles, Brussels, Belgium, (4)University of Birmingham, Birmingham, United Kingdom, (5)School of Psychology, University of Birmingham, Birmingham, United Kingdom

Background:

In recent years, there have been increasing discussions surrounding the appropriate terminology to talk about autism. Initially, this debate revolved around the use of person-first language (e.g., person with autism) vs. identity-first language (e.g., autistic person) but has recently expanded to other autism-related terms (e.g., deficits). The language used to describe autistic individuals is not just descriptive, it reflects individuals' cultural view of a condition and can have real-life consequences for those directly concerned. One important step in reducing stigma is to change the way we talk about autism to reflect the opinions of the people directly affected by this issue. However, to date, studies investigating autism-related language preferences have been limited to English-speaking countries, and little is known about preferences in other languages.

Objectives:

This study addresses this gap by investigating the language preferences of 541 French-speaking autistic participants (formal diagnosis and self-identified) in an online survey. We are conscious that the target population (i.e., speaking autistic adults having access to computers) is not representative of the ideas and preferences of all autistic people. Nevertheless, we think that accounting for their voices is a first step to render autism research and terminology more inclusive.

Methods:

We used an online questionnaire to ask 541 French-speaking autistic adults what terms they prefer to use to refer to: 1) the nomenclature of autism (i.e., the diagnostic labels used to refer to autism as a neurodevelopmental disorder); 2) an autistic person; 3) someone’s autistic identity; 4) autism more broadly; 5) the abilities of autistic people and 6) people without a diagnosis of autism. Participants also had the opportunity to tell us more about their language preferences in an open comment. Figure 1 shows all the different options available for each category and their English translation.

Results:

As illustrated in Figure 1, the most preferred terms were 1) “Autisme” Autism (\(z = 14.97, p < .001\)); 2) “Personne autiste” Autistic Person & “Autiste” Autistic (\(z = 11.10, p < .001\)); 3) “Est Autiste” Is autistic (\(z = 14.05, p < .001\)); 4) “Différence neurologique/cérébrale” Neurological/ brain difference (\(z = 8.61, p < .001\)); 5) “Différences” Differences & “Difficultés” Difficulties (\(z = 11.97, p < .001\)); 6) “Neurotypique” Neurotypical (\(z = 6.58, p < .001\)). Participants’ open comments were also analyzed, revealing further support for identity-first language and the social model of disability, and a preference for simple, precise, and validated terms.

Conclusions:

We previously knew about language preferences of English-speaking autistic people. This study extends these findings by showing that French-speaking autistic adults also prefer terms that reflect the ideas of identity-first language and the social model of disability. We also
show that these are not the only reasons behind language preferences: term simplicity, precision and validity are also important when talking about autism. These results have substantial implications for informing the language of researchers, clinicians and other professionals in the field, as well as the general public.

401.020 (Poster) Autistic Characteristics and the Investigation of Homeless Risk and Protective Factors
E. Osborn, R. L. Young and N. Weber, (1) psychology, Flinders university, tonsley, SA, Australia, (2) Flinders University, Adelade, Australia, (3) Flinders University, Adeladie, SA, Australia

Background:
A number of risk factors may lead to an individual becoming homeless. These factors may include childhood factors, individual factors (mental illness, addiction), social networks size, structural factors (housing), prior homeless experiences, and social economic status. Certain populations may be vulnerable to the risk of homelessness, including individuals with mental health conditions, disabilities, and neurodivergence, due to their increased chance possessing these known risk factors of homelessness. Indeed, autistic individuals are represented within the homeless community. Emerging research has begun to investigate the specific nature pertaining to the homeless risk for autistic individuals. Previous research has outlined the increased presence of autism in the homeless community, and the need to focus on autistic characteristics that may increase the chance of homelessness.

Objectives:
This study focused on investigating three important factors; 1) The probability of homelessness according to the known risk factors of homelessness according to diagnosis, 2) the additional contribution of autistic characteristics, and 3) exploring the protective nature of social relationships and specifically parental relationships.

Methods:
Three hundred and thirty-seven individuals (Autistic spectrum Disorder: ASD and non-ASD) completed a questionnaire regarding known homeless risk factors and autistic characteristics. Bayesian hierarchical modelling was used to predict homelessness according to prior diagnosis and Autism Quotient (AQ) cut-off scores.

Results:
The results demonstrated that prior diagnosis predicted a lower probability of homelessness, yet those with high ASD characteristics without a diagnosis demonstrated an 85 % probability of a non-zero relationship with homelessness, whilst holding other factors constant. This suggest that there may be a high proportion of non-diagnosed autistic individuals in the homeless community. The results demonstrated autistic traits decreased the chance of homelessness for those with a prior diagnosis, compared to those without a diagnosis. When considering those without a diagnosis stronger evidence was detected for communication differences, attention switching, and attention to detail characteristics. Further investigation demonstrated that the difference between autistic characteristics was not meaningful, suggesting that collectively these symptoms increase the chance of homelessness rather than independently. In terms of protective factors, the diagnosis was seen as the biggest protective factor for those with ASD. For those high on autistic characteristics without a diagnosis, family plays an important role in protecting them from instances of homelessness. This differed from those with low number of autistic characteristics who were likely to receive protection from partners, friends, and service providers.

Conclusions:
The influence of autism (as indexed by the AQ) on homeless risk should be considered in light of the interaction with known risk factors SES, and social and individual factors. The protective nature of diagnostic assessment is clear, early detection and support may provide protection from homelessness. in the absence of a diagnosis, it is important to find ways to foster these social networks in order to prevent this group from becoming homeless.

401.021 (Poster) Autistics Workers Experience of Stress : A Cross-Sectional Descriptive
M. Couture, M. Berrouard, S. Powell and M. Désormeaux-Moreau, (1) Rehabilitation, Université de Sherbrooke, Sherbrooke, QC, Canada, (2) Université de Sherbrooke, Sherbrooke, QC, Canada, (3) École de réadaptation, Université de Sherbrooke, Sherbrooke, QC, Canada

Background: While work is an occupation that can be rewarding, and which can promote the well-being of those engage in it; it can also be a source of stress and anxiety. Challenges to obtain and maintain a job has been well documented among Autistics, in whom higher levels of
anxiety have traditionally been observed, which can be explained by their neurominority status (Botha, & Frost, 2020). Exploration from the autistic workers’ point of view regarding their experience of stress at work is therefore, the most important.

Objectives: To explore Autistics’ work-related experiences of stress, by documenting: i) the sources and manifestations of stress or anxiety; and ii) the strategies implemented to deal with it.

Methods: This study was based on a cross-sectional descriptive online survey, launched between June and October 2021. To take part in the study, participants needed to: i) be Autistics (≥ 18 years of age); ii) work in Canada at the time of the study; iii) be capable of completing the online survey, offering an introspective perspective at their working experience. The survey comprised 36 questions (25 multiple choices; 9 short open answers; 2 visual analog scales) divided in 3 sections: current work (10 questions) context, stress at work (18 questions), socio-demographic (8 questions). Quantitative data were subjected to descriptive statistics while qualitative data were subjected to a content analysis.

Results: 32 autistic workers participated in the study (40.6%; male; 43.7%; female; 9.4% non-binary (6.5% missing info) M:39.6 years old; SD:7.9). Most participants worked 33 to 40 hours/week (71.9%) in a large company (64.5%). Half of them worked outside their home and 40% telecommuted, one not excluding the other. Findings show that participants’ main sources of stress came from the physical and social environment, either originating from unpredictable events or situations (53.1%), social interactions (31.3%), work overload (28.1%), sensory overload (25.0%) or uncertainty or lack of clarity (21.9%). Physical (headache, stomach pain, insomnia, etc.) and psychological (irritability, impatience, negative thoughts, etc.) manifestations were reported as impacting participants beyond the workplace (e.g., lacking energy to do anything else after work (40.6%). Strategies to deal with stress were mostly put in place by the participants themselves, while 50% mentioned having some support from colleagues or superiors. A third reported they never received professional support to help them manage their stress.

Conclusions: Not all sources of work-related stress can be eradicated, if only because it would be utopian to think of eliminating all unpredictable events and issues. However, many sources of stress that are energy consuming for the Autistic workers could be reduced. Universal design principles – including sensory and cognitive accessibility which is often neglected could be applied to the workplace to make it a more autistic or neurodiverse friendly environment. In addition, Neuro-Affirmative supports and practices in the workplace are essential to reduce systemic barriers to job inclusion and retention for Autistics (and more broadly neurodivergent workers).

401.022 (Poster) Camouflaging Behavior, Internalizing Symptoms, and Social Support in Autistic Individuals and Individuals Who Have Lost Their Clinical Autism Diagnosis
M. F. Dieckhaus, H. R. Thomas, M. Helt, D. A. Berger and I. M. Eigsti, (1)Psychological Sciences, University of Connecticut, Storrs, CT, (2)Trinity College, Hartford, CT

Background: Within autistic communities, camouflaging involves efforts to mask symptoms or actively blend in with others (Lai et al., 2019; Livingston et al., 2020). These efforts may be associated with internalizing symptoms, such as depression (Lai et al., 2017), though associations with anxiety are mixed (Cage & Troxell-Whitman, 2019; Schuck et al., 2019). Type and degree of camouflaging may interact with mental health outcomes (Hull et al., 2019) and individual and social factors. Our group studies individuals who were autistic early in development but no longer meet diagnostic criteria (i.e., they have lost the ASD diagnosis, LAD; Fein et al., 2013). To date, camouflaging has not been studied in LAD.

Objectives: We aimed to compare type and intensity of camouflaging in autistic, LAD, and neurotypical (NT) groups and examine associations between camouflaging type and intensity with internalizing symptoms and social support.

Methods: Adolescents and young adults (total n=72) completed videoconference interviews and online surveys. Groups did not differ on age, race, ethnicity, or family income. The NT group had more female-identifying individuals, and the ASD group had lower adaptive skills (Vineland Adaptive Behavior Scales). ASD was defined by clinical best estimate, based in part on ADOS-2 scores; Table 1. Camouflaging was measured via the Camouflaging Autistic Traits Questionnaire (CAT-Q; Hull et al., 2019) subdomains (Assimilation, Masking, Compensation). Caregiver-reported internalizing symptoms were assessed via the Achenbach Behavior Checklist subdomains (Depression, Anxiety, Somatic). Social support was assessed via the self-reported Multidimensional Scale of Perceived Social Support (MSPSS) subdomains (Total, Friend, Family, Significant Other Support). ANOVAs with pairwise comparisons assessed group differences and Spearman’s Rho correlations with FDR corrections probed for associations between camouflaging with internalizing symptoms and social support.

Results: Groups differed on CAT-Q Total and Compensation scores with medium and large effects (CAT-Q Total $\omega^2 = 0.07$; Compensation $\omega^2 = 0.13$; Table 2. The ASD group reported significantly more camouflaging and compensation than the NT group; LAD/NT and LAD/ASD scores did not differ. The ASD group reported more symptoms of anxiety and depression relative to LAD/NT groups. Only one correlation between Assimilation and Friends in the NT group remained significant following FDR correction ($p=.03$). LAD and ASD correlations were not significant.
Conclusions: Findings were consistent with prior work suggesting that autistic individuals engage in greater camouflaging behavior than NT peers and had more internalizing symptoms. LAD individuals displayed some camouflaging behaviors, suggesting that they face continued pressure to adapt behaviors in order to conform. Null associations between camouflaging and internalizing symptoms are consistent with some prior findings, but not others. Somewhat surprisingly, camouflaging was correlated with social support in the NT group only; feeling more supported by friends was related to fewer self-reported assimilating behaviors. These findings suggest that, at least in NT individuals, having supportive friendships may reduce the pressure to fit in with peers. Our ongoing research examines the role of social support and internalizing symptoms in autistic camouflaging behaviors to identify individual factors that may contribute to these relationships.

401.023 (Poster) Camouflaging Behaviors and Quality of Life in an Online Sample of Autistic Adults

M. Cola1, S. Manevich1, E. Dlugi1, B. C. Lyman1, S. L. Armstrong2 and H. E. Kratz3, (1)LaSalle University, Philadelphia, PA, (2)La Salle University, Philadelphia, PA, (3)Autism Spectrum Diagnostics and Consulting, Doylestown, PA

Background: Autistic self-advocates, family members, and community organizations have called for greater emphasis on enhancing quality of life (QoL) for autistic people. Prior research has found that autistic adults report a lower quality of life than the general population, particularly in domains such as meaning, purpose, and general life satisfaction. One potential explanation for this finding is that many autistic people are forced to camouflage their autistic traits due to the inequitable demands of living in an ableist society. Camouflaging includes masking (i.e., strategies used to hide autistic characteristics), assimilation (i.e., trying to blend into social situations), and compensation (i.e., strategies used to actively compensate for social difficulties). Emerging research suggests that camouflaging is negatively correlated with self-reported subjective wellbeing. To date, there is limited research exploring how the internal experiences and behaviors of autistic adults – including camouflaging – relate to their quality of life.

Objectives: Examine the relationship between quality of life and aspects of camouflaging (masking, assimilation, and compensation) in a sample of autistic adults.

Methods: One hundred sixty-two two-autistic adults aged 18 to 64 were recruited online. Participants completed the Camouflaging Autism Traits Questionnaire (CAT-Q) (producing total scores and compensation, masking, and assimilation factor scores) and the PROMIS Autism Battery-Lifespan (PAB-L) subjective well-being scales (general life satisfaction, positive affect, and meaning and purpose).

Results: In the primary analysis, CAT-Q total scores were used to predict each of the three PROMIS subjective wellbeing scales. Linear models revealed a significant main effect of CAT-Q total score on the PROMIS positive affect scale ($t = -2.63$, $p < .01$) and general life satisfaction scale ($t = -2.22$, $p = .03$), but not the meaning and purpose scale ($t = -1.68$, $p = .09$). The secondary analyses examined whether any of the single CAT-Q factor scores (assimilation, masking, compensation) accounted for the relationship between the CAT-Q total scores and PROMIS quality of life measures. Notably, across all three linear models, there was a significant main effect of CAT-Q assimilation scores on the PROMIS positive affect ($t = -5.86$, $p < .001$), general life satisfaction ($t = -4.51$, $p < .001$), and meaning and purpose ($t = -5.66$, $p < .001$) scales. There were no significant main effects of masking or compensation on any of the quality of life measures.

Conclusions: Research on the impact of camouflaging on autistic adults’ quality of life is in its infancy. Results from our primary analyses suggest that overall, greater self-reported camouflaging is related to poorer quality of life, specifically within the areas of life satisfaction and positive affect, but less clearly related to meaning and purpose. In addition, secondary analysis results suggest the relationship between self-reported camouflaging and quality of life variables were largely explained by the CAT-Q assimilation factor, such that greater self-reported assimilation was associated with poorer quality of life. Developing a more nuanced understanding of camouflaging behaviors, and how they relate to overall quality of life, is an important step towards ensuring that interventions are collaborative, client-centered, and promote autistic flourishing.

401.024 (Poster) Career Progression for Autistic People: A Scoping Review

J. Davies, M. Romualdez1, E. Pellicano2 and A. Remington1, (1)UCL Centre for Research in Autism and Education, London, United Kingdom, (2)University College London, London, United Kingdom, (3)UCL Centre for Research in Autism and Education, London, UNITED KINGDOM

Background:

Across the globe, there is an ongoing autism-employment crisis, with fewer autistic people in paid employment than in the general population, and even compared to other disability groups. Of those autistic people who are employed, many are in roles that do not reflect their skills, qualifications, and/or capabilities. Research in this area primarily examines entry into the workforce for autistic people. Obtaining a job is, however, only one step in the employment pathway. We assert that it is equally important to understand autistic people’s experience of career progression.
Objectives:

This scoping review sought to explore what is already known about autistic peoples’ experiences of career progression. Specifically, we sought to understand:

1. What are autistic people’s experiences of career progression?
2. What barriers do autistic people face in progressing in their career?
3. What factors facilitate autistic people to progress in their career?

Methods:

Following Arksey and O’Malley’s (2005) five-step scoping review process, a comprehensive search of six databases was conducted, complemented by an additional Google Scholar search. Searches were limited to articles published in English, with no restrictions on publication date. Studies were included if they reported data on (1) autistic people’s experiences of career progression; (2) career success for autistic people (e.g., increased salary, hours, responsibility), or (3) job-matching. Undergraduate and Masters dissertations were excluded.

In total 1,352 articles were identified (see Figure 1). Screening of titles and abstracts was conducted independently by two researchers resulting in 117 studies eligible for full-text review (96% agreement). The full-text review was conducted by three researchers (90% and 78% agreement). Discrepancies were resolved via discussion.

In total, 33 studies met inclusion criteria. A narrative thematic synthesis approach was used to identify, review, and synthesise relevant findings across the eligible studies. Quality appraisal of the eligible studies is ongoing.

Results:

The included studies involved 1,478 autistic people, 156 parents of autistic people, 96 employers of autistic people, and 61 professionals that worked with autistic people (e.g., educators, job mentors). Overall, 1,613 autistic people were represented.

While career progression was desirable to many (but not all) autistic people, poor job-matching resulted in few opportunities to progress. Several barriers to career progression were identified. Having and/or disclosing an autism diagnosis was the most common barrier discussed (8 of 20 studies, 40%), followed by inadequate employment support (5 of 20 studies, 25%), and ‘spiky’ education and employment histories (3 of 20 studies, 15%). The eligible studies indicated that adequate employment support (e.g., via job-coaches, employment support programmes, or via family/peers) was a crucial enabling factor. Other enablers included tailored opportunities for progression, and the implementation of workplace adjustments.

Conclusions:

While 33 studies met criteria for inclusion, few studies explicitly mentioned career progression for autistic people, and no studies directly aimed to explore the topic. Indirectly, we identified several potential barriers and enablers to career progression for autistic people. By identifying such barriers and enablers, we can help shape future practice and research agendas on the topic, ultimately supporting more autistic people to have meaningful and successful careers.

401.025 (Poster) Characterizing Retained Autistic Adults in SPARK, a National, Online, Longitudinal Research Study of Autism

Background:

The SPARK study launched in 2016 to recruit and retain a cohort of individuals with autism of all ages and their family members across the United States. Few studies have followed children with autism into young adulthood. In SPARK, minors provide assent, if capable, and a parent or guardian provides consent on their behalf. These participants are asked to re-consent, if legally independent, when they turn 18. Challenges emerge around re-consent and engagement of young adults at a critical time of transition. Little is known about how this process impacts engagement with research in adulthood.

Objectives:
To characterize the cohort of retained young adults and compare their engagement in SPARK to that of young adults over age 18 when they initially enrolled independent of guardians.

Methods:

This study includes 2,942 independent adults, between the ages of 18 and 25 years when they joined SPARK, and 379 independent participants retained into adulthood (representing 30% of all enrolled adults who turned 18 reported as independent) of the same age. Data collected and utilized in the analyses include information about autism diagnosis; sociodemographic characteristics; and information about study tasks, such as the number of measures completed. Independent t-test was performed to compare cohorts by age at diagnosis, and chi-squares were performed to compare cohorts on other demographic and study task characteristics.

Results:

Retained adults typically were male (75%) and White, non-Hispanic (85%). Most lived in a metropolitan area (94%) in the south or west of the United States. The modal age at diagnosis was 3 years, with a mean age of about 8 years (SD=4.3 years). Independently consenting adults were demographically similar in many respects. A similar fraction live in a metropolitan area (91%) and identified as White, non-Hispanic (81%). Independent adults who consented at the same age (18-25) were significantly more likely to be female, \( X^2 (1, N = 3321) = 113.188, p < .001 \), more likely to have returned a biospecimen, \( X^2 (1, N = 3321) = 66.388, p < .001 \) and significantly less likely to agree to affiliate with, and be contacted by, a clinical site, \( X^2 (1, N = 3321) = 917.168, p < .001 \). They were also significantly older at age of diagnosis (M=11.8 years, SD=6.8 years). \( n(3211) = 10.74, p < .001 \). In fact, while the modal age at diagnosis for this group was 3 years, about 40% reported receiving a diagnosis in adolescence or adulthood. Finally, those enrolled as independent adults were more engaged with the protocol; 10% of retained adults completed a core protocol measure themselves, the Background History Questionnaire, in comparison to 42% of independent adults.

Conclusions:

Findings from this study underscore the challenges of both recruiting and retaining a longitudinal cohort of young adults who previously participated as dependent children in research. Those who continue participating as adults differ considerably from those who first joined SPARK as adults. We need to develop more effective means of engaging adolescents and informing them about the SPARK study before and during the age of transition.

401.026 (Poster) Charades, Collages, and Self-Advocacy: A Participatory Approach to Helping Autistic Students Build Community

Background: As the number of autistic university students grows, educators increasingly realize that autistic students experience not only difficulties with social interaction, self-advocacy, executive functioning, mental health, and stigma but also key strengths (Accardo et al., 2019a; Bakker et al., 2019) including heightened intellectual self-confidence, writing skills, and/or nonverbal intelligence (Bakker et al., 2019; Gillespie-Lynch et al., 2020; Sturm & Kasari, 2019). Evidence of autistic university students’ strengths became increasingly apparent as research designs improved. For example, Bakker, 2022 sampled the full student body of a university in the Netherlands, examining 7 cohorts of autistic students in relation to their peers with other disabilities or with no disabilities. Autistic students were often older on entry and progressed slightly more slowly but exhibited as much persistence as non-autistic students. Bakker recommended that institutions support autistic students by providing developmentally adapted supports that: 1) focus on support systems to help students transition into college, 2) help students understand what is expected at college, and 3) provide ongoing social and executive functioning support to reduce anxiety.

Objectives: To share strategies from Building Bridges Project REACH, a participatory mentorship program for autistic students and students with other disabilities.

Methods: The Project REACH model aligns with key principles Bakker recommends. Supports are individualized, as students can choose to participate in one-on-one mentorship and/or two types of group mentorship (a relatively unstructured Creative Exploration group or a structured Skills Development group). Students who are entering college are encouraged to attend group meetings the semester before if interested to acclimate to college. Student group leaders (and mentees) share what they’ve learned about college and strategies to develop executive functioning, self-advocacy, and employment skills in a supportive environment. Programming is free for students, who can participate in optional assessments for gift cards. Mentorship has been largely online since COVID-19 hit, with increasing hybrid options. Surveys assess students interest in learning and perceived skills in varied domains. They also assess anxiety, autistic identity, well-being, belonging, and ASQoL. Ten students did pre-tests in the Fall of 2021 and nine did post-tests. Twelve did pre-tests in the Spring of 2022 and 17 did post-tests.
Results: When asked if they liked on-line learning or in-person learning more, 8 students liked online and in-person the same, 6 liked in person better, and 3 preferred online. Students’ self-reported skills tended to improve numerically from the beginning to the end of the Fall term (Table 1). Improvements were significant for self-advocacy and job skills ($ps < .05$). While students’ self-reported skills generally continued to improve numerically in Spring 2022, no skill improvements were significant in the Spring (Table 2). However, ASQoL improved from the beginning to the end of the Spring ($p < .05$).

Conclusions: Project REACH has continued to be a vibrant space for neurodivergent students to connect and share experiences during the pandemic. Students are not as interested in completing surveys as they were pre-pandemic but provide useful feedback to guide program development in end-of-session exit tickets. Student leaders have guided REACH to keep innovating.

401.027 (Poster) Community Participation Amongst Autistic Adults: The Impact of Leisure Activities on Quality of Life

M. L. Cook; L. G. Klinger, C. B. Klein, and E. M. Lamerche; (1)TEACCH Autism Program, UNC Chapel Hill, Carrboro, NC, (2)TEACCH Autism Program; Psychiatry, UNC TEACCH Autism Program, Chapel Hill, NC, (3)Psychiatry, TEACCH Autism Program, UNC Chapel Hill, Chapel Hill, NC

Background: Autistic adults consistently report lower quality of life (QoL) than non-autistic adults and have flagged this dynamic as a priority for clinical research in this field. The recent literature has established a variety of potential predictors of poor QoL, including autistic traits and employment (Mason et al., 2018), though findings have been largely mixed to date. Notably, the positive impact of community participation on QoL has been well documented in non-autistic samples and has recently been highlighted as an important area for further exploration with autistic adults (Cameron et al., 2022).

Objectives: This study aimed to explore the effects of community participation on caregiver-reported QoL in a diverse sample of autistic adults diagnosed as children through the UNC TEACCH Autism Program between 1969 and 2000.

Methods: As part of a larger longitudinal study, caregivers of 268 middle-aged autistic adults (average age=35.32; average childhood IQ = 61.12) completed an 87-item survey regarding the autistic adults’ current functioning and daily life along with standardized measures of autistic traits (SRS-2) and QoL (Quality of Life Questionnaire). Independent samples t-tests were computed to assess for significant differences in QoL based on autistic adults’ participation in various types of community activities. A hierarchical linear regression model was then performed to assess the cross-sectional predictive value of recreational participation on QoL when controlling for other known predictors (e.g., childhood IQ, employment status, autistic traits).

Results: Caregiver report indicated that autistic adults who had participated in at least one kind of community activity over the last year ($n=224, M=78.75, SD=14.43$) experienced significantly higher QoL than autistic adults who had not ($n=28, M=72.04, SD=12.43$) ($t(250)=-2.36, p<.05$). Specifically, autistic adults who had taken lessons (e.g., art, music, dance, foreign language, computers; $n=49, M=85.94, SD=13.22$), attended religious services ($n=140, M=81.12, SD=14.43$), gotten together with friends outside of organized activities ($n=89, M=86.62, SD=14.43$), or had been invited to others’ social activities ($n=77, M=86.10, SD=14.63$) reportedly experienced significantly greater QoL than those who had not. There were no significant differences in QoL based on more structured activities (e.g., participation in social skills groups or volunteer work). Furthermore, the hierarchical linear regression model was significant ($F(4, 208)=100.75, p<.001$, $R^2=.66$); even when controlling for childhood IQ ($B=.04, p=.11$) and other known predictors including current employment ($B=12.95, p<.001$) and current autistic traits ($B=-.51, p<.001$), participation in community activities remained a significant predictor of QoL ($B=2.21, p<.001$) such that those autistic adults who engaged in more recreational activities reportedly experienced higher QoL.

Conclusions: In this study, community participation in leisure activities significantly impacted caregiver-reported QoL for autistic adults beyond current intervention targets (i.e., employment, social responsiveness). These findings emphasize the importance of community participation as a meaningful form of intervention to improve QoL in the autistic community. Further work is needed to explore the specific benefits of community participation (e.g., social opportunity, executive function skill building, behavioral activation) as well as its direct impact on QoL through longitudinal follow up.

401.028 (Poster) Comparing Physical Activity and Sedentary Behaviours of Autistic Adults and the Non-Autistic Peers

C. Thompson and J. McVeigh; (1)School of Occupational Therapy, Social Work and Speech Pathology, Curtin University, Perth, WA, Australia, (2)School of Occupational Therapy, Social Work and Speech Pathology. Curtin University, Curtin University, Perth, WA, Australia

Background:

Background: An expanding evidence base indicates that autistic adults experience worse health outcomes than their non-autistic peers. Autistic adults have been observed to experience obesity and cardiovascular disease at three times the rate of non-autistic peers. Furthermore, autistic adults experience diabetes at approximately twice the rate of their non-autistic peers. This relationship is observed in almost all chronic diseases, whereby autistic adults relative prevalence is higher than their non-autistic peers. These chronic diseases can be
linked to lifestyle changes, such as insufficient physical activity and high levels of sedentary behaviours. There is currently limited reliable data regarding volumes and patterns of physical activity and sedentary behaviours in autistic adults. The current evidence suggests that autistic engage in lower volumes of physical activity than their non-autistic peers. It is currently unclear how the patterns of physical activity and sedentary behaviours compare between autistic adults and their non-autistic peers.

Objectives: The objective of this study was to characterise the volumes and patterns of physical activity and sedentary behaviours in autistic adults compared to their non-autistic peers.

Methods:

A case-control design was used to compare matched autistic and non-autistic adults. A total of 36 participants were recruited and matched based on age, gender, body mass index and estimated metabolic equivalent of task derived from the International Physical Questionnaire-Long Form.

The sample included 16 autistic adults (mean age = 29.1; SD= 8.1 years; 10 male, 6 female) matched with 16 non-autistic peers (mean age = 27.4; SD= 8.7 years; 10 male, 6 female).

The matched participants wore an activPal accelerometer over seven days to ascertain device-derived volumes and patterns of physical activity. The data were compared using unpaired t-tests.

Results:

Significant differences were noted between the sitting time of autistic and non-autistic peers (p=0.04). However, no differences were noted between the volumes of stepping and standing time. When examining the patterns over a seven-day period several statistically differences were noted. The data showed that the autistic group spent significantly less time stepping and had a lower total step count on Sundays, Mondays and Tuesdays when compared to non-autistic peers. Time spent in sitting was significantly higher for the autistic group on Tuesdays, Fridays and Sundays. Time spent in prolonged sitting was significantly higher for the autistic group on Mondays, Thursdays and Sundays. Time spent in standing was significantly higher for the neortypical group on Tuesdays and Sundays only. For the remaining days of the week, differences in patterns of PA and SB were not significantly different.

Conclusions:

The results of this study suggest that the differences in the volumes of physical activity and sedentary behaviour between autistic adults and their non-autistic peers may not be as pronounced as previously thought. However, the patterns of physical activity and sedentary behaviour are considerably different on several days of the week. It is possible that the increased rates of lifestyle diseases may be related to these different patterns of physical and sedentary behaviours.

**401.029 (Poster) Dating and Romantic Relationship Desires in Autistic Adults: Understanding Their Experience**

*R. Kamnes*, S. S. Gonzalez and E. A. Laugeson, (1)UCLA Semel Institute for Neuroscience and Human Behavior, UCLA PEERS® Clinic, Los Angeles, CA, (2)Semel Institute for Neuroscience and Human Behavior, UCLA, Los Angeles, CA, (3)UCLA Semel Institute for Neuroscience and Human Behavior, PEERS lab: UCLA PEERS Clinic, Los Angeles, CA

Background: Sexuality and dating for autistic adults has become an area of increased focus and research in recent years (Dewinter et al., 2020). It has also become a socially relevant topic with increased attention and representation of autistic adults as sexual beings in the media (Brooks, 2018). Sexuality and dating are important component of living a healthy and successful adult life, yet little is still known about the direct dating experiences of these adults, and what cultural differences may be present in these experiences (McMahon et al., 2021) It is important to learn more about these experiences to know what should be attended to when developing services such as dating apps or social skills programs.

Objectives: This study aims to explore the dating experiences of autistic adults to determine challenges, strengths and goals related to these experiences.

Methods: Semi-structured clinical interviews were conducted with 31 autistic adults (M_{age}= 25, SD = 5.5; 84% males) by doctoral-level trained clinicians. Interview questions regarding previous dating and relationship experiences as well as desires for future experiences were asked, including a mixture of quantitative queries (e.g. how many committed relationships have you been in) and qualitative questions (e.g. what are your biggest dating concerns). Transcriptions of the interviews were then analyzed using a thematic content analysis (Braun & Clarke, 2006) by two researchers with a background in disability and sexuality. Data were first analyzed by researchers separately at a semantic level, and then themes were discussed and created at the latent level of analysis and merged to inform the results (Creswell, 2007).
Results: Twenty-seven participants identified their sexual orientation as straight, two as bisexual, and two were unreported. Initial results indicated that the majority (17) of participants indicated no previous dating experience. Of the 14 with dating experience, most described having been on less than 5 dates total and indicated they met these people in-person. Across all participants, 23% indicated they had tried online dating but had been unsuccessful. Only seven participants reported having been in at least one previous committed relationship. Participants often described feeling unaware of how to be in a successful relationship, and 26% of participants described experiencing exploitative or inappropriate relationships or dating experiences. Overarching themes regarding dating challenges centered around issues related to flirting and engaging in conversations on dates, as well as understanding and enforcing relationship boundaries and avoiding exploitation. The most common relationship goal involved finding a long-term partner.

Conclusions: This study provides further insight into the dating experiences and desires of autistic adults. Results show that these adults often struggle with the nuances of dating (flirting, boundaries, etc.) and would benefit from direct instruction in these areas. Additionally, results suggest that while the majority of these adults are lacking any dating or relationship experience at all, they still desire these experiences. Further research and community programming should look into providing and tailoring dating resources and experiences for autistic adults.

401.030 (Poster) Mental Health and Heterosexist Discrimination Among Autistic-LGBTQ+ Individuals

M. R. Maroney, E. Coombes, D. Shinbine, and H. Levitt, (1) Counselling Psychology, University of Calgary, Calgary, AB, Canada, (2) SKIP Lab, Occupational Therapy, University of Alberta, Edmonton, AB, Canada, (3) University of Calgary, Calgary, AB, Canada, (4) Clinical Psychology Department, University of Massachusetts, Boston, Boston, MA

Background: In recent years, there has been an increase in research focused on the higher likelihood of being a sexual minority or lesbian, gay, bisexual, or queer (LGBQ+) among autistic individuals (George & Stokes, 2018). Both autistic and sexual minority individuals are more likely to experience heightened psychological distress than their non-autistic and heterosexual counterparts. The minority stress model explains these mental disparities as being related to the impact of both distal and proximal stressor events, which in turn negatively impact the mental health outcomes of sexual and gender minority individuals (Meyer, 2003; Hendricks & Testa, 2012), and more recently, autistic individuals (Botha & Frost, 2020). Heterosexist or prejudicial events differentially impact the mental health of individuals with multiple marginalized identities (Balsam et al., 2011), as exemplified by research on autistic-LGBTQ+ people, which has documented worse mental health outcomes among transgender autistic people (as compared to cisgender autistic counterparts), including lower well-being and higher stress (George & Stokes, 2018).

Objectives: In the present study, we analyzed archival data from an intervention study designed to cope with heterosexist stigma through expressive writing interventions. For the present study, we analyzed the baseline data of participants who identified as autistic and LGBQ+ to explore the relationship between heterosexist discrimination, gender expression, and mental health.

Methods: Participants (N=54) all identified as a sexual minority and autistic (both diagnosed and self-identified), and more than half identified as transgender, nonbinary or gender diverse. We collected data on depressive symptoms, the impact of trauma/stressor symptoms, and negative affect. Multiple linear regression was used to examine the relationship between heterosexist stigma (HHRDS; Szymanski, 2006), discrimination based on gender expression (DHEQ; Balsam et al., 2013) and trauma/stressor symptoms (IES-R; Weiss & Marmar, 1996).

Results: Approximately 75% of the sample endorsed clinically significant depressive symptoms, while 62% endorsed PTSD symptoms of clinical concern. 87% of participants rated their chosen heterosexist event from moderately to extremely distressing. Participants varied in their levels of outness and came out to themselves as LGBQ+ at an average of 16.6 years of age. Most were out to friends and family, although approximately 14% reported that they had not come out to parents, with several noting they did not intend to due to worry about rejection. Results indicated that the model explained 45.3% of the variance and that the model was a significant predictor of trauma/stressor symptoms, F(2,51) = 22.9, p = .001.

Conclusions: The high rates of mental health distress in this non-clinical sample are notable because participants were recruited based on their autistic-LGBTQ+ status and the presence of a troubling heterosexist event rather than for elevated scores on measures of depression or trauma. Participants who present with more gender nonconformity in their gender expression may be more likely to experience heterosexist discrimination and be at risk for developing heightened stressor symptoms. Clinical interventions and conceptualization should attend to the role of sexual minority-based stigma related to elevated mental health distress, which will be discussed by the presenters.
Background: Evidence suggests that autistic individuals achieve relatively lower education levels than others; however, existing studies employ relatively small samples (<7700 autistic individuals) and fail to consider the educational attainment of non-autistic individuals with high autistic traits, henceforth high AQ.

Objectives: To understand the educational attainment patterns of autistic and high AQ individuals in the United Kingdom (UK).

Methods: This study leveraged responses to a self-report, cross-sectional, online survey. Autistic and high AQ individuals were matched to non-autistic individuals exactly 5:1 on age, gender, and UK region. Autism status was self-reported. Autistic traits were measured by the 10-item version of the Autism Spectrum Quotient (AQ-10), with a score ≥6 corresponding to high autistic traits (vs. low autistic traits). Adjusted binomial logistic regression models assessed educational attainment at the following levels: (1) less than A-level qualifications, (2) A-level qualifications, (3) undergraduate qualifications, or (4) postgraduate qualifications and controlled for age, gender, UK region, ADHD, bipolar disorder, depression, learning disability, OCD, and schizophrenia. A p-threshold of 0.005 was employed to account for multiple testing.

Results: The study comprises two samples: (1) n=14,519 autistic vs. n=72,595 non-autistic individuals, and (2) n=37,458 non-autistic individuals with high autistic traits (high AQ) vs. n=187,290 non-autistic individuals with low autistic traits. Both samples were biased toward women, younger participants, and specific regions within the UK. As expected, there were group differences in AQ-10 score and rates of neurodevelopmental and psychiatric conditions.

Using group differences in university-level qualifications as a reference-level, we found that autistic and high AQ individuals were over-represented among those with ‘less than A-Level’ or ‘A-level’ qualifications. Autistic individuals were also marginally over-represented among those with ‘Postgraduate qualifications’; however, the opposite pattern was seen among high AQ individuals—who were markedly less likely to complete postgraduate qualifications than matched controls. Further analysis of gender-stratified samples revealed that this effect was driven by high AQ women exclusively.

Conclusions: Using the largest sample to date, this study illustrates that both autistic and high AQ individuals are dramatically over-represented at relatively lower levels of educational attainment. These results underline that current educational systems are failing to meet the needs of individuals diagnosed as autistic as well as a much broader group along the spectrum of autistic traits. Interestingly, a greater number of autistic individuals than expected (based on group differences in university-level qualifications) achieved a postgraduate degree compared to demographically-matched peers (10% vs. 11%); yet high AQ women were less likely to achieve a postgraduate degree than demographically-matched peers (15% vs. 18%). These results may suggest that a subset of autistic individuals manage (or receive appropriate support) to achieve postgraduate degrees, but that these same advantages are not afforded to high AQ females. It should be noted that the sample is likely subject to a range of biases due to its convenience-sampling and self-report design. Thus, these results must be confirmed in large, population-based studies. Nevertheless, these findings highlight possible benefits of obtaining a diagnosis (particularly for females/women who may have greater barriers to timely diagnosis) and have clear implications for educational policies.

401.032 (Poster) Do Autistic LGBTQ+ Adults Report Greater Depression & Anxiety Symptoms Compared to Their Autistic Non-LGBTQ Counterparts? A Large-Scale Survey Study

Background: The Minority Stress Model proposes that minority statuses, such as autism, and the stress and oppression minorities experience may contribute to increased mental health challenges (Botha, Frost, 2018). Dual minorities are people who identify with two minority groups, and thus may face even more stress, and predisposition to mental health challenges. LGBTQ+ autistic adults are twice as likely to have a psychiatric diagnosis compared to their non-LGBTQ+ autistic counterparts (Hall et al., 2020). In our previous poster, we measured co-occurring mental health diagnoses using a single self-report survey item and found that dual minority statuses of autism and LGBTQ+ are associated with higher rates of co-occurring conditions such as depression and anxiety.

Objectives: 1) To examine if autistic adults in the LGBTQ+ community have more symptoms of depression and anxiety, as measured by the BDI-II and GAD-7, than non-LGBTQ+ autistic adults 2) To examine if a greater proportion of LGBTQ+ autistic adults in this sample meet clinical cutoffs for depression and anxiety (on the BDI-II and GAD-7) than their non-LGBTQ+ autistic counterparts.

Methods: “Surveying Thinking Patterns and Health in Adults with Autism Spectrum Disorder” is an online SPARK Research Match study that includes participants (aged 18-45 years) with a self-reported or professional diagnosis of autism. A self-report survey was used to collect demographic information, including information regarding co-occurring diagnoses. There was no item that asked specifically about LGBTQ+ identity, and thus, in this study we define LGBTQ+ status as an inclusive grouping of any participants who did not identify as cisgender and heterosexual. Chi-square tests, Fisher's exact test, and independent sample t-tests were used to compare LGBTQ+ and non-LGBTQ+ autistic adults on demographics, BDI-II and GAD-7 total scores. Raw scores of 20 or greater on the BDI-II indicate moderate or severe depression symptoms. On the GAD-7, a raw score of 10 and above indicates moderate to severe anxiety.
Results: 610 autistic participants (Mage= 30.8 years old) completed the survey. Forty-five percent (n= 280) identified as LGBTQ+ (non-heterosexual and/or non-cisgender). On average, participants reported mild depression and anxiety symptoms (Table 1). LGBTQ+ autistic participants reported significantly greater depression symptoms and greater anxiety symptoms compared to their non-LGBTQ+ counterparts (Table 1). A greater proportion of autistic LGBTQ+ participants met clinical cutoffs for moderate and severe depression (LGBTQ+ 52.5%, non-LGBTQ+ 38.8%, p=0.001) and anxiety (LGBTQ+ 45.4%, non-LGBTQ+ 33.9%, p=0.005) than non-LGBTQ+ autistic adults.

Conclusions: We found that autistic LGBTQ+ adults report significantly more symptoms of depression and anxiety compared to their non-LGBTQ+ counterparts. Recent work shows that LGBTQ+ autistic adults face numerous barriers in accessing healthcare (Hall et al., 2020). Our findings underscore the fact that clinicians should provide necessary resources including LGBTQ+ and autistic-affirming mental health supports. Future studies should examine racial differences as an additional minority status affecting mental health outcomes for autistic LGBTQ+ people, and large survey studies with autistic participants should routinely collect data on sexuality and gender identity.

401.033 (Poster) Masking Among Gender Minority Autistic Adults
A. Pearson, Psychology, University of Sunderland, Sunderland, United Kingdom

Background: Autistic masking/camouflaging is an emerging area of research that focusses on understanding the attempt to suppress/manage aspects of autistic identity, or use non-native social and/or cognitive strategies. Recently, there has been a concerted effort to understand whether and how masking might contribute to diagnostic biases. To date, much masking research has focussed on differences in masking between cisgender men and cisgender women, with small numbers of trans and/or non-binary (TNB+) participants. It is important that samples in autism research are gender diverse, as having multiple social minority identities can result in intersecting, compounding, or interacting forms of stress including more complex masking.

Objectives: We aimed to examine the experiences of masking in TNB+ autistic adults, in order to understand how having a dual minority identity impacts on autistic people.

Methods: We recruited 230 TNB+ autistic adults to take part in the current study via social media (e.g. reddit). Participants had to be over the age of 18 to take part, but no further exclusion criteria applied. The sample comprised 173 non-binary people, 23 trans women, and 34 trans men.

This study had a mixed methods design, collecting both quantitative (not discussed here) and qualitative data. Participants completed the study via an online survey hosted on the platform Qualtrics. The qualitative questions focussed on how people mask, the contexts they mask in, reasons for masking, and how they feel about their own personal identity. We analysed the data using reflexive thematic analysis.

Results: Participants described masking both autistic characteristics (e.g. forcing themselves to make eye contact, avoiding stimming) and their gender (e.g. trying to appear more masculine). Many participants reported work and socialising as primary contexts for masking, but many people felt that they masked everywhere, even when alone. Social pressure and wanting to appear ‘normal’ drove masking, in addition to wanting to be liked, and avoiding victimisation. Many people reported feeling a loss of identity, not knowing who they were, and only feeling safe around similar others who could validate them.

Conclusions: Our findings suggest that autistic people with dual minority identities may engage in masking across multiple aspects of identity. Some aspects of masking are specific to being autistic (e.g. suppressing stims) and some are a more general artefact of stigma (e.g. avoiding discrimination).

401.034 (Poster) Employment Sector Distribution of Autistic Employees Compared to the Netherlands Workforce
F. Assion, S. Begeer and Y. Goldfarb, (1)VU University Amsterdam, Amsterdam, Netherlands, (2)Clinical Developmental Psychology, Amsterdam, Netherlands, (3)Occupational Psychology, School of Behavioral Sciences, The Academic College of Tel Aviv-Yaffo, Tel-Aviv-Yaffo, Israel

Background:

Most adults spend the greater part of their waking hours at work, making employment participation a fundamental part of adult life. Previous research on employment outcomes of autistic adults commonly assessed if they work and under what terms, with mostly anecdotal descriptions of where they work. There is a common assertion that autistic people are more fitted for the Information Technology (IT) sector (Bury et al., 2019), due to characteristics such as preference for detail-oriented task or a tendency towards systemizing (Baron-Cohen et al., 2009; Simmons et al., 2009). At the same time, job-interests of autistic adults appear to expand to other directions, such as human and social sciences and creative fields (Kirchner & Dziobek, 2014). Additional studies offer an in-depth understanding of employment experiences of autistic professionals in performing arts (Buckley et al., 2021) and teaching (Wood & Happé, 2021). Thus, broad participation of autistic employees in various job-market sectors is probable, but not supported by evidence.
Objectives:

The study aimed to identify employment sector distribution of autistic employees compared to the Netherlands workforce, and to explore if background variables can predict sector integration.

Methods:

Participants included 1115 employed autistic adults (476 male, 627 female, 12 other; mean age: 40.75) registered at the Netherlands Autism Register, who completed questionnaires assessing employment sector, gender, age, age at diagnosis, level of education, degree of autistic traits (AQ-Short; Hoekstra et al., 2010) and presence of focused interests. Netherlands workforce data was retrieved from the Centraal Bureau voor de Statistiek (CBS). Absolute numbers were transcribed into proportions for each group, and split by gender. Sector-distribution differences across the two populations were tested with Mann-Whitney U-test. To test predictions, binary logistic regressions were employed for the three most common sectors of autistic employees.

Results:

Significant differences in the distribution of occupational sectors were found across the two populations ($U=83, p<.05$). Autistic adults were over-represented in the healthcare & welfare sector, the public-army-charity sector and IT, which were the three most-common sectors of employment (20.2%, 13.1% and 10.7% respectively). Under-representation of autistic employees was found in economics & finances, and industry & construction sectors. Splitting sector-distribution by gender showed that most autistic employees in the healthcare and welfare sector were females (Figure 2). Accordingly, working in healthcare and welfare was predicted by gender. Level of education and gender predicted placement in IT, but the proportion of autistic females working in IT was higher in comparison to females in the Netherlands workforce. Other tested variables did not predict specific sector integration.

Conclusions:

The widespread distribution of autistic employees between job-market sectors supports the need to for an individual approach tailoring each person’s needs and characteristics in making employment decisions. Greater job-marked diversity can promote realization of talent, leading to personal, social and economic benefits. While a relatively high representation of autistic employees in IT aligns with previous assumptions, the less expected high proportion of autistic women in healthcare and welfare may spark new insights and initiatives related to career integration for autistic women.

401.035 (Poster) Mental and Physical Health and Healthcare Utilization for LGBTQA+ Autistic Adults: Compounded Inequities

Background: Research has demonstrated that a substantial group of autistic adults are LGBTQA+. Both LGBTQA+ adults and autistic adults experience health inequities, and holding these intersecting identities may compound mental and physical health inequities. Information about autistic LGBTQA+ health outcomes and healthcare utilization can be used to inform targeted interventions.

Objectives: We used cross-sectional electronic medical record (EMR) data (2015-2019) to examine health outcomes and healthcare utilization patterns of autistic LGBQ and transgender (TG) adults compared to autistic cisgender heterosexual (CH) adults.

Methods: The setting was Kaiser Permanente North California (KPNC), a large integrated healthcare system serving over 4.3 million members. Participants were all individuals with an autism diagnosis recorded in their EMR by January 1, 2015. LGBQ individuals were identified via a self-report questionnaire and TG individuals via a stepwise method involving computerized searches of EMR and free-text clinical notes for stakeholder generated diagnostic codes and keywords, followed by chart review for eligibility. Multivariate logistic regression controlling for age, race/ethnicity, and (for LGBQ models only) gender were used to investigate differences in outcomes and utilization. Utilization models also controlled for health diagnoses.

Results: Of 4160 autistic participants, n=122 were identified as LGBQ and n=90 as TG. CH participants were older on average (M=29 years) than LGBQ (M=27 years) and TG (M=23 years). Compared with autistic CH, autistic LGBQ and TG were 2-5 times more likely to be diagnosed with mental health conditions including anxiety (LGBQ: OR=2.7, CI [1.8-3.9]; TG: OR=5.1, CI [3.2-8.4]) and depression (LGBQ: OR=2.9, CI [2.0-4.3]; TG: OR=4.5, CI [2.9-7.0]). LGBQ were more likely than CH to have diagnoses of alcohol (OR=3.8, CI
Compared with autistic CH, autistic LGBTQ were also more likely to have physical health diagnoses including pain (LGBQ: OR=2.9, CI[1.8-4.5]; TG: OR=2.4, CI[1.7-3.5]), migraine (LGBQ: OR=2.0, CI[1.2-3.5]; TG: OR=2.4, CI[1.4-4.4]), gastrointestinal disorders (LGBQ: OR=2.4, CI[1.6-3.5]; TG: OR=2.2, CI[1.4-3.4]), genitourinary disorders (LGBQ: OR=2.7, CI[1.6-4.3]; TG: OR=2.5, CI[1.4-4.5]), hypermobility syndrome (LGBQ: OR=43.6, CI[6.5-293.4]; TG: OR=38.9, CI[6.2-244.6]) and fibromyalgia (LGBQ: OR=2.8, CI[1.5-5.5]; TG: OR=3.7, CI[1.7-7.9]). Additionally, LGBQ were more likely than CH to have autoimmune conditions (OR=1.5, CI[1.0-2.3]) and renal disorders (OR=2.0, CI[1.3-3.1]).

In terms of healthcare utilization, LGBQ were more likely to have laboratory (OR=2.5, CI[1.4-4.5]), OB/GYN (OR=3.0, CI[1.9-4.8]), radiology (OR=1.7, CI[1.1-2.6]), other specialties (e.g., dermatology, sleep medicine; OR=2.0, CI[1.2-3.2]) or emergency department visits (OR=1.6, CI[1.0-2.3]). TG were more likely than CH to have mental health (OR=1.8, CI[1.1-3.0]) or other specialties visits (OR=3.2, CI[1.7-6.1]).

**Conclusions:** Compared to autistic cisgender heterosexuals, autistic LGBTQ adults experience health disparities, have higher rates of mental and physical health conditions, distinct patterns of healthcare utilization, and may need specialized supports. Healthcare providers across many different specialties must anticipate and be trained to provide care for autistic LGBTQ people in order to promote mental and physical health and health equity for this population.

401.036 *(Poster)* Equal Opportunities of Autistic Women in Working Life - Results of the Project AUT-CIA
**K. Reich.** B.B.W. St. Franziskus Abensberg KJF Regensburg Projekt AUT*CIA. Abensberg, Germany

**Background:**
A whole series of international studies as well as quite a few national references draw attention to the fact that women and girls with high-functioning autism (HFA) or Asperger's syndrome (AS) experience disadvantages in the world of work compared to the male gender, which make it more difficult to enter the workforce and lead to higher stress levels and adaptation problems. This leads to frequent job changes and even complete withdrawal from the workforce. Evidence to date suggests that the expectations women with autism face in the workforce lead to specific occupational stresses that differ from the challenges and stresses faced by autistic men. (Literature references in the full text).

**Objectives:**
However, there is a lack of knowledge as to what the particular stresses can be attributed to and what assistance women need in order to remain sustainably employed in their working lives and to find stabilization in their personal development. For this reason, the project AUT*CIA - Equal Opportunities for Severely Disabled Women with HFA/AS in Working Life was initiated. The project is designed as a practical research project.

**Methods:**
In a first step, the problem situations and support needs of women with HFA/AS are elicited using a mixed-method approach. This paper presents the results of the quantitative survey. The online questionnaire was sent nationwide (Germany) to over 6500 institutions dealing with the topic of autism and the link was published in various groups in social media. In order to be able to generate comparative data, the survey was directed at to autistic persons of every sex. (Response: N=840: male n=356; female=463; diverse=48).

**Results:**
The present study shows that autistic women are disadvantaged in all areas of life. With a mean value of 30 years, the age of diagnosis of the autistic women involved is higher than that of the men (21 years). Autistic women show more pre-diagnoses (f=62%; m=40%) as well as comorbidities (f=83%; m=73%). Both the assessment of life satisfaction (dissatisfied: f=44%, m=38%) and job satisfaction (dissatisfied: f=39%, m=28%) are lower among the autistic women surveyed. The assessment of various areas of life is also more negative among women. The most stressful areas of life are the job search (80%), own health issues (68%) and employment. Just under a third (30%) of the women surveyed stated that they were unemployed. The need for support at work is rated higher by women than by men. The need for support in solving conflicts within the team is rated as high or very high by 54% of the women and represents the highest category. Only 38% of the women surveyed feel sufficiently supported.

**Conclusions:**
The establishment and expansion of gender-specific counseling and support services must be promoted. The focus must be on all areas of life. Starting with improved access to diagnostics, to counseling services concerning the organization of private life, to support measures at the workplace in order to reduce the specific burdens and to sustainably increase the participation of autistic women in the workforce.

**401.037 (Poster) Examination of Prevalence Rates, Psychological Correlates, and Treatment Outcomes Among SGM and Non-SGM College Students with and without ASD**

*E. F. Soto, D. Orantes, N. Russo and K. Antshel, Department of Psychology, Syracuse University, Syracuse, NY*

Background: Both the prevalence rates of young adults diagnosed with autism spectrum disorder (ASD; Bakker et al., 2019) and those identifying with a sexual and gender minority (SGM) group (ACHA, 2020) have been increasing each year. While both ASD and SGM status are independently associated with a myriad of psychiatric conditions and functional impairments, research focusing on their intersection has been limited, especially among college students. Prior studies suggest SGM individuals with ASD face more barriers to healthcare access compared to non-SGM individuals (Hall et al., 2020). However, the extent to which these findings are driven by SGM status, a diagnosis of ASD, or their compounding effects associated with each is unknown. Understanding these topics are important, given theoretical models (minority stress theory, intersectionality theory) indicating that individuals belonging to minority groups tend to experience higher rates of mental health problems due to compounding stressors that may be further exacerbated in the presence of two or more intersecting minority identities (Meyer, 2003; Crenshaw, 1989).

Objectives: The current study builds on existing literatures on ASD and SGM and is the first to examine prevalence rates, associated functional impairments, and treatment engagement levels for SGM and non-SGM populations with and without ASD via a large nationwide college-student sample cross-sectionally across 3 years.

Methods: Analysis were completed using data from the American College Health Association-National College Health Assessment (ACHA-NCHA) III. Participants included 82,030 college students between the ages of 18-25 years old randomly selected from 75 US colleges and universities. ACHA-NCHA-III measures assessing demographics, self-reported ASD diagnosis, self-reported SGM membership status, mental health symptomatology, stress, and academic impairment were used for analyses. Participants were assigned into one of four groups based on their reported ASD and SGM statuses: ASD-only (n=567), ASD+SGM (n=489), SGM-only (n=17,507), and control (n=63,3467). Analysis was conducted using MANCOVAs, ANCOVAs, and chi-squared tests to assess 1) the prevalence rates of ASD within SGM and non-SGM groups, 2) group differences among psychological correlates (i.e., stress, resiliency, loneliness, non-suicidal self-injurious behaviors, etc.) and associated academic impairments, and 3) group differences across treatment engagement levels.

Results: Results indicated ASD prevalence rates were significantly higher in the SGM-only group (2.7%) as compared to the non-SGM group (0.9%), χ²(1)=370.94, p<.001. Group differences emerged for psychological correlates and academic impairments (all p’s <.05). Follow-up pairwise comparisons will be presented and discussed in detail. Data analyses for examination of group differences across treatment engagement is currently ongoing and is expected to be completed prior to 2023.

Conclusions: This study provides a comprehensive view of the prevalence rates, associated psychological correlates, and treatment engagement outcomes experienced by SGM and non-SGM college students with and without ASD. Conclusions of this study suggest important implications for college students with these intersecting identities, including overlapping treatment goals in counseling centers and enhanced college supports.

**401.038 (Poster) Examining Physical and Mental Health Service Needs, Conditions and Other Correlates of Subjective Well-Being of Autistic Adults**

*L. P. Grosvenor1, C. L. Errichetti1, C. B. Holingue1, J. B. Beasley1 and L. G. Kalb2,3, (1)Department of Mental Health, Johns Hopkins Bloomberg School of Public Health, Baltimore, MD, (2)Center for Autism and Related Disorders, Kennedy Krieger Institute, Baltimore, MD, (3)Institute on Disability, University of New Hampshire College of Health and Human Services, Durham, NH*

Background:

Mental health research involving autistic adults has historically focused on psychopathology. The growing field of positive psychology seeks a different perspective, viewing life from the angle of what makes it worth living (often termed “subjective well-being”), rather than solely focusing on what is wrong. The PERMA Profiler, a 23-item self-report measure, encapsulates the construct of well-being across five domains (Positive emotion, Engagement, Relationships, Meaning, Accomplishment), though a prior study among autistic adults suggested PERMA is best represented as one overall well-being construct (not five domains). Examining well-being may inform targets for positive psychological interventions and identify factors protective against psychopathology. However, there have only been a few studies of subjective well-being involving autistic adults.

Objectives:
The objective of this study was to identify potentially modifiable correlates of subjective well-being among a large sample of autistic adults.

**Methods:**

Participants (> 18 years of age and identified as autistic or as having autism) were recruited through Simons Powering Autism Research for Knowledge (SPARK). A custom, 68-item survey including the PERMA Profiler and questions about sociodemographics, employment, physical and mental health conditions, and health service needs, utilization and satisfaction was collected online through SPARK in August 2021. Multivariable linear regression models were fit with overall PERMA Profiler well-being as the outcome. Covariates in the final model included physical health (problems with sleep, seizures, gastrointestinal, or immune systems), mental health (presence of depression or anxiety), unmet health services need, social supports, and current employment status. Descriptive statistics were also presented on key covariates.

**Results:**

A total of 517 autistic adults completed the survey (17% response rate; M\text{age} = 39; SD\text{age} = 13; 85% White; 50% Female; 51% with a collegiate degree; 52% currently employed; 69% experiences with depression and 82% with anxiety). The mean overall well-being was 5.6 out of 10 (SD = 1.9). Among the 213 (41%) participants who reported having unmet health services needs in the past 12 months, 26% were related to general medical care, 33% specifically to mental health care, 35% to dentistry and 5% to other health services. Presence of unmet health needs had the strongest negative association with well-being, followed by having a mental health disorder, experiencing little to no social support, and increasing age (all p<0.01). Being currently employed was also strongly associated with higher overall well-being (p<0.001). Having physical health problems and experiencing higher social support (compared to “some” support) were not significantly associated with well-being.

**Conclusions:**

Subjective well-being among this sample of autistic adults recruited online was considerably lower than prior research using the PERMA Profiler. Unmet health needs, presence of mental health conditions, low social support, and lack of employment were all strong correlates of well-being. These data provide clear targets for interventions to improve well-being, which can function as a protective factor against future depression. Increasing access to mental health services (evidenced-based psychological therapies), connecting autistic adults with each other and loved ones, and providing gainful employment – all of which were directly impacted by COVID-19 – would address many of these needs.

401.039 (Poster) Examining Responses to Uncertainty and Its Role in Anxiety and Autism

**Background:**

The consensus is that Intolerance of Uncertainty (IoU) plays a significant role in anxiety in autism (Maisel et al., 2016). However, emerging evidence from qualitative studies (e.g., Lennuyeux-Comnene et al., under review) suggests that not all uncertainties are equally problematic for autistic individuals. Therefore, questions remain about what types of uncertainties induce anxiety. Studies have sought to find ecologically valid behavioural paradigms to measure intolerance of uncertainty in anxiety (e.g., Jacoby et al., 2014 and Ladouceur et al., 2000), and this study expands on this work.

**Objectives:**

Based on the existing evidence, the current study sought to examine how the manipulation of different types of uncertainty impact upon information-seeking behaviour in autistic and non-autistic adults with varying degrees of self-reported levels of anxiety and IoU.

**Methods:**

In this 16-trial experiment, 136 participants (74 autistic and 62 non-autistic) had to decide on the predominant colour of jellybeans in a jar with differing ratios (25/75, 30/70, 35/65 or 40/60) of green and red jellybeans. After that, on each trial, they rated their confidence in this decision. Only on half the trials were the participants told the ratio of green to red jellybeans, thus increasing the uncertainty about the contents of the jar on the trials when they were not. In addition, only on half the trials were the participants told that they would be given feedback on their decision at the end of the trial, thus manipulating uncertainty about the outcome of their decisions on the trials when they were not.
Two 2 (autistic vs. non-autistic group) x 2 (ratio known/unknown) x 2 (outcome known/unknown) x 4 (proportion of beans) mixed factors ANOVAs and two linear regression analyses were conducted in SPSS, with Draws to Decision (DTD) and Confidence Ratings as DVs and group, anxiety and IoU scores as IVs.

Results:

Participants requested more jellybeans as the proportion got closer to 50/50 (p < .001), particularly when the ratio was unknown (proportion x ratio interaction; p = .018). They were less confident as the proportion got closer to 50/50 (p < .001), however overall, more confident when not knowing the ratio (p=.003), particularly for the easier ratios (proportion x ratio interaction; p = .001). Overall, Autistic participants were less confident (p=.007), as were the more anxious (p = .001) and those higher in IoU (p= 008). Otherwise, there were no main effects or interactions.

In a regression model with Group, scores in anxiety and IoU as IVs, only anxiety and IoU were predictors of confidence (p=.079, p < .001, p=.012, respectively).

Conclusions:

The results indicate that in this task, autistic participants behave in a similar manner to non-autistic participants but are less confident in their decisions. The regression analysis indicates this could be because they are more anxious and more intolerant of uncertainty. Furthermore, although participants consistently respond to increasing uncertainty by seeking more information, the fact that knowing the ratio decreases confidence, indicates that they may be using different strategies to manage different types of uncertainties.

401.040 (Poster) Examining the Link between Social Connectedness and Mental Well-Being in Caregivers of Autistic Children

H. Salavati, C. L. McIntyre, V. C. Fong, and G. Iarocci, (1)Psychology, Simon Fraser University, Burnaby, BC, Canada, (2)Simon Fraser University, Burnaby, BC, Canada

Background: There is a breadth of research examining the impact of social support on the mental health and well-being of caregivers of autistic children (Gouin et al., 2016). However, no studies to date have explored the impact of social connectedness (SC) on caregivers of autistic children. SC is defined as the ability to care for and feel cared for by others while having a subjective sense of belongingness in your environment or community (O’Rourke & Sidani, 2017). Social connectedness differs from social support in that the latter is typically operationalized as the objective presence or absence of social ties, whereas the former involves more of a subjective psychological component (Ashida & Heaney, 2008). Thus, it is possible for caregivers to perceive the availability of social support yet still feel disconnected and lonely. Understanding the link between SC and the mental well-being of caregivers is important to consider when developing services and interventions to support parents of autistic children.

Objectives: The objective of this study is to examine the impact of SC on the mental well-being of parents of autistic children, while controlling for demographic variables such as income, caregiver age, and ethnicity.

Methods: Seventy-three caregivers (M_{age}=43.75, SD=7.571) of autistic children (M_{age}=11.85, SD=4.957) were recruited from advertisements through the university, community disability organizations, and health service centers. Caregivers completed the Warwick Edinburgh Mental Well-Being Scale (WEMWBS) and the Social Connectedness Scale (SCS; Lee & Robbins, 1995). First, Pearson correlation coefficients between demographic and main study variables were conducted. Second, a hierarchical multiple regression was conducted to examine the impact of caregivers’ social connectedness on their mental well-being after controlling for demographic variables. At step one, income, caregiver age, and ethnicity, were entered. At step two, social connectedness was entered.

Results: Correlational analyses showed social connectedness was positively associated with mental well-being (r(73)= .292, p = .006), and caregiver age (r(73)= .215, p = .034). A positive correlation was also found between caregiver age and income (r(72)= .214, p = .034). Step one of the hierarchical multiple regression indicated that income, caregiver age, and ethnicity accounted for 4.9% of the variance in mental well-being, resulting in a significant model (R^2 = .49, F(3, 69) = 1.194, p = .319). In step two, social connectedness was entered and accounted for an additional 8.0% of the total variance, resulting in a significant model (R^2 = .129, F(4, 68) = 2.522, p = .049).

Conclusions: The current findings highlight the important impact of SC on the mental well-being of caregivers of autistic children. Parents of autistic children experience various challenges and high caregiving responsibilities which contribute to elevated levels of stress and lower levels of well-being (Marsack & Hopp, 2019). The findings of this study demonstrate that providing targeted support which addresses parents’ sense of belonging and connectedness may mitigate some of the negative impacts that parents of autistic children experience. A limitation of the study is the relatively small sample size of seventy-three participants (Females = 71, Males = 2).

401.041 (Poster) Experiences of Autistic College Students in Higher Education and Their Relations with Faculty
Background: Autistic students are increasingly enrolling in postsecondary institutions. While studies examining faculty-student relations are rising, there are few to no studies looking at how these relations may impact academic self-concept for autistic youth.

Objectives: The purpose of this study was to investigate autistic college students’ academic self-concept and their interactions with faculty.

Methods: A sample of 12 participants was recruited for investigation regarding autistic college students’ experiences and interviewed using a semi-structured protocol. A phenomenological approach was followed, in which the goal was to understand several individuals’ common or shared experiences of relations to faculty and academic self-beliefs. Focused codes were classified into themes by relating the material to aspects about the phenomenon of interest.

Results: The interviews with students revealed that most students have a positive academic self-concept due to factors like personal motivation to do well, following family values, striving for high academic achievement, and proving someone wrong. Other factors were also found to have an impact on academic self-concept in general. These included accommodations (disclosing based on necessity, The Disabilities Services Office failing to provide necessary supports, and community colleges providing better accommodations), impact of the pandemic, and learned self-awareness. Faculty relations with students seemed to vary where each student had situations with both positive and negative interactions. The theme of accommodations was prevalent as it was found that faculty play an important role in students receiving both formal and informal accommodations needed to succeed in their courses.

Conclusions: Post-secondary institutions should consider how they can provide faculty training and professional development around supporting autistic students and managing accommodations.

401.042 (Poster) Exploring Grit and Its Associations with Psychological Well-Being in a Sample of Autistic Adults

C. I. Parenteau, S. Zheng; L. A. Lampion and S. Bishop, (1)Psychiatry and Behavioral Sciences, Center for ASD and NDDs, UCSF Dept of Psychiatry, San Francisco, CA, (2)Psychiatry and Behavioral Sciences, University of California, San Francisco, San Francisco, CA

Background: Autistic adults experience a wide range of positive and negative life experiences. However, empirical data on individual-level protective and risk factors are sparse, limiting research and clinical practices in promoting positive outcomes in this population. Grit is a construct that has been explored in the neurotypical population to show predictability of success and psychological well-being, but has yet to be studied in autistic adults. Specifically, multiple studies have associated grit with mental health factors (e.g., depression and anxiety) and quality of life in the neurotypical population. Given the observed high rates of mental health challenges in autistic adults, the construct of grit holds the potential to elucidate possible individual processes of psychological well-being.

Objectives: To provide preliminary data on grit in an autistic adult sample by (1) exploring the structure of grit as measured by the Grit scale, and (2) examining the overall patterns of item endorsement and its associations with mental health symptoms and quality of life.

Methods: A sample of 211 autistic adults between the ages of 20-36 completed self-reported measures of the Grit scale, mental health symptom measures (Beck Depression Inventory-II [BDI-II]; Depression Anxiety Stress Scale[DASS]), and a quality of life measure (Autism Spectrum Quality of Life [ASQoL]), as part of a larger study focused on mental health and mental health services.

The Grit scale (Duckworth, 2007), a 12-item self-report scale, is currently the only measure available to assess the level of grit. Thus, exploratory factor analysis was performed on the Grit scale to explore the structure of the construct of grit in this autistic adult sample. Next, the item endorsements of the Grit scale were calculated to show patterns of discrete characteristics of grit. Lastly, Pearson’s correlation coefficients between the grit scale, mental health, and quality of life scales were generated.

Results: Results of the exploratory factor analysis indicated that a two-factor structure showed the best fit in this autistic adult sample (see Table 1 for factor loadings). The factor structure resembles the proposed two-factor structure shown in the general population study of grit (Duckworth, 2007). The average score of overall Grit is 3.09 (SD=64) in the current sample, lower than the national average of U.S. adults (Duckworth, 2007). The patterns of item endorsement showed that autistic adults were most likely to endorse that they “were hardworking/diligent” and “had overcome obstacles”, but “had difficulty focusing” or “could be distracted by new ideas”. Moreover, the total grit score showed a moderate negative correlation with depression (r=-.47 (BDI-II); r=-.49 (DASS)), a small negative correlation with anxiety (r=-.3 (DASS)); and a small positive correlation with quality of life (r=.34).

Conclusions: Our findings provided preliminary evidence that grit had two factors, as is in the general population, and showed small to moderate correlations with depression, anxiety, and quality of life. Given the high endorsement rate on specific items, next steps involve in-depth investigations at the item level to understand what grit-related qualities mean to autistic adults and how those characteristics...
influence their psychological well-being and life experiences.

**401.043 (Poster) Exploring the Lived Experience of Autistic Mental Health**

K. M. Browne, S. McGarry, W. Lawson, M. T. Scott, S. J. Girdler and B. T. Milbourn, (1) School of Occupational Therapy and Social Work, Curtin University, Bentley, Western Australia, Australia, (2) School of Occupational Therapy, Social Work and Speech Pathology, Curtin University, Perth, Australia, (3) Macquarie School of Education, Self, Macquarie University, NSW, Australia, (4) School of Allied Health, Curtin University, Bentley, Western Australia, Australia, (5) School of Allied Health, Curtin University, Perth, Australia

Background: The Autism Spectrum is a lifelong, heterogenous neurodevelopmental disorder that can cause significant social, behavioural and communication challenges. Recent studies have highlighted the severity of the mental health crisis within the autistic community. While many studies have investigated the prevalence of contributing factors and the atypical presentations of specific mental health issues, such as depression, anxiety and suicidality, few studies have investigated the overall mental health of autistic adults from a lived experience perspective.

Objectives: This research investigated the lived experience of mental health of autistic adults.

Methods: Mental health factors were explored through constructivist grounded theory underpinned by a co-production framework. The principal researcher for this project was herself a member of the autistic community, as was one of the supervisors on the research team. In addition, a steering group of autistic adults informed the questions for the semi-structured interviews which were conducted with autistic adults concerning their lived experiences of mental health.

Results: Eighteen adult autistic individuals (male=7, female=11), aged between 22 and 54 years (mean=38, SD=10.6) were purposively sampled. Participants received an autism diagnosis from 15 to 52 (mean=34, SD=12.2) years of age and reported a wide variety of life experiences, with half of the participants being parents and half currently in a romantic relationship. A variety of employment and education statuses were reported including full-time, part-time, casual, self-contract and disability pension.

Preliminary findings identified that seven themes captured participants lived experience of mental health. The themes included the impact of autism diagnosis on identity, supportive relationships as a protective factor for positive mental health, sensory input as a risk factor for poor mental health, therapies need to adapt to the individual, parenting ‘a double-edged sword’, the complexities of employment and masking autistic traits.

Conclusions: Preliminary findings suggest that having supportive environments, relationships, and societal attitudes are key in protecting the mental health of autistic adults. Several of the themes identified, such as the topics of sensory input and masking, do not feature in non-autistic mental health research, suggesting these factors are unique to autistic individuals and are overlooked in current models of care and support. Findings suggest that therapies and strategies for improving mental health need to be tailor-made and targeted for the individual rather than applying a one-size-fits-all approach that is currently applied by many professionals.

**401.044 (Poster) Exploring the Lived Experiences and Health of Older Autistic Adults: Findings from a UK Research Programme on Autism in Adulthood**

J. R. Parr and S. Brice, (1) Newcastle University, Newcastle, United Kingdom, (2) Population Health Sciences Institute, Newcastle University, Newcastle upon Tyne, United Kingdom

Background:

The lived experiences of older autistic adults remain poorly understood. The Adult Autism Spectrum Cohort-UK was designed to investigate the skills and needs of autistic people across the lifespan. Through ongoing programmatic research aligned with community priorities, we have sought to understand autistic people’s lived experiences, quality of life (QoL), and mental and physical health and service use, to inform the development and evaluation of novel intervention approaches.

Objectives:

From programmatic research describe: 1) the lived experiences and healthcare needs of older autistic adults; and 2) lessons learned in the development and evaluation of health interventions.

Methods:

Autistic people and relatives were recruited to the Autism Spectrum Cohort-UK study via health, voluntary sector organisations and the autism community. Over 3200 autistic adults and relatives completed a registration questionnaire about many aspects of their lives, the
Background: Adaptive functioning has been shown to be an important determinant of outcome in individuals with Autism Spectrum Disorder (ASD), determining the level of independence that an individual can achieve in adulthood. This must be one of the main therapeutic objectives when working with people with ASD and for this it is needed valid and easy tools to evaluate both, functioning of individuals and causes of failure to achieve it.

Objectives: Taking this into consideration, the first aim of the present study is to adapt the original six-factor model of the FAST to ASD population in order to create the FAST-ASD, which we hypothesize, will be more suitable for evaluating adaptive behavior in this particular population. The second objective of the study is to explore the differences in socially and clinically relevant variables between functioning groups in adults with ASD that may explain the heterogeneity of adaptive functioning in this group.

Methods: A sample of 164 adult participants with ASD from the population monitored within the ASD specialized program from a tertiary Hospital was included. The inclusion criteria were: 1) being between 18 and 65 years old; 2) diagnosis of ASD according to the diagnostic criteria of the DSM-5. The linguistic and cognitive barriers of the respondents were considered as exclusion criteria. Principal component analysis (PCA) with Varimax rotation was performed to explore the factorial structure of the FAST. Those items with loads lower than .30 were excluded and a criterion of at least 3 items per component was set. With this result, the FAST-ASD was established. A hierarchical cluster analysis was carried out using Ward's method to explore the distribution of the participants according to their responses on the instrument. Finally, a one-way ANOVA with the resulting clusters as factor was carried out to analyze differences in the subscales of the FAST-ASD instrument, as well as in clinically significant variables.

Results: The PCA found a structure of four components (Cognitive functioning, Work/Academic functioning, Independent life and Social/Community Participation), with a total of 22 items in the FAST-ASD. Cluster analysis detected four clusters based on participants' scores in the FAST-ASD. Significant differences were found between the four clusters in subscales of the FAST-ASD, with all clusters presenting difficulties in social functioning. In addition, significant differences were found between clusters in distribution by sex, age, severity of autism, intellectual functioning, and presence of psychiatric symptoms.

Conclusions: The FAST-ASD appears to be a valid instrument for the rapid assessment of adaptive functioning in the adult population with ASD. Of interest, people with ASD could be classified into different groups based on their adaptive functioning. This could be of enormous
help for the development of specific intervention programs to improve the functioning of this population. Limitations include the small number of participants, as well as the underrepresentation of adults with higher levels of support. More studies are needed to replicate the results found here in non-clinical populations with ASD.

401.046 (Poster) Facial Expressions of Emotion in Adults with ASD without Intellectual Disability: A Comparative Study to Objectify Atypicalities in the Kinetics and Accuracy of Imitation Using Automatic Facial Analysis Software

K. Briot1, A. Pizano, J. Cazalets, O. Bogdanova, M. P. Bouvard, V. Bogdanov and A. Amestoy2,3, (1)Department of child and adolescent psychiatry, Centre Hospitalier Charles Perrens, Bordeaux, France, (2)Aquitaine Institute for Cognitive and Integrative Neuroscience, INCIA, UMR 5287, CNRS, Bordeaux, France, (3)Medical Sciences Department, University of Bordeaux, Bordeaux, France, (4)Pôle universitaire de psychiatrie de l'enfant et de l'adolescent, Centre hospitalier Charles-Perrens, Bordeaux, France, (5)Aquitaine Institute for Cognitive and Integrative Neuroscience, INCIA, UMR 5287, CNRS, Université de Bordeaux, Bordeaux, France, (6)Centre hospitalier Charles Perrens, Pôle Universitaire de Psychiatrie de l'enfant et de l'adolescent, Centre Ressources Autisme Aquitaine, Bordeaux, France, (7)Collège Science de la Sante, Institut Universitaire des Sciences de la Réadaptation (IUSR), Laboratoire EA 4136 – Handicap Activité Cognition Santé HACS, Université de Bordeaux, Bordeaux, France, (8)Department of child and adolescent psychiatry, Centre Hospitalier Charles-Perrens, Bordeaux, France

Background:
Facial expressions of emotion (FEEs) are described as atypical in subjects with Autism Spectrum Disorder (ASD). It has recently been suggested that inadequacies of FEEs in ASD individuals in relation to expected emotion were related to a potential lower quality and coordination of facial muscle movements, especially in the eye area. However, confounding effects have been identified and could impact the interpretation of the results in many studies.

Objectives:
Our main aim was to characterize the accuracy and kinetics of the FEEs production in adults with ASD compared to healthy adults, controlling for the attention on the others’ face using eye-tracking methods and adjusting for clinical factors that could influence the production of FEEs such as gender, depressive symptoms and alexithymia. Objective automatic facial analysis methods were used in this study to assess the voluntary production of different FEEs.

Methods:
We recorded 30 adults with ASD without intellectual impairment and 30 matched controls from the French AUTICOPP study. Participants' facial expressions during imitation of standardized dynamic facial expressions of basic emotions were translated qualitatively and quantitatively using the Face Reader software which automatically analyzes facial expressions. A comparison of the production of the different emotions between the groups with and without ASD was performed using the intensity level of emotional arousal of each participant as a baseline. The recognition score of dynamic facial emotions was also assessed.

Results:
Multivariate analysis revealed that the voluntary FEEs production of adults with ASD differed from non-ASD participants regarding quality and kinetic characteristics.

Conclusions:
Facial emotion production is a complex developmental process impacted in ASD. This study provided new evidence for abnormalities in the sequence of facial muscle activation with potential spatial and kinematic chain motion dysfunctions in individuals with ASD. More specifically, asynchrony seems to be involved in the abnormal production of voluntary FEEs, contributing to deficit in social reciprocity.

401.047 (Poster) Factors Associated with a Positive Transition to an Autism-Friendly Residence Facility

E. St-Jean1, A. M. Nader, I. Courcy2, B. Forgeot d’Arc and R. Godbout1, (1)Psychiatry, Université de Montréal, Montréal, QC, Canada, (2)CIUSSS Nord-de-l'Île-de-Montréal, Montréal, QC, Canada

Background: A majority of autistic adults stay with their families or in residential facilities. However, residential resources are limited, and few are specifically built to meet the needs of autistic adults. Few studies systematically investigated the various facets of the individual's well-being, including quality of life (QoL), anxiety, and adaptive functioning, before and after transitioning from family home
to residential facility. Building autism-friendly residence facilities (i.e., specific architectural and clinical approaches), and identifying factors surrounding a positive transition, might support the transitioning and living experience of autistic adults into their own home.

Objectives: The aims of this study are to (1) assess the impact of transitioning to an autism-friendly residence on well-being, specifically on QoL, anxiety and their level of functioning; and (2) identify factors, as perceived by parents, associated with a positive transition to an autism-friendly home.

Methods: This is a mixed-methods (quantitative and qualitative) longitudinal study of 12 autistic adults (21-55 years; 8F:4M), all residing in the same autism-friendly residence. The majority of participants (92%) come from a family setting, and all require a mild to moderate level of support. Residents were followed for 13 months: three months before entering the residence (T1) and 10 months after their arrival (T2). Data collection combined information from (a) clinical records (e.g. IQ, associated diagnoses); (b) questionnaires completed by parents, measuring QoL (San Martin Scale - Quality of Life Assessment for People with significant disabilities), emotional and behavioral well-being (Emotional Problem Scales; EPS), and level of adaptive functioning (Adaptive Behavior Assessment System – 2nd edition), (c) semi-structured interviews with autistic adult parents before and after integration. Analyses are based on a multiple-case design series and include qualitative content thematic analyses.

Results: Objective 1. The results show that at T2, 50% of parents reported an increase in the residents' QoL and 83% noted a maintenance or an increase in adaptive functioning. Distinctly, results on the anxiety subscale of the EPS questionnaire show that 25% of residents appear to show a decrease in anxiety, 8% show an increase, while 67% remain unchanged. Objective 2. Three relevant key themes were associated with a positive transition from the family home to the new residential environment: (a) upstream preparation with the future resident helps reduce the uncertainty associated with a new living environment and increase the resident’s feeling of control over the situation; (b) staff knowledge of both challenges and strengths/interests of the resident as a lever for social participation; (c) parental involvement in the process in order to share knowledge and maintain regular contacts with their child.

Conclusions: The transition to a residence designed specifically in accordance with autistic needs seems to ease their adaptation and increase their well-being. Despite limits of this study (e.g. sample size, absence of direct input of autistic adults), these results fill a knowledge gap about the impacts of the transition from a family setting to an autism-friendly residence facility. Further analyses will aim to identify the contribution of specific architectural, clinical and lifestyle components to the current results.

401.048 (Poster) Ensuring Data Integrity Against Bots and Frauds in Online Surveys of Autistic Students

B. E. Cox, B. R. Nachman, J. L. Taylor, K. Gillespie-Lynch, N. Gelbar and E. Raclaw, (1)Educational Leadership and Policy Studies, Florida State University, Tallahassee, FL, (2)NC State University, Madison, WI, (3)Vanderbilt University Medical Center, Nashville, TN, (4)Department of Psychology, CUNY Graduate Center, Staten Island, NY, (5)University of Connecticut, Mansfield, CT, (6)Marquette University, Milwaukee, WI

Background: As scholars have increasingly turned their attention to autistic individuals’ postsecondary experiences, the number of studies on the topic has accelerated in recent years. However, problems with the samples for these studies severely limit their utility. Datasets on autistic college students’ experiences are often small, homogenous, and frequently exclude students who have not disclosed their diagnoses to their campus disability services office. Several scholars and self-advocates have encouraged community-engaged participatory approaches to overcoming these limitations (Fletcher-Watson et al., 2019; Nicolaidis, 2012). In one recently launched study, however, efforts to apply several principles of participatory research created one unanticipated challenge that required quick and comprehensive countermeasures: data contamination by automated bots and fraudulent responses.

Objectives: To help other researchers avoid potential complications in their own work, this presentation draws from an ongoing study to offer explicit guidance for how to protect the integrity of data collected through online surveys. Specifically, we will outline the 13-step process we developed to assess data quality, confirm the authenticity of respondents, and ensure we don’t waste thousands of dollars compensating robots, scammers, and cheats.

Methods:

When seeking autistic college students to participate in an online survey, we partnered with autism and disability-centered organizations to spread the word to their thousands of followers on social media and via email list-servs. We also sent targeted emails to autism and higher education researchers, directors of autism-specific college support programs, autistic self-advocates, and disability practitioners who furthered distribution through personal outreach or social media. Our project team also held information sessions in a webinar and at a conference, shared it on our social media, and emailed personal contacts. Eligible participants would receive $25 gift cards as compensation for their time. We anticipated receiving no more than 200-250 survey respondents spread out over 3 months of data collection.

To our surprise, a total of 1,122 responses were recorded within just 4 days of the survey’s launch. Our review of those responses, however, made it clear that more than 90% of responses were fraudulent, duplicates, or completed by automated bots. Over the subsequent week, we
implemented a series of digital countermeasures that dramatically reduced these types of responses. We have subsequently developed a 13-step manual process that helps us identify and remove any fraudulent responses that made it past our digital defenses.

**Results:** Although many online survey platforms offer response validation and bot-detection tools, we have found those integrated tools to be woefully inadequate. With our project, the software flagged fewer than 5% of what we subsequently determined to be a fraudulent response. Far more effective were a set of researcher-defined filters targeting study-specific indicators of likely fraud (e.g., reverse-coded items with nonsensical responses) followed by a multi-step manual data verification process.

**Conclusions:** By leveraging recent advances in technology maximizing engagement with the autism community, researchers are increasingly able to recruit from larger and more diverse pools of potential participants. But doing so effectively will require implementation of comprehensive protections against fraudulent responses.

---

**401.049 (Poster) Genetic Testing History in Adults with Autism Spectrum Disorder**

S. B. Mierau, R. Thom, C. Ravichandran, A. Nagy, C. L. Macenski, C. Rice, M. L. Palumbo, C. J. Keary, C. J. McDougle and A. M. Neumeyer, (1)Lurie Center for Autism, Massachusetts General Hospital, Lexington, MA, (2)Psychiatry, Massachusetts General Hospital, Lexington, MA, (3)Lurie Center for Autism, Massachusetts General Hospital for Children, Belmont, MA, (4)Neurology, Massachusetts General Hospital, Boston, MA, (5)Psychiatry, Massachusetts General Hospital, Boston, MA, (6)Massachusetts General Hospital Institute of Health Professions, Boston, MA, (7)Lurie Center for Autism Massachusetts General Hospital, Lexington, MA

**Background:**

Many genes have been identified in autism spectrum disorder (ASD; Vorstman et al, 2017). For clinicians, the genetic cause provides critical information about prognosis and associated medical problems. For adults with ASD, the genetic cause informs care and facilitates connection to support groups for specific genetic conditions. For researchers, the genetic cause aids mechanistic and novel therapeutic studies. Despite the availability of genetic testing and utility to multiple stakeholders, little is known about how many adults with ASD receive recommended genetic testing and their outcomes.

**Objectives:**

Estimate (1) the percentage of adults with ASD who have received genetic testing among those represented by our ASD specialty clinic patients; (2) associations of demographic and clinical characteristics with receiving recommended testing; (3) the percentage with positive findings and findings of unknown significance among those receiving recommended testing.

**Methods:**

Adults were identified and ASD diagnoses confirmed using record review by consensus of psychiatrists specializing in ASD, as previously described (Thom et al., 2022), but with no exclusions based on genetic conditions. Electronic medical records were manually reviewed and clinical and genetic history data recorded. Patients were included (N=630) who had at least one visit with a qualifying clinician from our hospital between 5/1/2010 and 12/15/2020 and had demographic data available. Risk regression quantified associations of characteristics of adults with recommended testing.

**Results:**

Only 41% of the adults with ASD (261/630) had a history of genetic testing documented in the medical record. Genetic testing was declined by the patient or family for 11% (72) of records and not recorded in 47% (297). Mean (SD; range) age for the 261 adults with testing documented was 28.5 (5.3; 22-58) years. Sixty-seven (26%) were identified as female, 14 (6%) as Asian, 8 (3%) as Black or African American, 226 (89%) as White, 6 (2%) as other race, and 2 (1%) as Hispanic. 189 (73%) had intellectual disability. Ninety-one percent (236) had the genetic testing method recorded. Figure 1 displays percentages with different testing methods. Only 54% (95% CI: 47%, 60%) of patients had testing using a recommended method (chromosomal array, autism/intellectual disability sequencing panel, or exome sequencing). Few adults had received testing with sequencing technologies. Presence of microcephaly, macrocephaly, or dysmorphic facial features was associated with 1.57 (1.14, 2.16) times the frequency of recommended testing after adjustment for age, sex, and seizure history (p=0.005). Age, sex, intellectual disability, family history of ASD, and seizure history were not significantly associated. Outcomes of genetic testing by method are presented in Table 1.

**Conclusions:**

Current genetic testing can offer clinical and research insights. Yet it is underutilized in this population of adults with ASD. Nearly half of the adults in our sample lacked documentation of recommended genetic testing. Thus, the percentage of adults with confirmed ASD who had any recommended genetic testing may be even lower than reported. Many adults with ASD may benefit from having their genetic
testing history reviewed in the clinic and the latest genetic testing performed.

401.050 (Poster) Group Interpersonal Synchrony Effectiveness for Young Autistic Adults in a Pre-Military Training Program – Preliminary Results

T. Dvir1, C. Elefant2 and T. C. Rabinowitch3, (1)The school of Creative Arts Therapies, University of Haifa, Israel, Hifa, Israel, (2)The School of Creative Arts Therapies, University of Haifa, Haifa, Israel

Background: The prevalence of cognitively-abled autistic adults that successfully integrate into the world of work is limited due to difficulties in adapting to social and stressful work environments. The global transition to a hybrid work approach might increase these difficulties by promoting distance socializing. Therefore, there is a growing interest in forming tailored interventions that will enhance prosociality and reduce work-related stress among this group of individuals. Interpersonal synchrony is observed when two or more individuals are sharing body movements or sensations (such as gaze, affect, voice and touch) simultaneously or as a responsive behavior, and is a powerful force in holding human groups together.

Objectives: This preliminary study aims to assess the effect of group interpersonal synchrony on prosociality and work-related stress of young adults who participate in an innovative Israeli program “Roim Rachok” (Looking Ahead). Roim Rachok designed to integrate cognitively-abled autistic adults first into the Israeli army workforce, and later into the free market.

Methods: The study is a between-subjects randomized controlled trial, which investigates two conditions of movement-based group intervention: synchronous (N=21) and non-synchronous (N=24), providing each participant with only one type of intervention. The participants, 45 young adults between the age of 18- to 21 years, are diagnosed with autism and recently joined the “Roim Rachok” program. The two condition groups were matched by gender, handedness, army-related profession and belongingness. Hour-long intervention sessions were performed by the researcher, a professional Dance Movement therapist, once a week for the duration of seven weeks, using two protocols designed specifically for the program. The protocols differed in terms of using synchronous movement activity forms vs. using non-synchronous movement activity forms. They did not differ in terms of movement type and duration to control for their effect on the study’s dependent variables. Each intervention group contained between 7- to 10 participants (three groups for each condition). Data collection using questionnaires and behavioral tasks was conducted for each participant during two points of time: pre and post intervention period. The effect of the intervention over time was examined using a two-way mixed model ANOVA.

Results: No significant difference was found between intervention groups in terms of improvement in prosociality and reduction in work-related stress. Participants in the synchronous group had more close friends within the group before the intervention but fewer close friends within the group after the intervention, compared to participants in the non-synchronous group. After the intervention, participants in the non-synchronous group felt closer to their peers and had a higher sense of belonging to the group, compared to participants in the synchronous group.

Conclusions: The preliminary results are inconsistent with findings among neurotypicals. We discuss the need to control for the number of perceived close friends within the group before the intervention since it might influence the outcomes. A mixed methods approach might enable an in-depth understanding of the quantitative results by incorporating the participants’ qualitative perspectives.

401.051 (Poster) Growing up with Autism: Perspectives from Emergent Adults with Autism on Quality of Life and Its Relation to Everyday Functioning

E. Øverland1,2, E. Pellicano3, A. L. Hauge4, E. W. Skogli5, S. Orm1, M. G. Øie6 and P. N. Andersen7, (1)Innlandet Hospital Trust, Lillehammer, Norway, (2)Inland Norway University of Applied Sciences, Lillehammer, Norway, (3)Macquarie School of Education, University College London, Sydney, NSW, United Kingdom, (4)University of Oslo. Oslo, Norway, (5)Department of Psychology, University of Oslo, Oslo, Norway, (6)Inland Norway University College of Applied Sciences, Lillehammer, Norway

Background:

Adults with autism seem to have a poorer Quality of Life (QoL) throughout their lifespan when compared to neurotypical adults, and when measured with instruments designed for the general population. However, there is no agreement on what constitutes a good QoL for people with autism. QoL may be perceived as something different for people with autism than for people in the general population, and hence traditional measures of QoL may not sufficiently tap into what QoL means for people with autism.

Objectives:

Given that oral, qualitative descriptions can capture richer, subjective experiences than questionnaire-based measures, we sought to understand how emerging adults with autism experience, describe and reflect on what constitutes a good Quality of Life from their own perspective. We examined particularly how perceived quality of life relates to participants’ everyday functioning.
Methods:

Participants were recruited from the Lillehammer Neurodevelopmental 10-year follow-up study (LINEUP) in Norway. Fourteen emerging adults with autism (3 female, 11 male) agreed to take part of in-depth, semi-structured interviews. They ranged in age from 21-29 years. The majority were students, some were employed part or full time, and a few did not have any organised daily activity. Most participants lived independently. We asked probing questions about their perceived Quality of Life and how they set out to achieve it.

We followed Braun and Clarke’s method for reflexive thematic analysis using an inductive (bottom-up) approach to identify patterned meanings within the dataset. The reflexiveness in thematic analysis brings in the awareness that we, as researchers, must be aware of our pre-existing assumptions, as we bring them to bear on the interpretation of the findings.

Conclusions:

Initial analysis suggests that, despite often-substantial challenging experiences during childhood and adolescence, the majority of our interviewees described having meaningful lives in emerging adulthood, particularly centered around participating in activities that captured their interests. Ongoing mismatches in communication between emerging adults with autism and professionals are one key barrier to achieving a good quality of life. Future research should seek to address this barrier for autistic adults at this particular stage of life.

401.052 (Poster) How Are Social-Emotional, Educational, and Vocational Outcomes Related to Structural Language in Autism Spectrum Disorder and Loss of Autism Diagnosis?

Background: Long-term outcomes in autism spectrum disorder (ASD) are heterogeneous, including individuals diagnosed with ASD in childhood who no longer meet criteria for ASD in adolescence or adulthood, referred to as “loss of autism diagnosis” (LAD; Charman et al., 2005; Fein et al, 2013; Pickles et al., 2020; Zachor & Ben-Itzhak, 2020). The current study examines associations between heterogeneity in structural language and long-term outcomes in ASD and LAD.

Objectives: Our pre-registered (https://osf.io/tzvpq) research questions (RQ) were: 1) How do social-emotional, educational, and occupational outcomes in adolescence and adulthood differ in ASD and LAD versus NT peers? 2) To what extent is structural language associated with outcomes in ASD and LAD versus NT peers?

Methods: Participants were adolescents and young adults with ASD (n = 24), LAD (n = 31), or NT (n = 32; Table 1). Social-emotional, educational, and vocational outcomes were measured using the Achenbach System of Empirically Based Assessment (ASEBA), Vineland Adaptive Behavior Scales 3rd edition, and online surveys (RQ1). Structural language was measured with the Clinical Evaluation of Language Fundamentals 5th edition, a grammaticality judgment task (structural language processing), and via parent report of early language milestones (age of first words/phrases; RQ2).

Results: Descriptive results (Table 1) indicate group differences in Socialization and Daily Living Skills. The ASD group had the lowest scores, the LAD group had intermediate scores, and the NT group had the highest scores (p’s < .05). Young adults with ASD had significantly higher ASEBA Total Problems scores relative to the LAD (p < .01) and NT (p < .01) groups, who did not differ significantly (p = .88). This evidence suggests greater challenges in social and adaptive functioning in ASD than in LAD or NT. Structural language skills were associated with ASEBA Anxiety/Depression for adolescents with ASD (p’s < .05; e.g., Figure 1), but not LAD or NT. The same was true for history of early language delay. This finding indicates that relatively better structural language and no history of early language delay were associated with relatively less anxiety and depression symptomology in ASD. Better structural language skills was also associated with lower ASEBA Withdrawn and Total Problems scores across ASD and LAD adolescents (p’s < .05). On-time language milestones was associated with full time student or employment status versus less than full time status across ASD and LAD young adults (p’s < .05), and with fewer supports in college courses for LAD young adults (p < .05). Relatively better structural language processing was associated with more working hours and fewer supports at work across ASD and LAD young adults (p’s < .05).
Conclusions: Findings suggest that current structural language skills and early language development have implications for long-term social-emotional, educational, and vocational outcome. Relatively better language skills may represent a protective factor in psychopathology symptoms and in participation in educational and vocational systems in ASD to a greater degree than in individuals with LAD and in NT peers.

401.053 (Poster) Strengths, Functioning and Support Needs from the Perspective of Autistic Adults in Australia
K. Evans1,2, M. Hayden-Evans3, B. Vinci4, A. Chamberlain14,5, E. D’Arcy6,7,8, A. J. Whitehouse5,9,10, S. J. Girdler11,12,13, S. Bolte3,5,14,15 and B. T. Milbourn16,17,18

Background:
An assessment of functioning is increasingly required for autism diagnosis, funding eligibility and support planning. According to the Australian guideline for autism assessment and diagnosis, a comprehensive assessment of functioning should identify activity and character strengths, functioning as defined in the International Classification of Functioning, Disability and Health (ICF), current supports and unmet needs.

Objectives: This study aimed to explore the self-reported strengths, functioning and support needs of Australian autistic adults.

Methods: Data collection was via an online cross-sectional survey that included fixed-response questions designed for this study (including a comprehensive ICF Core Sets for Autism measure) and a series of standardized measures. These included the Global Assessment of Character Strengths (GACS-24), World Health Organization Disability Assessment Schedule (WHODAS 2.0), and Craig Hospital Inventory of Environmental Factors (CHIEF). Data were analysed using descriptive statistics.

Results:
Thirty autistic adults provided data about their strengths, functioning and/or support needs. They ranged from 18 to 55 years old (median = 40), were predominantly female (n=23, with 4 males and 3 not identifying with either gender label) and did not report any cultural or linguistic diversity.

Strengths – Results from the ICF Core Sets for Autism measure showed the most frequently reported activity strengths were related to Learning and Applying Knowledge (followed by Major Life Areas and Mobility) and the strongest environmental resources were related to Products and Technology (followed by Support and Relationships and Services, Systems and Policies). According to the GACS-24, the highest character strengths were Fairness, Honesty and Love of Learning, and the most endorsed virtue was Wisdom.

Functioning – Results from the ICF Core Sets for Autism measure showed the most frequently reported impairments were associated with Mental Functions, activity limitations with General Tasks and Demands and participation restrictions with Interpersonal Interactions and Relationships. Based on the WHO-DAS 2.0, they experienced greater activity limitations and participation restrictions than more than 90% of the population, particularly with Getting Along with People and Life Activities. The ICF Core Sets for Autism measure scores suggest the greatest environmental barriers were in relation to Natural Environment and Human-Made Changes to Environment (followed by Attitudes and Services, Systems and Policies). According to the CHIEF, overall, they experienced mild to moderate environmental barriers across domains.

Support Needs – In response to questions designed for this study, the autistic adults provided information about 70 support needs (median = 4 per person). These were most frequently categorized as needing assistance with Social, Economic and Community Participation and Capacity Building. Of those who selected ‘other’, additional categories included support from family members, public mental health services and healthcare funding. Nearly one-third of the support needs were classified as high and over half of the support needs were...
described as moderate. On a sliding satisfaction scale (where 0% = not at all satisfied and 100% = completely satisfied), median satisfaction with current supports was 60%.

Conclusions: These results highlight a complex interplay between strengths, functioning and support needs that need to be considered during assessment, diagnosis and support planning.

401.054 (Poster) How Autistic Students Define Success: Getting Beyond Grades and Graduation
(1) Educational Leadership and Policy Studies, Florida State University, Tallahassee, FL, (2) NC State University, Madison, WI, (3) Department of Psychology, CUNY Graduate Center, Staten Island, NY, (4) University of North Carolina, Chapel Hill, NC, (5) University of Connecticut, Mansfield, CT, (6) Marquette University, Milwaukee, WI

Background: Much of the published research about college students with autism operates from an implicit deficit perspective, often describing these students as having poor postsecondary outcomes, particularly when compared to other student populations using traditional indicators of college achievement like GPA (e.g., McLeod et al., 2019) or degree completion (e.g., Newman et al., 2011). Many autistic students, however, have much broader definitions of college success. For example, autistic students have emphasized the desire for college to help them feel “like part of a community” and develop “the tools necessary to prepare for the workplace” (Autistic Self-Advocacy Network, 2020), outcomes which are largely overlooked by the empirical literature to date.

Objectives: Using data provided by autistic students themselves, our participatory research project is working to develop alternate definitions of college success for autistic students and identify key factors affecting these students’ ability to thrive while in college.

Methods: Our multi-institutional sample of US undergraduates is being recruited through partnerships with 1) postsecondary institutions hosting autism-specific support programs; 2) autism advocacy organizations; and 3) individual autistic self-advocates and allies, all of whom are working to maximize the participation of women and gender non-binary, racially minoritized, LGBTQ+, and community college students.

Data are collected using a survey instrument developed by a team of multidisciplinary scholars and practitioners, in consultation with an advisory board of autistic self-advocates, addressing five domains of autistic students’ lives: personal, social, psychological, academic, and professional. Participants articulate their personal definitions of college success through open-ended narratives and responses to a series of Likert-scale questions about the relative importance of 20 potential college outcomes. Analyses include group comparisons (e.g., t-tests, ANOVA), structural equation modeling (ESEM), and multi-level modeling (HLM). Results described in this abstract are drawn from basic descriptive analyses of early respondents. Data collection will continue throughout Fall 2022 and is expected to yield 175-225 students for the final analytic sample.

Results: More than 90% of respondents indicated that “having good mental health” was “somewhat” or “very” important to their definition college success. More than 80% endorsed the importance of getting a job in their area of interest and that allows them to be financially independent. Similar numbers highlighted the importance of being “comfortable with their identity as autistic” and “being part of a community of people like them.” In contrast, fewer than half of the students indicated that having a romantic relationship or joining a student organization was important. Overall, students ranked graduation as only the 6th most important indicator of success; getting good grades was tied for 12th on the list. As one student summarized, success means “to learn and achieve one’s intellectual goals without sacrificing health and happiness.”

Conclusions: While in college, autistic students’ highest priorities relate to maintaining mental health, getting a good job, and embracing their autistic identity individually and as part of a community. Therefore, we encourage researchers, practitioners, and policy makers to embrace a more holistic definition of college success that incorporates these goals alongside traditional measures like grades and graduation.

401.055 (Poster) I Am a Part of Something Bigger Than Me: Supporting and Measuring Authentic Autistic Engagement in a Multi-Site Comparative Effectiveness Trial for Suicide Prevention

Background: Autistic people have long supported authentic engagement in research through campaigns such as “Nothing about us without us.” However, few randomized controlled trials in autism research involve autistic people as study team members. Further, many studies involving autistic people do so in tokenistic ways. Major research funders have begun to recognize that research requires a paradigm shift towards authentic and meaningful involvement of autistic people in research. However, limited information exists about the use and impact of specific engagement approaches.
Objectives: This presentation describes preliminary engagement approaches and outcomes from Y1 of a 5-year multi-site comparative effectiveness research study on suicide prevention. This study includes autistic people in all aspects of the project, including study design, outcome measure selection and revision, clinician training program development, delivering the training, and data collection and analysis.

Methods: The RE-AIM framework was used to contextualize program evaluation of engagement approaches. Reach was quantified by representation of autistic people on study teams and rates of participation in study team meetings. Effectiveness was quantified by anonymous ratings of engagement by autistic and other collaborators on the psychometrically sound “Stakeholder-Centric Engagement Evaluation” (SCEE; Martinez et al., 2021). Adoption refers to autistic participation in decision-making via a co-developed process, and adoption by Principal Investigators (PI) of autistic input. Implementation refers to study staff reports of use of engagement strategies in the broader study context outside of the engagement team (not able to be measured in Y1), and Maintenance refers to long-term use of engagement skills by the research team (not able to be measured in Y1).

Results: Presentation of specific engagement approaches will be described, including the development of a Governance Document, decision-making process, and evaluation metrics in collaboration with our autistic members. Within the broad study team, 18 autistic people or care partners of autistic people are represented in 4 of 7 main core teams (Leadership; Training & Implementation; Stakeholder Engagement; Dissemination). Participation rates by autistic people in the Leadership meetings were >99%, Training & Implementation team meetings was >90%, and in Stakeholder Engagement team meetings was 91%. No Dissemination meetings have been scheduled so engagement has not yet occurred. Engagement ratings on the 23-item SCCE were positive overall (average of >4.5 on a scale of 1-5 on all but two items). Areas of improvement rated lower than average included “Streamline study communication” (M=4.29, range=2.5-5.0) and “Use multiple methods of communication for autistic partners to give input that fits communication preferences/needs” (M=4.40, range 2.0-5.0). Our decision-making process was felt to be useful, and autistic people felt comfortable using this process to disagree with proposed decisions, which ultimately resulted in PIs adoption of revision of outcome assessments, consent forms, and methods for sharing study outcomes.

Conclusions: Other research teams will benefit from the explicit guidance and recommendations learned from this study for supporting meaningful and authentic engagement of autistic research partners. Engagement can be measured, and the use of process and procedure documents was helpful for defining principles of engagement important to autistic partners.

401.056 (Poster) Identifying Work System Barriers and Facilitators to Quality Healthcare for Middle Aged and Older Autistic Adults

Background: Better understanding how the healthcare environment can best serve the needs of autistic adults is necessary in order to identify how to best support autistic adults’ health and healthcare access as they age. The Systems Engineering Initiative for Patient Safety (SEIPS) model of work system and patient safety provides a framework for understanding structures, processes, and outcomes and their relationships within healthcare environments. The SEIPS model depicts how specific work system structures (person, tasks, technology and tools, environment, and organization) interact to impact processes and outcomes and emphasizes the role of feedback from processes and outcomes to inform work system re-design. This model is particularly useful in providing a framework for identifying relevant elements within the healthcare work system that can be adapted to improve processes and outcomes.

Objectives: To use the SEIPS model to identify and describe work system characteristics that middle aged and older autistic adults specified as important barriers or facilitators to receiving quality healthcare.

Methods: We conducted a series of one-on-one interviews with middle aged and older autistic adults (N=15). Autistic adults were eligible to participate if they: (1) were age 35+; (2) had an administrative, professional, or suspected diagnosis of autism spectrum disorder; and (3) were able to communicate in English. Our second round of recruitment targeted adults who identify as BIPOC (Black, Indigenous, and people of color) and/or as transgender or nonbinary. Semi-structured interviews probed experiences with health and healthcare across four domains: (1) health habits; (2) health problems; (3) health services; and (4) autism and aging impact. Data were transcribed and analyzed using conventional content analysis. Transcripts were analyzed consecutively. Themes were identified in the text and aligned with components of the SEIPS model (person, organization, tasks, tools/technology, environment, care processes, and patient outcomes).

Results: Several themes that aligned with components of the SEIPS model were identified and repeated across the interviews with the autistic adults. Within the organization component for instance, barriers and facilitators that impacted their receipt of care included having informal and formal support, the length and strength of their relationships with healthcare providers, doctors' understanding and experience with autistic adults, as well as state and national healthcare policies and regulations. Many autistic adults noted that lights, noises, smells, and accessibility and layout of healthcare spaces impacted whether they would engage in work system tasks like visiting a healthcare provider when something is bothering them or accessing preventive care. Participants identified personal challenges, including sensory differences and executive functioning challenges that impacted their ability to communicate and advocate for their healthcare needs.

Conclusions: Through the SEIPS model of work system and patient safety, we described the interactions between middle aged and older autistic adults and their healthcare systems in order to identify points for improvement and intervention. Our model suggests that in order to
improve healthcare outcomes, interventions must target both personal factors such as challenges with executive functioning as well as organizational and environmental factors, such as doctors' training in autism or the physical accessibility of healthcare spaces.

401.057 (Poster) Impact of Executive Functioning and Enjoyment on Higher Education Success for Neurodivergent Students
L. J. Kennedy, A. L. Richdale, and L. P. Lawson, (1)La Trobe University, Clayton, Australia, (2)Olga Tennison Autism Research Centre, La Trobe University, Brisbane, QLD, AUSTRALIA, (3)Department of Psychology, Counselling & Therapy, La Trobe University, Melbourne, VIC, AUSTRALIA

Background:

More neurodivergent students are enrolling in higher education, but completion rates are reported as lower than neurotypical students. Most research focuses on autistic students attending university, however, other neurodivergent conditions (i.e., attention deficit/hyperactivity disorder, specific learning disorders, communication, tic, and developmental coordination disorders) remain understudied. Success in higher education has been linked to executive functioning (EF), mental health conditions and enjoyment for neurotypical students. EF has been found to affect academic success in autistic students, but it has not been investigated in other neurodivergent conditions. Understanding which factors affect success may enable more tailored supports for neurodivergent students, thus increasing retention and completion rates.

Objectives:

The aim of this study was to determine which factors contribute to higher education success for neurodivergent students, and whether this differed to neurotypical students.

Methods:

Neurodivergent ($n=131$, $M_{age}=31.34$) and Neurotypical ($n=73$, $M_{age}=33.16$) Australasian higher-education students (18-60 years, 70.4% female) completed an anonymous online survey, which captured diagnosis, enjoyment of higher-education experience, use of supports, academic success (defined as units completed in the previous term or semester: none, some or all), autistic traits (SRS2), ADHD traits (ASRSv1.1), executive functioning (EFI), self-efficacy (NSES), sensory sensitivities (GSQ), anxiety (GAD7), depression (PHQ9), wellbeing (WEMWBS), and social support (SSQ). Excluding missing data, the final sample for the following analyses included 89 Neurodivergent ($M_{age}=31.29$, 78.7% female) and 50 Neurotypical ($M_{age}=34.36$, 73.5% female) students. The study was designed with and informed by paid neurodivergent and lived experience advisors.

Results:

ANOVA, Kruskal-Wallis, Chi-square, and Fisher’s Exact analyses were used to identify significant potential predictors of success. EF and enjoying HE were significantly associated with success for neurodivergent students, while EF, sex-at-birth and accessing supports in HE were significantly associated with success for neurotypical students. For neurodivergent students, ordinal regressions showed that HE enjoyment was a significant predictor of success ($p = .008$) with an odds ratio of 4.13. An increase in EFI scores was also associated with an increase in success ($p = .004$), with an odds ratio of 1.08. For neurotypical students, EFI scores was the only significant unique predictor. Ordinal regressions showed that an increase in EFI scores was associated with an increase in success ($p = .033$), with an odds ratio of 1.10.

Conclusions:

The factors contributing to success in higher education differed for neurodivergent and neurotypical students. For neurodivergent students, enjoying the overall higher-education experience increased the odds of completing more units of study. Regardless of neurotype, higher executive functioning skills were associated with increased odds of completing more units. These results indicate that supports to improve executive functioning skills may be worthwhile for all higher education students. Additionally, for neurodivergent students, tailoring efforts to increase enjoyment of the higher-education experience may improve retention and completion rates.

401.058 (Poster) Impact of the COVID-19 Pandemic on Autistic Adults: A Scoping Review
A. M. Scheeren, L. Crane, E. Pellicano, and M. Heyworth, (1)Vrije Universiteit Amsterdam, Amsterdam, Netherlands, (2)Institute of Education, Centre for Research in Autism and Education, UCL Institute of Education, University College London, London, UNITED KINGDOM, (3)Macquarie School of Education, University College London, Sydney, NSW, United Kingdom, (4)Macquarie School of Education, Macquarie University, Sydney, NSW, Australia

Background: The COVID-19 pandemic and its associated restrictions have had a significant impact on people’s everyday lives, including the lives of Autistic adults. The pandemic may have had a negative effect on Autistic adults in particular (Pellicano & Stears, 2020), as this
group is at greater risk of experiencing mental health problems (Lai et al., 2019) and may depend significantly on (in)formal support from others.

Objectives: We aimed to a) synthesise all papers currently published on the impact of the COVID-19 pandemic on Autistic adults, and b) identify lessons for the care and support of Autistic adults in pandemic and post-pandemic times.

Methods: We searched for relevant empirical quantitative and qualitative studies in electronic databases (e.g., Pubmed) and autism-related journals using pre-specified search terms. During an initial search in May 2022, we identified 747 abstracts of which 105 were selected for a full paper read (98% inter-rater agreement). Of these 105 papers, 47 papers were found eligible (94% inter-rater agreement). During a second search in August 2022, we identified an additional eight eligible papers, yielding a final list of 55 studies (see Figure 1). We assessed the quality of studies using the Mixed Methods Appraisal Tool (MMAT; Hong et al., 2018).

Results: The 55 eligible papers were categorized as follows: 1) direct effects of the COVID-19 virus on Autistic adults including infection risk, hospitalisation, death, and vaccination rates (n=10); 2) effects of COVID-19 restrictive measures on care, support and services for Autistic adults (n=11); 3) COVID-19-related effects on the wellbeing of Autistic adults (n=32); and 4) other (n=2). Most studies took place in the US (n=13; 24%) and the UK (n=12; 22%), and most (n=34; 62%) collected data at least partly in the earliest phase (March-May 2020) of the pandemic. Many studies had a relatively poor methodological quality.

Together, the studies suggest that Autistic adults are likely to have been disproportionately impacted by the COVID-19 pandemic in several ways: (1) they were at increased risk of contracting COVID-19 and experiencing serious health threats as a result; (2) they often struggled to access critical services and supports as a result of stay-at-home restrictions; and (3) despite some positive uplift due to reduced external pressures to adapt to ‘neurotypical’ norms, many experienced challenges to their mental health – particularly those with pre-existing mental health issues and limited social support.

Conclusions: Study findings are consistent with the pandemic’s detrimental effects on disabled people more broadly, also referred to as the “triple jeopardy” (Shakespeare et al., 2021). Moreover, our review likely underestimates the negative impact of COVID-19 on Autistic adults, since most reviewed studies focused on speaking Autistic adults in high-income countries. Few studies reported actively including Autistic adults or their allies in the research process. Actively involving the Autistic community in research will ensure that future research, clinical services and care are aligned with the needs and priorities of Autistic people.

401.059 (Poster) Measurement of Emotion Reactivity and Emotion Regulation in Autistic Adults: A Systematic Review
M. Fok and A. Scarpa, Department of Psychology, Virginia Tech, Blacksburg, VA

Background:
Emotion reactivity and regulation underlie the psychopathological processes experienced by autistic adults (AA) but there is limited research in how emotion reactivity and regulation are described in AA. Weiss et al. (2014) reviewed emotion regulation in autistic youth and identified a variety of physiological measures used but did not focus on adults. Additionally, no systematic review has been conducted in emotion reactivity in AA. Given the methodological heterogeneity, a systematic review of the extant literature of emotion reactivity and regulation in AA is warranted.

Objectives:
We conducted a systematic review of studies that examined emotion reactivity and regulation in AA and reported findings across four levels of analysis according to the NIH research domain criteria to depict current understanding and directions for future research.

Methods:
The existing literature was systematically searched for peer-reviewed publications that measured emotion reactivity and/or regulation in a sample of AA up to March2022 (Figure1). Reactivity refers to the frequency/intensity/duration of an emotional response and regulation as the modification or maintenance of an emotional response.

Results:
Across the 24 included studies, 16 examined only reactivity, six examined only regulation, and two examined both reactivity and regulation. The 18 studies that measured reactivity, physiology was the most common level of analysis (Table 1); however, there was a variety of seven different physiological methodologies represented with skin conductance response as the most used method. Examination of circuitry of reactivity almost always consisted of fMRI techniques to measure activation in the frontal, occipital, and temporal lobes and
Amygdala. Of the eight studies of regulation, seven relied on self-report questionnaires and one study solely examined the patterns of brain activation and pupillometry (Table 1). Reactivity to negative emotion was studied more often than positive emotion and consisted of more specific negative emotions (fear/threat, anger, sad, aggressive, explicit, unpleasant) whereas studies that looked at positive emotion were limited to depictions of happy, pleasant, or positive. For the studies that utilized a laboratory paradigm to measure reactivity and regulation, the most common set of emotional stimuli used, mostly of facial expressions, were from the NimStim database compared to the other reported databases (Pictures of Facial Affect, Karolinska Emotional Faces, IAPS). The most commonly used self-report measure for reactivity was the Self-Assessment Manikin (Bradley & Lang, 1994) and for regulation was the Emotion Regulation Questionnaire (Gross & John, 2003). Behavior was measured rarely in reactivity and not at all in studies of regulation.

Conclusions:

AA demonstrated differences in reactivity at the circuitry and physiological levels when compared to non-AA but their differences do not represent a consistent pattern of deficits given the variety of different emotional paradigms used. For regulation, AA reported using more maladaptive strategies compared to non-AA, but these effects were not examined thoroughly at the other levels of analysis. Study design heterogeneity limits ability to infer how emotion reactivity and regulation are described in AA. Considerations for future studies include establishing standard methodological procedures across multiple levels of analysis (especially for emotion regulation) and exploring negative and positive emotions together.

401.060 (Poster) Internalized Stigma Moderates the Relations between Social Camouflaging and Self-Reported Anxiety and Depression in Autistic Adults

M. Waite, T. Q. Boucher, N. E. Scheeren, V. Ly, P. Hood, H. Aime, and G. Iarocci, (1)Psychology, Simon Fraser University, Burnaby, BC, Canada, (2)Psychology, Wilfrid Laurier University, Waterloo, ON, Canada

Background: Autistic adults are at an elevated risk for experiencing mental health difficulties and social exclusion (Mitchell et al., 2021). Autism is a stigmatized social identity and internalizing this stigma has been demonstrated to negatively impact autistic adults’ mental health (Han et al., 2022). One response to this internalized stigma and its associated consequences is concealing one’s autistic traits, termed social camouflaging. Applying Social Identity Theory, social camouflaging may act as an individualistic strategy to alleviate the negative effects of stigma through allowing individuals to distance themselves from their social identity (Tajfel & Turner, 2004). However, previous research has established that social camouflaging may also negatively impact autistic adults’ mental health (Bradley et al., 2021). Therefore, further examining how internalized stigma and social camouflaging together are related to the mental health of autistic adults is of interest.

Objectives: Examine relations between internalized stigma, social camouflaging, and mental health in autistic adults.

Methods: 60 autistic adults (8 male, 33 female, 19 nonbinary/two-spirit/Agender/gender-diverse) ages 18 to 67 (M=36.10, SD=11.46) participated in this study online. Participants completed the Autism Spectrum Quotient (AQ) as a measure of autistic traits, the Internalized Stigma of Mental Illness (ISM-10) as a measure of internalized stigma, and the Camouflaging Autistic Traits Questionnaire (CAT-Q) as a measure of social camouflaging. Additionally, three measures of mental health were completed, the Anxiety Scale for Autism-Adults (ASA-A), the depression subscale of the Depression, Anxiety and Stress Scale (DASS-21), and the Suicide Behaviours Questionnaire-Revised (SBQ-R).

Results: To examine relations between internalized stigma, social camouflaging, and mental health, separate hierarchical regression analyses were conducted for each mental health measure. Participants’ AQ scores, gender, and age were controlled in Block 1, centered internalized stigma and social camouflaging scores were entered in Block 2, and a two-way interaction term between internalized stigma and social camouflaging was entered in Block 3. Internalized stigma and social camouflaging accounted for 38% of the variance in anxiety (F(2,54)=20.13, p<.001), 10% of the variance in depression (F(2,54)=3.56, p=.035), and an insignificant portion of variance in suicidal behaviour (F(2,54)=2.23, p=.117). The interaction term accounted for 14% of the variance in anxiety (F(1,53)=20.41, p<.001) and 5% of the variance in depression (F(1,53)=4.02, p=.050), such that social camouflaging was positively associated with anxiety and depression only for participants with no-to-mild internalized stigma, and not for participants with moderate-to-severe internalized stigma.

Conclusions: Internalized stigma and social camouflaging were found to be significant predictors of anxiety and depression, but not suicidal behaviours. Relations between social camouflaging and both anxiety and depression varied by severity of internalized stigma. These results may suggest that social camouflaging does not negatively impact the mental health of autistic adults with more severe internalized stigma; however, camouflaging may be distressing for those who hold a less stigmatized view of their autistic identity. A limitation to the generalizability of these findings is that females were overrepresented in the sample. Better understanding relations between internalized stigma, social camouflaging, and mental health is important as autistic adults commonly experience social exclusion and mental health issues.

Background: Autism has long been viewed as a paediatric condition, resulting in a ‘lost generation’ of autistic adults who were not diagnosed as children. Diagnosis is a critical element on the pathway to good healthcare for autistic people. Community prevalence surveys in the UK and Sweden suggest that the true rate of autism has been stable for the past 70 – 80 years, implying that recent higher rates of diagnoses in younger people reflect better autism awareness/ access to assessments.

Objectives: We aimed to estimate numbers of diagnosed and undiagnosed autistic people in the UK, and explore age-related inequalities in access to diagnostic assessments. We did this by comparing the prevalence of diagnosed autism within the database across different age groups to estimates of community prevalence, derived from published surveys and also from the rate of diagnosed autism in the database for children and young people, who have had better access to diagnostic assessments compared to older generations. We also examined how diagnostic rates in the UK differed in relation to socio-demographic factors between 2000 and 2018.

Methods: This was a population-based cohort study of prospectively-collected UK primary care data from the IQVIA medical research database. 1,840,036 individuals registered at a primary care practice in 2018 and 8,292,873 individuals registered between 2000 and 2018 were included.

Results: As of 2018, 0.74% of people in the database were diagnosed autistic: 1.15% of males and 0.33% of females. Diagnostic rates were higher in children/young people vs. adults and older adults: 2.84% of 10- to14-year-olds were diagnosed (1 in 35), vs. 0.02% aged 70+ years (1 in 5,000). As of 2018, an estimated 526,700 people (0.79% of the UK population) were diagnosed autistic, and an estimated
Conclusions: Major age-related inequalities in autism diagnoses persist in the UK. Even conservative estimates of true autism prevalence suggest that at least nine out of 10 autistic people aged 50+ in the UK are undiagnosed. A step-change in access to diagnostic services is needed to reduce health inequalities experienced by autistic adults due to underdiagnosis.

401.063 (Poster) Language and Intellectual Ability Profiles in Autistic Adults: A Clinical Database Study
L. Tuller, A. Yildiz, F. Briand, E. Houy-Durand, M. Manenti, S. Morel-Kohlmeyer, D. Wobrock and P. Prévost, (1)UMR iBrain 1253, Inserm, University of Tours, Tours, France, (2)CNRS/Université Sorbonne-Nouvelle, Paris, France, (3)UMR 1253, iBrain, Université de Tours, Inserm, Tours, France, (4)Exac-T, Centre universitaire de pédopsychiatrie, CHRU de Tours, Tours, France, (5)Imagery & Brain (iBrain) UMR 1253, Université de Tours, Inserm, Tours, France

Background: The ICD-11 classification for autism proposes five codes for application of specifiers for Co-occurring "Disorder of Intellectual Development" (DID) and "Degree of Functional Language Impairment" (LI): four categories resulting from crossing these two specifiers and a fifth category for individuals with no/almost no functional language, who also have DID (WHO, 2022). While characterization of these categories has been documented for children (Silleresi et al., 2020), little research has been devoted to investigation of language and intellectual ability profiles in adults (Bradshaw et al., 2020). The robustness of this classification for adults remains an open question. This question deserves study as part of efforts to document adult autism profiles, but also because there is evidence for significant language "catch-up" in autism (Magiati et al., 2014; Howlin et al., 2014), and that LI, with or without ASD, may contribute to lowered nonverbal intelligence quotients (NVIQ) over time (Gallinat & Spaulding, 2014; Botting, 2005; Conti-Ramsden et al. 2012; Luyster et al., 2007; Simonoff et al., 2021), suggesting that language/intellectual ability profiles could be markedly different in autistic adults compared to children. Generally, links between nonlinguistic cognition and language in autism are in need of clarification (Lewis et al., 2008).

Objectives: To explore whether ICD-11 language/intellectual ability profiles are observable in autistic adults and what their prevalence is.

Methods: Adults with an ASD diagnosis, and no conditions associated with language/cognitive impairment, drawn from a university hospital patient database were considered for inclusion. We retained those for whom there were language assessment results (two scales providing Expressive language and Receptive language scores) and intellectual ability assessment results (from a general cognitive scale for all, and, for most, a standard nonverbal test): 241 individuals, ages 18 to 58 (M=29yrs, SD=10). Autism symptomatology was explored via ADI-R subscales and via two ordinal clinical severity scales (Hameury et al., 1995). Language and intellectual ability profiles were identified via K-means clustering, compared for autism symptomatology, and validated using Rand Index metric and Random Forest classification.

Results: Three K-means cluster analyses using language measures and a measure of intellectual ability performed over the entire group of 241 individuals based on a measure of general intellectual development, a subgroup of 92 individuals for whom there was an available NVIQ, and a subgroup of 89 individual for whom there was an available nonverbal developmental age, returned clusters corresponding to ICD-11 homogenous categories (both DID and LI/absence of language or neither), but just one heterogeneous category, with DID and with mild or no LI. Missing was a without-DID-and-with-LI cluster. Hand inspection revealed five such individuals (2% of sample). Measures of autism symptomatology failed to distinguish most clusters from each other.

Conclusions: Language/intellectual ability profiles in autistic adults appear to differ from those found in autistic children. Notably, a common profile in autistic children, absence of DID with presence of LI, the profile of Developmental Language Disorder, was found to be extremely marginal in adults, possibly due to language catch-up, but also to NVIQ lowering in the presence of significant LI.

401.064 (Poster) Life Outcomes and Quality of Life in the Maudsley Cohort, a Longitudinal Follow-up
D. Mason, Social, Genetic and Developmental Psychiatry Centre, Institute of Psychiatry, Psychology and Neuroscience, King’s College London, London, United Kingdom

Background: A number of studies have reported poor objective outcomes (typically a composite rating made up of employment, living status, and social relationships) for cohorts of autistic adults. Typically, higher IQ and fewer autism characteristics are common predictors of having a better outcome.

Objectives: To investigate the objective and subjective life outcomes (i.e., quality of life) in the Maudsley cohort (a cohort of autistic individuals originally diagnosed as autistic children in the 1950s, 1960s, and 1970s).

Methods: This study employs a mixed methods approach. Autistic participants completed the ADOS, WAIS-4, and multiple self-report measures (including mental health and quality of life). Relatives of autistic participants completed the Family History Schedule, Vineland
Adaptive Behaviour Scales, and the current items on the ADI-R. A subset of the autistic participants in this sample were recruited to an interview study, in order to explore their experiences of ageing and how they have changed over time.

Results: Preliminary analyses suggest that the objective outcomes of autistic adults are comparable to previous studies using this measure. Specifically, 17.1% of participants were rated as having a good or very good outcome, 24.1% were rated as having a fair outcome and 58.8% were rated as having a poor or very poor outcome. Qualitative data however, such that – of those interviewed – life had become better over the lifespan. Specifically, many had found fulfilling work and had accepted their differences.

Conclusions: Objective life status in this cohort may not be comparable to normative goals, however, autistic people thought that, often, their ageing trajectory had been positive and reported a strong sense of positive autistic identity.

401.066 (Poster) Analysis of State Records to Characterize Frequencies of State Identification, Voting, Marriage, and Child Birth Among Autistic Adults

A. V. Kirby1, A. V. Bakian1, D. A. Bilder2 and W. M. McMahon3, (1)University of Utah College of Health, Salt Lake City, UT, (2)Psychiatry, University of Utah, Salt Lake City, UT

Background: Studies of outcomes for autistic adults have focused primarily on employment and living arrangements, with less known about other important aspects of autistic adult life participation. However, available evidence indicates that autistic adults are often not satisfied with their level of community participation and social roles. State-level administrative data offer opportunities to understand autistic adult participation in certain meaningful activities in adulthood.

Objectives: In this study, we accessed state administrative data on autistic adults and matched comparisons to examine participation in receiving a form of state identification, voting, marriage, and parenting children.

Methods: We conducted secondary data analysis with state-level data in the U.S. state Utah. Secure linkages were performed with state administrative records to the Utah Registry of Autism and Developmental Disabilities to identify autistic adults. For this analysis, we accessed data on N=9,560 autistic adults born between 1920 and 2005, and who were subsequently each age- and sex-matched to three non-autistic residents (N=28,624). To compare autistic adults to the other state residents, we calculated counts, percentages, and 95% confidence intervals for receipt of state identification (driver’s license or other state ID), voting participation, marriage and divorce/separation, and parenting a child born in Utah (i.e., a child born with the individual listed as one of the parents on the birth certificate). We also analyzed the number of children, range, mean, standard deviation, and 95% confidence intervals between autistic adults and comparisons who had parented children.

Results: The autistic group was 76.9% male, with a mean (standard deviation) age of 24.28 (9.82) years. The non-autistic comparison group was also 76.9% male, with a mean (standard deviation) age of 24.33 (9.90) years. Just over half of autistic adults had a form of state identification, compared with over 90% of the non-autistic adults. Voting participation was low in both groups, with autistic adults slightly but significantly less likely to vote (see Table 1). Autistic adults were also significantly less likely to have ever been married (3.8% vs. 13.9%) and to have children (3.9% vs. 19.1%), but slightly more likely to have been divorced (0.9% vs. 0.4%). Autistic adults who had been a parent had fewer than 2 children on average, compared with over two in the comparison group.

Conclusions: Rates of state identification were substantially lower among autistic than non-autistic adults. Holding a valid form of identification can be important for various kinds of participation in the community such as attending events or traveling; thus, these findings suggest a need for concerted efforts to support autistic youth and adults to acquire an official form of ID. Rates of voting, marriage, and parenting children were all also lower in the autistic than comparison group—autistic adults interested in these pursuits may require additional support and resources. Finally, it was notable that more autistic adults had been through divorce; this may signal a need for tailored relationship support for autistic adults and couples. There may also be a need for tailored supports for autistic adults navigating divorce.

401.067 (Poster) Diagnostic Associations with Suicide Death: A U.S. Statewide Analysis of Mental and Physical Health Conditions Among Autistic People Who Died By Suicide

A. V. Kirby1, A. V. Bakian1, D. A. Bilder2, B. Keeshin3 and H. Coon4, (1)University of Utah College of Health, Salt Lake City, UT, (2)Psychiatry, University of Utah, Salt Lake City, UT, (3)University of Utah, Salt Lake City, UT, (4)Intermountain Healthcare, Salt Lake City, UT

Background: A growing body of research indicates that autistic individuals are at higher risk for death by suicide than the general population. Suicide is known to be highly associated with mental health conditions such as anxiety, bipolar disorder, depression, personality disorders, psychosis, and substance abuse; studies also point to numerous physical health conditions (e.g., asthma, brain injury, cancer, diabetes, epilepsy, and pain conditions) associated with higher rates of suicide. However, less is known about co-occurring risk of suicide among autistic people with co-occurring mental and physical conditions.
Objectives: The current study is an investigation of co-occurring conditions observed among autistic individuals who died by suicide in one U.S. state.

Methods: Secondary data analysis was conducted with state-level data in Utah. Secure linkages were performed to match medical billing data (i.e., ICD-9 and ICD-10 codes) to a statewide database of individuals determined by the state medical examiner to have died by suicide. Billing data was provided from the two largest healthcare systems in Utah (covering >85% of the state) as well as from the Utah Population Database, which houses all inpatient codes from hospitals throughout the state. An additional linkage was performed to a statewide database of individuals classified as autistic (the Utah Registry of Autism and Developmental Disabilities). Analyses included descriptive statistics and chi-squared tests to compare autistic people who died by suicide to other suicide decedents, as well as examining sex differences in the autistic group.

Results: We accessed billing codes for 7,284 individuals who died by suicide in Utah between 1998-2017: 47 autistic individuals (i.e., autistic suicide decedents) and 7,237 other individuals (i.e., non-autistic suicide decedents); see Table 1. Autistic suicide decedents were significantly more likely than non-autistic suicide decedents to have received codes for depression, anxiety, substance abuse problems, bipolar or cyclical mood disorders, sleep disorders, attention-deficit or impulsivity conditions, psychosis, personality disorders, post-traumatic stress, and obsessive-compulsive disorder. Autistic decedents were also more likely to have had documented asthma, epilepsy/seizures, obesity, and pain codes. No significant differences were identified for autoimmune disorders, cancer, diabetes, eating disorders, gastrointestinal symptoms, or brain injury. Autistic women who died by suicide were significantly more likely than their male counterparts to have anxiety, post-traumatic stress, psychosis, and personality disorders.

Conclusions: Depression and anxiety were the most common co-occurring conditions coded in medical records of autistic individuals who died by suicide. Results indicated that these and other mental and physical health conditions were more common among autistic decedents than among other people who died by suicide in Utah. The reported frequencies of many of the examined conditions were also significantly higher in the autistic decedents than reported in U.S. ICD-code based studies of conditions co-occurring with autism. Co-occurring conditions should be considered along with other suicide risk factors to understand autistic community risk and potential prevention needs. These preliminary findings suggest that both mental and physical health conditions should be considered in future studies, and in the development of suicide risk assessments and prevention approaches for autistic individuals.

401.068 (Poster) Do Autistic Traits Affect Creativity in College Students?
J. Joseph and J. L. Frymiare, (1)Ursinus College, Collegeville, PA, (2)Ursinus College, Collegeville, PA

Background: There is a widespread belief that autistic individuals are not creative. The Autism-Spectrum Quotient, a common measure of autistic traits, even includes an imagination subscale. However, autistic traits may be associated with divergent thinking, a component of creativity. Creativity and the autism spectrum is a relatively unexplored topic.

Objectives: The current study investigated whether college students with high levels of autistic traits differed from college students with low levels of autistic traits in creative problem solving or self-reported creativity.

Methods: Seventy-four college students (M = 19.7 years, SD = 1.4) completed the Remote Associates Test (RAT). For each of 125 problems, participants were given three words (e.g., pine, crab, sauce) and asked to come up with a single word (e.g., apple) that creates a compound word or common phrase with each of the provided words (e.g., pineapple, crab apple, applesauce). If participants solved a problem within the 30-second time limit, they were asked if the solved the problem with insight (i.e., an aha! experience) or without insight. Afterwards, participants completed the Creative Achievement Questionnaire (CAQ) to assess creativity achievement in 10 domains (visual arts, music, creative writing, dance, drama, architecture, humor, scientific discovery, invention, and culinary) and the Autism-Spectrum Quotient to assess level of autistic traits. Participants were divided into low and high autistic trait groups using a median split on the AQ.

Results: Insight solutions were more accurate (F(1, 69) = 69.53, p < .001) and faster (F(1, 69) = 28.66, p < .001) than non-insight solutions. Participants with high levels of autistic traits tended to be more accurate than participants with low levels of autistic traits (F(1, 69) = 3.46, p = .07); however there was no difference between participants with high and low autistic traits in reaction time (F(1, 69) = 0.11, p = .74). Type of solution (insight or noninsight) did not interact with level of autistic traits for either accuracy (F(1, 69) = 0.14, p = .71) or reaction time (F(1, 69) = 0.01, p = .92). Furthermore, autistic trait groups did not differ in the percentage of problems solved (t(72) = 0.75, p = .46) or the percentage of problems solved with insight (t(72) = -0.19, p = .85) on the RAT. Finally, autistic trait groups did not differ in total CAQ scores (t(72) = 0.66, p = .51) or any of the individual domains (all ps > .10). Similarly, total AQ scores were not correlated with total CAQ scores (r(72) = -0.02, p = .90). Only the imagination subscale of the AQ showed a marginal correlation with CAQ scores (r(72) = -0.22, p = .06).

Conclusions: College students with higher levels of autistic traits did not differ from college students with lower levels of autistic traits in two measures of creativity: a creative problem-solving task, and self-reported creativity across multiple domains. While these findings need to be replicated with a more representative sample and in autistic people, they suggest autistic traits are unrelated to creativity.
Background: Extensive research has been conducted regarding implicit and explicit attitudes for gender and race. Recent research has considered implicit and explicit attitudes towards disability; however, the focus has been on visible disabilities such as physical disabilities. Very few studies have considered implicit and explicit attitudes towards the autism spectrum.

Objectives: The current study investigated implicit and explicit attitudes toward the autism spectrum in adults. Furthermore, the study assessed whether contact with individuals on the autism spectrum, autistic traits, and self-identifying as autistic are related to implicit and explicit attitudes.

Methods: Four hundred sixteen adults (M = 42.3 years, SD = 14.1) were recruited from Amazon Mechanical Turk. The majority of participants were non-autistic (94.5%). Participants completed the Implicit Association Test (IAT) where they sorted good and bad words and/or autism-related and non-autism related words. This task detects the strength of the automatic association between the autism spectrum and good or bad. Afterwards, participants completed an adapted version of the Societal Attitudes Towards Autism Scale (SATA), a measure of explicit attitudes toward the autism spectrum. Participants also completed a brief questionnaire about their contact with individuals on the autism spectrum and the Autism-Spectrum Quotient (AQ), a measure of autistic traits.

Results: Participants had a significant implicit bias (M = -0.27, SD = 0.50) against the autism spectrum, (t(416) = -10.9, p < .001, d = -0.53). Implicit attitudes were positively associated with contact with individuals on the autism spectrum (r(414) = .25, p < .001), but not autistic traits (r(414) = .06, p = .21) or explicit attitudes (r(414) = -.05, p = .30). Implicit attitudes were negatively associated with age (r(414) = -.20, p < .001). An exploratory analysis revealed that participants who self-identified as autistic had significantly more positive implicit attitudes toward the autism spectrum than participants who identified as non-autistic (t(364) = 4.90, p < .001, d = 1.13). Participants who self-identified as autistic had more contact with individuals on the autism spectrum (t(364) = 7.50, p < .001, d = 2.06) and more negative explicit attitudes toward the autism spectrum (t(362) = 2.55, p = .01, d = 0.59).

Conclusions: Overall, adults have an implicit bias against the autism spectrum and non-autistic adults have a more negative implicit bias than autistic adults. Implicit attitudes are unrelated to explicit attitudes, suggesting that conscious and unconscious attitudes toward the autism spectrum are independent. Furthermore, non-autistic adults have more positive explicit attitudes than autistic adults, suggesting social desirability may affect explicit attitudes of non-autistic adults. Greater contact with individuals on the autism spectrum is associated with more positive implicit attitudes towards the autism spectrum. Future research should consider more direct tests of how contact with autistic individuals may affect implicit attitudes. Finally, age is negatively associated with implicit bias, suggesting that younger participants may have more positive implicit attitudes toward the autism spectrum. This may reflect minor improvements in implicit attitudes across generations. These results highlight the need to confront unconscious attitudes as a source of ableism.

Objectives: The current study investigated camouflaging behaviors in a sample of college students and the general population. More specifically, we explored the relationship between autistic traits, camouflaging behavior, and cognitive style.

Methods: Fifty-one undergraduate students between ages 18 and 22 years (M = 19.1, SD = 1.1) were recruited from a small, east coast liberal arts college and 105 adults between 18 and 28 years were recruited from Amazon Mechanical Turk (M = 24.6, SD = 1.9). Approximately 5% of participants self-identified as autistic (undergraduates: 5.6%; Mechanical Turk: 5.7%). All participants completed the Cognitive Reflection Test (CRT). The seven-item multiple-choice CRT comprised math word problems involving arithmetic and supposedly easy to manipulate numbers with four possible solutions: a primed intuitive answer, a mathematically correct answer, and two answers indicative of a failure to correctly determine how to frame and solve the problem. Reflectiveness and intuitiveness scores indicate the number of correct reflective responses and incorrect intuitive responses, respectively. Participants also completed the Camouflaging Autistic Traits Questionnaire (CAT-Q). The CAT-Q is a 25-item Likert-scored (5 reverse scored) self-report of camouflaging behaviors based on the masking, assimilation, and compensation strategies autistic people reported as methods for camouflaging their autistic characteristics. Finally, participants completed either the Broad Autism Phenotype Questionnaire (BAPQ) or the Autism-Spectrum Quotient (AQ) to assess autistic traits.

Results: Autistic traits were significantly positively correlated with camouflaging behaviors in both the undergraduate (r(49) = .68, p < .001) and Mechanical Turk (r(103) = .45, p < .001) samples. Specifically, autistic traits were positively correlated with masking behaviors in the undergraduate sample (r(49) = .38, p = .006), but not the Mechanical Turk sample (r(103) = .01, p = .33). Autistic traits were also
correlated with assimilation (undergraduate: r(49) = .79, p < .001; Mechanical Turk: r(103) = .72, p < .001) and compensation (undergraduate: r(49) = .52, p < .001; r(103) = .31, p = .001) behaviors in both samples. In the undergraduate sample, autistic traits were positively associated with reflective responses (r(49) = .36, p = .009), but not intuitive responses (r(49) = -.05, p = .73). Camouflaging behaviors also tended to be positively associated with reflective responses (r(49) = .27, p = .05), but not intuitive responses (r(49) = .02, p = .89). In the Mechanical Turk sample, neither autistic traits nor camouflaging behaviors were correlated with reflective or intuitive responses (all ps > .30).

Conclusions: People with greater autistic traits exhibit greater degrees of camouflaging behavior, including masking, assimilation, and compensation behaviors. The association between cognitive reflection, autistic traits and camouflaging behavior was mixed, warranting further investigation.

401.071 (Poster) How Do Autistic People Fare in Adult Life and Can We Predict It from Childhood?

Background:

Young autistic adults face variable but often substantial challenges in adult life. Understanding childhood predictors of outcomes in adulthood is important as to set expectations for autistic people and their families, inform theory of developmental mechanisms, and identify new areas for intervention. With a few exceptions, existing studies on outcomes in adulthood for autistic people have not sought representative samples, limiting the generalisability of their findings. In this work we report on outcomes in adulthood from the Special Needs and Autism Project (SNAP), an influential cohort formed by screening all children living in a particular area with an autism diagnosis or judged to be at risk of autism and conducting diagnostic interviews on a stratified sample.

Objectives:

The aim of this study is to describe parent report social, mental health, and quality of life outcomes in adulthood and examine childhood predictors in SNAP, a longitudinal population-based cohort and to place these findings in the context of the general population and other studies of autistic adults.

Methods:

Autistic children were enrolled at age 12 and parents reported outcomes 11 years later when their children were age 23 (n = 121). Regression analysis were carried out to identify childhood predictors of outcomes.

Results:

Thirty six percent of autistic adults were in competitive employment or education and 54% had frequent contact with friends. Only 5% of autistic adults were living independently, and 37% required overnight care. Moderate or severe anxiety and depression symptoms were found for 11% and 12% of young adults, respectively. Subjective quality of life was similar to UK national average except for social relationships. Using childhood IQ, autism traits and adaptive functioning, meaningful predictions can be made of living situation, employment and education and physical health. Prediction was poor for friendship, mental health outcomes and other aspects of quality of life.

Conclusions:

Young autistic adults are less likely than the general population to live independently, be in employment, have close friendships and may have worse physical and social quality of life. Previous studies of normative social outcomes may however have overstated the challenges
autistic adults face in these areas. Participants in this cohort also were reported to have better mental health and quality of life than had been found in previous studies.

Good prediction from childhood is possible for living situation and employment and education and this may support targeted intervention in these areas. IQ, autism traits and adaptive functioning are most useful for predicting outcomes. After accounting for these factors, childhood measurements of behavioral and emotional problems and language offered little improvement in prediction of adult outcomes. For mental health or quality of life we found prediction from childhood to be much more challenging. For these outcomes our findings suggest that it is inappropriate to set expectations as to what outcomes may be in adulthood, that good outcomes may be possible for autistic people regardless of their childhood characteristics, and that interventions to support those with difficulties in these outcomes should be available for all.

401.072 (Poster) Developing Prediction Models for Outcomes in Adolescence and Adulthood for Autistic Children

G. Forbes, O. Pearson, L. Horvath, V. Carter Leno, E. Simonoff and A. Pickles, (1)Institute of Psychiatry, Psychology and Neuroscience, King’s College London, London, United Kingdom, (2)Institute of Psychiatry, Psychology and Neuroscience, King’s College London, London, UNITED KINGDOM, (3)Institute of Psychiatry, Psychology and Neuroscience, Institute of Psychiatry, London, United Kingdom

Background:

There is considerable variability in outcomes for autistic children in adolescence and adulthood, with some autistic people having high support needs or experiencing poor mental health, or lower quality of life. Across these different aspects of life there is more or less certainty in outcomes. To date longitudinal studies have identified predictors of outcomes, however it is extremely challenging to translate knowledge of predictors into individual level predictions for a particular autistic child. A solution to this problem is to create statistical models that provide individual level prediction. Prediction models however, require greater sample sizes than models for statistical inference, and these sample sizes are larger than are available in any single existing longitudinal study. We propose to combine data from cohorts of autistic people and general population cohorts with large autistic sub-populations and conduct an individual participant data (IPD) meta-analysis to develop prediction models. We will present findings from a systematic review to identify longitudinal studies of autistic people, descriptive data of the identified samples, and the protocol for the development of the prediction models

Objectives:

The objective of the systematic review was to identify longitudinal studies of autistic people that contain data that can be used for the development of prediction models for outcomes in adolescence and adulthood.

Methods:

We conducted a systematic review of the literature (PROSPERO registration CRD42021286449). We searched MEDLINE, EMBASE, PsycINFO and Web of Science. Eligible studies have more than 50 autistic participants with at least 2 years of follow up, and an initial assessment prior to age 14. Studies must include assessments of either behavioral and emotional problems in adolescence or one of a broad range of outcomes in adulthood (eg. living situation, employment or education, mental health outcomes, quality of life). Risk of Bias assessments are conducted using the PROBAST risk of bias tool, specifically developed for prediction modelling meta-analysis.

Results:

Twenty two longitudinal studies were identified that meet the eligibility criteria with a total eligible sample size over 3000. If combined, the studies would include over 400 females (16%). Across studies with available IQ data, mean IQ is 77. Further details of identified studies will be presented, including risk of bias assessments and key findings alongside the proposed methodology for the development of prediction models.

Conclusions:

We have identified a rich collection of longitudinal studies that together can be used to develop prediction models which may be applied directly in clinical practice. Combining datasets will create the largest dataset to date which follow autistic children into adulthood. As well as improved sample size, combining data sets allows the generalizability of models developed to be assessed by considering variation in model performance across the different samples included. The large sample size will also allow differences in outcomes in under-represented groups to be fully examined. This rich resource may go on to be used to interrogate developmental mechanisms and answer questions of direct clinical relevance.

401.073 (Poster) Gender Affirmation, Regardless of Level of Autistic Traits, Predicts Lower Mental Health Distress in Gender-Diverse and Transgender Adults
Background: Somewhere between 4.8% and 26% of adults presenting to gender dysphoria clinics have an autism diagnosis and some studies have shown that there are elevated rates of autistic traits in those who are gender diverse. Both autistic and gender-diverse people have higher rates of mental health conditions including anxiety and depression and are more likely than the general population to experience suicidal ideation and to attempt to die by suicide. This double burden puts gender-diverse autistic people at high risk for developing intense mental health concerns that negatively impact their quality of life. Some work suggests that gender affirmation leads to better mental health outcomes, but this has not been studied directly in autistic adults who identify as gender-diverse or transgender.

Objectives: To assess the impact of gender affirmation on mental health outcomes for gender-diverse autistic and non-autistic adults.

Methods: Data regarding gender diversity, gender affirming care history, depression, anxiety, autistic traits, and executive functioning were collected via an online survey as part of a larger project. Data were analyzed for 100 gender-diverse adults, 49% of whom identified as autistic, either through formal (18%) or self-diagnosis (31%). Ages of participants ranged from 19 to 56 (M = 27.3, SD = 7.7). 72% of participants were assigned female at birth. 35% of participants identified as male, 17% identified as female, 28% identified as nonbinary, and 19% identified with another undisclosed identity or were exploring their gender and were not sure about their gender identity. 75% of participants identified as white, 3% identified as Middle Eastern/North African, and 22% identified as multiracial. 80% of participants disclosed that they have a disability.

Results: To assess overall mental health distress, we combined scores from the Beck Depression Inventory-II and the Beck Anxiety Inventory. To quantify aspects of gender affirmation we counted steps a participant had completed (i.e., social transition, puberty blockers, gender affirming hormones, gender affirming surgical procedures). Autistic traits were measured dimensionally using the 50-item Autism Spectrum Quotient. Regression analysis of the impact of gender affirmation on mental health distress indicated that there is a significant effect for gender affirmation (r = -3.945, p = 0.001), but not for autistic traits (r = 0.54, p = 0.59) (F(2) = 8.03, p = 0.002). This suggests that the variance in mental health in our sample is better explained by gender affirmation than by autistic traits, though both gender diversity and autistic traits have been previously linked to both anxiety and depression.

Conclusions: These findings suggest that while there is a double burden of being both autistic and gender diverse in developing mental health conditions such as anxiety and depression, gender affirmation improved mental health outcomes for gender-diverse adults, whether or not they exhibit high degrees of autistic traits. This suggests that for gender-diverse autistic adults, gender affirmation is a clear pathway toward improved mental health outcomes.

401.074 (Poster) Mental Health Distress Impacts Executive Functioning More Than Autistic Traits or Gender Affirmation

K. M. Normansell-Mossa1, D. L. Limon1, M. South1 and R. A. Lundwall1, (1)Clinical Psychology, Brigham Young University, Provo, UT, (2)308 W North Temple, Brigham Young University, Salt Lake City, UT, (3)Psychology & Neuroscience, Emory Autism Center, Decatur, GA, (4)Psychology & Neuroscience, Brigham Young University, Provo, UT

Background: Navigating the world as a gender-diverse person requires a great deal of executive functioning capacity. Deciding who is safe to come out to, navigating the medical system to receive gender affirming care, and planning, organizing, and making big decisions regarding gender care is an exhausting process. Between 4.8% and 26% of adults presenting to gender dysphoria clinics have an autism diagnosis and some studies show that there are elevated rates of autistic traits in the remaining. Executive functioning challenges have been observed in both autistic and gender-diverse people and intersectionality may lead to an extra cognitive load on executive functioning resources.

Objectives: To assess the impact of gender affirmation, mental health distress, and autistic traits on executive functioning in gender-diverse adults.

Methods: Data regarding gender diversity, gender affirming care history, depression, anxiety, autistic traits, and executive functioning were collected via an online survey as part of a larger project. Data were analyzed for 100 gender-diverse adults, 49% of whom identified as autistic, either through formal (18%) or self-diagnosis (31%). Ages of participants ranged from 19 to 56 (M = 27.3, SD = 7.7). 72% of participants were assigned female at birth. 35% of participants identified as male, 17% identified as female, 28% identified as nonbinary, and 19% identified with another undisclosed identity or were exploring their gender and were not sure about their gender identity. 75% of participants identified as white, 3% identified as Middle Eastern/North African, and 22% identified as multiracial. 80% of participants disclosed that they have a disability.

Results: To assess overall mental health distress, we combined scores from the Beck Depression Inventory-II and the Beck Anxiety Inventory. To quantify aspects of gender affirmation we counted steps a participant completed (i.e., social transition, puberty blockers, gender affirming hormones, gender affirming surgical procedures). Autistic traits were measured dimensionally using the 50-item Autism Spectrum Quotient. We measured executive functioning using the Global Executive Composite from the Behavior Rating Inventory of
Executive Function for Adults. Regression analysis of the impact of gender affirmation, autistic traits, and mental health distress on executive functioning indicated that there was a significant effect overall ($F[3] = 9.31, p < 0.001$) that can be attributed to the impact of mental health distress ($t = 4.83, p < 0.001$), but not to autistic traits ($t = 0.54, p = 0.60$) or gender affirmation ($t = 1.51, p = 0.14$).

Conclusions: These findings suggest that there is a pathway to help support gender-diverse autistic people by supporting them in managing their mental health distress that can improve their overall executive functioning. This is likely because mental health distress also consumes executive functioning resources, further depleting a low-capacity and high-need resource. It is important to note that though the data do not suggest that gender affirmation is impacting executive functioning in our sample, it is established that there is a link between gender affirmation and improved mental health in gender-diverse people, so this pathway can be impacted by improving access to gender affirming care and other forms of gender affirmation in addition to treating depression and anxiety directly.

**POSTER SESSION — ADULT OUTCOME: MEDICAL, COGNITIVE, BEHAVIORAL**

**420 - Adult Outcome: Medical, Cognitive, Behavioral II**

**420.001 (Poster) Mortality Rate and Age of Death Among Medicare-Enrolled Autistic Older Adults in the United States**

M. Krantz, D. Dalmacy, L. Bishop, J. M. Hyer and B. N. Hand; (1) The Ohio State University, Columbus, OH, (2) University of Wisconsin - Madison, Madison, WI, (3) Health and Rehabilitation Sciences, The Ohio State University, Columbus, OH

**Background:** An emerging body of evidence suggests that autistic people are at greater risk for mortality than non-autistic people. Most of this literature focuses on autistic children and young adults or combines autistic older adults (age 65 or older) with younger age groups, making it hard to differentiate mortality rates among autistic older adults specifically. By the year 2050, there will be about 1.16 million autistic adults aged 65 years or older in the United States, necessitating a better understanding of this populations’ health needs and outcomes. As a result, data about mortality rates in older autistic adults are needed to inform initiatives by healthcare systems, providers, and policy makers to maximize life expectancy among autistic older adults.

**Objectives:** Compare mortality rate and age of death among Medicare-enrolled autistic and non-autistic older adults.

**Methods:** We performed a retrospective cohort analysis of 2016 through 2020 Medicare Standard Analytical Files (SAF). Medicare is a nationally administered program that provides nearly universal healthcare coverage to Americans aged 65 and older (including autistic and non-autistic older adults). Autistic older adults (n=4,685) were included if they: (1) were age 65 and older; (2) were enrolled in Medicare for at least 6 months to ensure enough follow up time; and (3) had at least one inpatient or outpatient claim with an autism diagnosis during January 1, 2016 through December 31, 2017. We also identified a population comparison (PC) group of age and sex-matched adults without autism diagnoses (n=46,850). The primary outcome of this study was the number of years from age 65 to the beneficiary’s death, which is recorded in the SAF and validated by the United States Social Security Administration. Beneficiaries with no recorded date of death by December 31, 2020 were assumed to be alive at the end of the observation period. Cox proportional hazard regression models were used to compare overall survival between autistic and PC beneficiaries while controlling for demographic characteristics.

**Results:** Table 1 provides sample characteristics. More autistic beneficiaries died during the study period (36.1%) than PC beneficiaries (15.3%). Autistic decedents were a median age of 72 years (interquartile range [IQR]=68, 78) while the corresponding figure for PC decedents was 74 years (IQR=69, 83) (Figure 1). The hazard rate of death for autistic beneficiaries was 2.37 times higher than that of PC beneficiaries (Adjusted Hazard Ratio [95% Confidence Interval]; 2.37 [2.21-2.54]).

**Conclusions:** To our knowledge, our study is the first to use US national data to examine mortality rates among autistic older adults. Many trends regarding mortality observed in younger samples of autistic people were also observed in our study. Specifically, rates of mortality were greater among autistic than PC older adults. However, we found a two-year difference in median age at death between autistic and PC decedents, which is a much smaller disparity than reported in some other studies. Although preliminary, our findings may indicate that autistic people who survive into older adulthood live to a more similar, though somewhat reduced, age as their non-autistic peers.

**420.002 (Poster) Musical and Linguistic Prediction in English-Speaking Individuals with Autism**

A. Loutrari, C. Crasto, A. Vetić, C. Zhao, A. Patel, T. Williams, B. Chakrabarti, C. Jiang and F. Liu; (1) University of Reading, Reading, United Kingdom, (2) School of Psychology & Clinical Language Sciences, University of Reading, Reading, United Kingdom, (3) University of Manchester, Manchester, United Kingdom, (4) Tufts University, Boston, MA, (5) Centre for Autism, University of Reading, Reading, UNITED KINGDOM, (6) Music College, Shanghai Normal University, Shanghai, China

**Background:** Storing structural regularities, present both in music and language, and drawing upon learnt associations are essential mechanisms for making accurate online predictions (Cannon et al. 2021; Perruchet & Pacton 2006). Research into predictive processing in autistic individuals has pointed to impairments in making reliable predictions about upcoming information (Lawson et al. 2014; Pellicano & Burr 2012; Sinha et al. 2014).
**Objectives:** The overarching aim of this work was to compare predictive processing in music and language, and to determine how predictive musical processing in autistic individuals compares to analogous judgements in the speech domain.

**Methods:** To this end, four tasks with 45 trials each were designed: a melodic cloze task, a sentence cloze task, a melodic rating task, and a sentence rating task. High- and low-constraint melodies/sentences were employed, with high-constraint items corresponding to trials whereby the probability to complete a stem with a given note/word was high. In the melodic tasks, high probability items were those eliciting strong expectations given the tonal structure of a melody; in the speech trials, higher probability responses were those better fitting the semantic context of a sentence based on established norms (Arcuri et al., 2001). Twenty-one English-speaking autistic participants and forty-nine non-autistic controls took part in the study. Participants were expected to produce a note/word for the two cloze tasks and expectedness ratings for the stimuli in the other two tasks.

**Results:** The performance of the two groups was not found to differ significantly in the melodic cloze task, but autistic participants performed significantly worse on the sentence cloze task. Autistic participants displayed faster reaction times than controls on the melodic cloze task but a slower response on the sentence cloze task. No significant group differences were found for the melodic or sentence rating task. Autistic participants outperformed controls in singing higher probability notes and assigning higher ratings to higher cloze probability melodies (see Figures 1 and 2).

**Conclusions:** Our findings suggest that autistic individuals have implicit knowledge of tonal regularities despite their difficulties in making semantic predictions. Their preserved ability to form melodic expectations could be attributed to efficient statistical learning in the domain of music (Foti et al. 2015; Obeid et al. 2016). However, this ability does not seem to be matched by performance on the sentence cloze task; autistic participants’ linguistic prediction was impaired, in line with previous findings (e.g., Booth & Happé 2010; Henderson et al. 2011; Jolliffe & Baron-Cohen 1999). Similar difficulties in autism have been traced to ‘weak central coherence’ (Happé & Frith 2006), poorer vocabulary (Brown et al. 2013; Lucas & Norbury 2014), and more limited world knowledge (Howard et al. 2017), among other theories. Nevertheless, typical performance on the sentence rating task suggests that when sentences are already completed, autistic individuals seem sensitive to semantic expectancies, perhaps pointing to a production-perception dissociation. Speech production impairments in particular do not seem to impinge on the ability to process melodic information and to produce appropriate responses based thereon.

**Background:**

Autistic people in professional roles, such as education and health, are at risk of underemployment and working in positions below their qualifications. Issues of poor participation, exclusion and impoverished longer-term outcomes require urgent remediation. Here, understanding people’s own lived experiences is not only valuable, but completely essential.

**Objectives:**

The experience of autistic professionals is an area where little high quality research is available. In this study, we qualitatively explored the experiences of autistic teachers and autistic health professionals in Scotland. We explore supportive factors described by autistic people, identify how context, including organisational culture or environment contribute, and understand their journey to successful employment.

**Methods:**

The project has worked closely with autistic people, with two autistic researchers in the team. There were two study phases: (1) systematic review of qualitative research on the experiences of autistic adults in health or education roles (2) online qualitative interviews with autistic people in Scotland. Data is being collected for both studies. For the qualitative study, forty participants will be enrolled by January 2023 (15 to date). Inclusion criteria was diagnosis of Autism, aged>18, ability to participate in interview, currently working in statutory role in health (e.g. doctor) or statutory education role (e.g. schoolteacher). Each participant completes a 60-90 minute semi-structured interview focussed on their training, recruitment, work, disclosure of autism, and recommendations. Additional data collected include demographics, diagnosis history, age and previous working history. For the systematic review electronic databases were searched using a broad range of keywords, to identify English-language primary studies on autistic experiences in health and education roles. Data extraction and synthesis followed PRISMA. Quality appraisal was completed. Full details of the review methodology are available [PROSPERO].
Results:

For the systematic review, a very small pool of research has been identified. The limited literature that does exist provides some indication around how to best develop employment opportunities for autistic people, but overall, there remains limited research. Preliminary data from the primary qualitative study reflects a high level of interest in the need for greater understanding of autistic people in health and education roles. Initial analysis suggests that autistic adults desire support (individually and/or environmental modifications) to manage sensory preferences, social communication, and with specific areas of work, such as interviews and recruitment. Participants have expressed contrasting views on disclosure, with this being an individual choice. Non-disclosure is linked to fear/prejudice. Recommendations have been made for improvements and training needed for professionals and organisations. Further qualitative analysis is underway and will be synthesised with the extant research on completion.

Conclusions:

It is necessary to understand how individuals have achieved their employment positions to increase participation and to understand problems with career engagement and success, and what barriers may be modifiable to improve engagement and outcomes. This research will be used to support development of experience-based good practice guides focused on making health and education careers and workplaces more accessible and less discriminatory for autistic people.

420.005  (Poster) Neuroimaging Markers of Early Aging in Autism Spectrum Disorder

Background: Autism spectrum disorder (ASD) is a lifelong diagnosis with developmental impacts that persist across the lifespan. Studies focused on aging populations in autism using administrative data indicate ASD is associated with a shorter life expectancy, higher rates of serious physical and mental health issues, and higher rates of dementia and motor disorders. Yet, the majority of autism neuroimaging research studies have investigated the brain in children and adolescents. The Interdisciplinary Science to Learn about Autism (ISLA) longitudinal study represents one of the longest running longitudinal neuroimaging studies of autistic adults, collecting up to 6 timepoints of data over 18 years.

Objectives: Utilize neuroimaging data acquired as part of the ISLA longitudinal sample to investigate patterns of aging in the autistic brain, specifically focused on cortical and microstructural measures of the brain derived from structural and diffusion MRI methodologies.

Methods: Participants included 176 individuals (n=87 ASD) between 12 and 57 years of age who underwent imaging on a Siemens 3T PRISMA scanner using a 64-channel head coil. A sagittal MP2RAGE scan with 1 mm isotropic resolution was additionally acquired to assess cortical morphometry, while a 4-shell diffusion imaging protocol was performed to assess the white matter microstructure. MP2RAGE T1-weighted images were processed using FreeSurfer while diffusion images were processed using an in-housing processing pipeline utilizing functions from DIPY toolkit, FMRIB Software Library (FSL), and MRtrix software packages. Mixed effects models were used to investigate longitudinal patterns of cortical thickness from FreeSurfer derived measures. Group differences and age-by-group interactions of diffusion MRI metrics were examined using linear models with R software.

Results: Preliminary analysis of ASD vs TDC longitudinal cortical thickness across 5 timepoints demonstrated longitudinal differences that were predominantly in the frontal and parietal lobes: all left parietal lobe regions in ASD were thinner by 20 years of age. Analysis of white matter microstructure showed widespread significant differences between ASD and TDC subjects, such that the ASD group had significantly lower neurite density across the white matter, including the genu of the corpus callosum, superior longitudinal fasciculus, and uncinate fasciculus (p<0.05, corrected).

Conclusions: Utilizing advanced structural and diffusion MRI, we observed significant differences and age-related deviations in the autistic brain. Regional temporal lobe thinning was localized, suggesting regionally dynamic cortical thickness changes are not consistent across the entire brain. The ASD vs TDC differences suggest ongoing atypical brain maturation in ASD. Future studies utilizing state-of-the-art quantitative imaging techniques to investigate biologically sensitive measures of brain microstructure and function will be of critical importance for further understanding of aging related patterns in autism. In particular, the ISLA-A Network, a newly funded NIH Autism Center for Excellence, will build upon the foundation that the ISLA longitudinal study has provided and perform a comprehensive prospective longitudinal study that will focus on aging in autism.

420.006  (Poster) Perceived Misdiagnosis of Psychiatric Conditions in Autistic Adults
V. Kentrou, S. Begeer, R. Grove, R. A. Hoekstra and L. A. Livingston, (1)VU University Amsterdam, Amsterdam, Netherlands, (2)Clinical Developmental Psychology, Amsterdam, Netherlands, (3)University of Technology Sydney, Sydney, NSW, Australia,
Background: Many autistic people do not receive an autism diagnosis until adulthood, delaying their access to timely support and clinical care. One possible explanation for a delayed diagnosis is that autistic traits may initially be misinterpreted as symptoms of other psychiatric conditions. This may lead some individuals to experience misdiagnosis of other psychiatric conditions prior to their autism diagnosis. However, very little is currently understood about the frequency and nature of psychiatric misdiagnoses in autistic adults.

Objectives: This study is one of the first of its kind – using a large sample of autistic adults – to explore the frequency of perceived misdiagnoses of psychiatric conditions that were given before a diagnosis of autism was obtained, as well as to investigate possible gender differences.

Methods: Using data from a longitudinal register of autistic adults in the Netherlands, this study explored the frequency of psychiatric diagnoses perceived as a misdiagnosis before receiving an autism diagnosis. Gender differences in perceived misdiagnoses were explored using logistic regression. A sample of 1211 autistic adults (52.6% women, mean age 42.26 years) was evaluated.

Results: Results showed that 24.6% \( (n = 298) \) of participants reported at least one previous psychiatric diagnosis that was perceived as a misdiagnosis. Personality disorders were perceived as misdiagnoses most frequently (12.3%), followed by anxiety disorders (6.6%), mood disorders (6.2%), chronic fatigue syndrome/burnout-related disorders (9.6%), and attention-deficit/hyperactivity disorder (4%). Women and men were equally likely to report at least one perceived misdiagnosis. However, women were significantly more likely than men to report a perceived misdiagnosis of personality disorders, anxiety disorders, and mood disorders.

Conclusions: The findings suggest that there is a high frequency of perceived misdiagnoses across a range of psychiatric conditions, with significant gender differences observed specifically in relation to personality disorders, anxiety, and mood disorders. Current findings highlight the need for healthcare professionals to screen for autism earlier in adults presenting with numerous prior diagnoses or existing diagnoses such as personality, anxiety, or mood disorders. Mental health assessments should form an integral component of clinical care with regular screening, evaluation, and treatment done as part of ongoing support for autistic adults, rather than treating psychiatric conditions in isolation.

420.007 (Poster) Perception of Parents of Adults with Autism Spectrum Disorder Regarding Their Quality of Life and That of Their Child
A. Lampron, N. Moussa and N. Poirier, (1)Psychology, Université du Québec à Montréal, Montréal, QC, Canada, (2)Psychology, Université du Québec à Montréal, Montreal, QC, Canada

Background: Autism Spectrum Disorder (ASD) is a neurodevelopmental disorder that affects the quality of life of parents, through the special needs of the child, the level of help required and the severity of symptoms. Similarly, ASD also affects the quality of life of the person with the disorder. Since most adults with ASD remain dependent on others to meet their needs, their quality of life depends on the people who provide support.

Objectives: The objective of this study is to analyze how parents of adults with ASD perceive their quality of life and that of their adult child.

Methods: The sample is composed of 20 parent-child dyads with ASD. The parents are mostly mothers and are on average 24 years old. A socio-demographic questionnaire as well as two questionnaires, namely the Scale of quality of life for parents of a child with ASD and the Scale San Martin – Evaluation of the quality of life of people with special needs, were completed by the parents. The first questionnaire focuses on the impacts of the ASD diagnosis on seven aspects of the parents’ quality of life: daily activities, professional relationships, social relationships, family and couple relationships, the relationship with the child with ASD, psychological well-being and personal development. The second questionnaire assesses the quality of life of adults with significant impairments according to eight quality of life components: self-determination, emotional well-being, physical well-being, material well-being, rights, personal development, social integration and interpersonal relationships.

Results: Results showed that 24.6% \( (n = 298) \) of participants reported at least one previous psychiatric diagnosis that was perceived as a misdiagnosis before receiving an autism diagnosis. Gender differences in perceived misdiagnoses were explored using logistic regression. A sample of 1211 autistic adults (52.6% women, mean age 42.26 years) was evaluated.

Conclusions: The findings suggest that there is a high frequency of perceived misdiagnoses across a range of psychiatric conditions, with significant gender differences observed specifically in relation to personality disorders, anxiety, and mood disorders. Mental health assessments should form an integral component of clinical care with regular screening, evaluation, and treatment done as part of ongoing support for autistic adults, rather than treating psychiatric conditions in isolation.
Background: Despite having many strengths, autistic adults often experience challenges in obtaining and maintaining employment (Scott et al., 2019). Thus, development of interventions to support autistic employment has become a burgeoning research area. One such intervention, PEERS® for Careers, adapts evidence-based methods to teach employment-related social skills (Moody et al., 2022). Although PEERS® for Careers produces significant benefits in autistic employment outcomes, autistic heterogeneity and intersectionality (Georgiades et al., 2013) require investigation into moderators of treatment response to ensure equity and inform individualized treatment planning. This is especially important given the wide use of career coaching as an intervention component for autistic adults (Kim et al., 2022).

Objectives: This study aimed to explore predictors of treatment response following PEERS® for Careers, focusing on participant and career coach characteristics.

Methods: Participants included 106 autistic adults (Mage=22.9, SD=3.6; 81% male; 49.1% White) with cognitive abilities in the average or above average range (IQ³85). Following enrollment in PEERS® for Careers, 53 young adults were randomly assigned to receive a career coach, who included undergraduate and graduate students who supported participants’ practice and application of employment skills. Participants and coaches completed demographic and employment surveys, as well as the Test of Employment Social Skills (TESS; Moody et al., 2022) pre- and post-intervention. Participants were administered the Wechsler Abbreviated Scales of Intelligence, 2nd Edition (WASI-II; Wechsler, 2011) and Social Responsiveness Scale–Second Edition, self-report (SRS-2; Constantino & Gruber, 2012).

Results: After the 20-week PEERS® for Careers program, participants showed greater engagement in employment activities and significant increases in employment-related social skills knowledge (TESS), feelings of preparedness for employment, and social responsiveness (p=.01), with the Coach group demonstrating greater improvements. Young adult race, gender, age, and cognitive ability did not significantly predict treatment response on any outcome measures. Similarly, baseline social responsiveness did not predict employment-specific outcomes. However, those with greater baseline impairments on the SRS-2 did show greater improvements in social responsiveness post-treatment, p=.001. Participants enrolled in college also showed significantly greater gains on the SRS-2, p=.031, and a marginal greater likelihood of gaining paid employment from pre- to post-intervention, p=.067, when compared to those not in college. With respect to coach characteristics, neither coach age, employment-related social skills knowledge, nor paid employment history emerged as significant predictors of young adult treatment response. However, coaches’ own feelings of preparedness for employment at baseline significantly predicted positive changes in young adults’ social responsiveness, p=.013, and had a trending association with obtaining of employment/internships, p=.059. Forthcoming analyses will explore these characteristics as predicting ongoing success at 10- and 20-week follow-up assessments.

Conclusions: Findings generally indicate that PEERS® for Careers improves employment-related outcomes similarly for autistic adults across multiple diversity dimensions. Only enrollment in college marginally differentiated employment outcome post-intervention, suggesting that young adults’ postsecondary experiences may further expand job opportunities and success. Additionally, although career coaches added significant benefit beyond the didactic curriculum alone, only coach feelings of preparedness for employment related to young adult treatment response.

Background: Autistic youth who graduate high school with a regular diploma are afforded with opportunities such as acceptance to post-secondary education and employment that requires a high school diploma. Yet, little is known about the outcomes of this population, and the predictors of those outcomes. We focused on identifying malleable factors in high school that predicted post-school outcomes in this population.

Objectives: In this study we examined the extent to which emotional wellbeing, executive functions, and the ability to self-manage daily life tasks were associated with young adult outcomes in autistic youth who recently graduated high school with a diploma.

Methods: Participants were parents and 36 autistic diploma-track youth (ages 17-20) who completed measures during the last year of high school (T1) and approximately 14 months after youth high school graduation (T2) (see Table 1). Measures included the Pediatric Evaluation of Disability Inventory – Computer Adaptive Test – ASD version (PEDI-CAT-ASD; Haley et al. 2012), the Depression Anxiety Stress Scale (DASS; Lovibond & Lovibond, 1994), the Behavior Rating Inventory of Executive Function, Adult (BRIEF-A; Roth et al., 2005), and a researcher-developed measure of post-school outcomes that summed objective and subjective (satisfaction) indicators in 3
domains: productivity (employment or post-secondary education), social well-being (frequency of contact with friends), and living situation (autonomy). Outcome indicators were developed using items from the Adult Behavior Checklist (ABCL; Achenbach & Resclora, 2003), the Adult Self-Report (ASR; Achenbach & Resclora, 2003), and items developed by the research team.

Results: Number of youth positive post-school outcomes ranged from 2 to 6; one-quarter of the sample had positive outcomes on all 6 indicators. Bivariate correlations indicated that a higher number of positive post-school outcomes at T2 was associated with the following at T1: fewer depressive symptoms (youth report on the DASS; r = -.520, p = .002), better ability to self-manage daily life tasks (parent report on the PEDI-CAT-ASD; r = .463, p = .007), and fewer metacognitive executive function impairments (parent report on the BRIEF-A; r = -.392, p=.022). Parent reported youth social cognitive and self-care skills on the PEDI-CAT-ASD, and youth reported anxiety on the DASS, were not associated with post-school outcomes. In an ordinary least squares regression analysis, only DASS depression significantly predicted T2 post-school outcomes (see Table 2). The ability to self-manage daily life tasks and metacognitive executive function skills did not contribute additional unique variance to the prediction of T2 post-school outcomes.

Conclusions: The finding have important implications for high school supports and interventions for diploma-track autistic youth. Although the ability to self-manage daily life tasks and executive function skills were associated with positive post-school outcomes, depression symptoms were a stronger predictor. This suggests that attention to youth depression should be prioritized. The fact that youth social and self-care abilities, and anxiety symptoms, were not associated with post-school outcomes may be due to the unique nature of the sample and the fact that they had relatively stronger general cognitive and academic capabilities. Further research is needed to substantiate these findings with larger samples.

420.010 (Poster) Predictors of Depression in Autistic College Students

E. J. Adler, S. A. Lehman, M. K. Guell and A. V. Van Hecke, Psychology, Marquette University, Milwaukee, WI

Background: Research suggests that autistic college students report higher rates of depression than their neurotypical peers; however, the current literature on factors contributing to depressive symptoms in this population is limited (McLeod et al., 2020). Depressive symptoms have been shown to predict lower grade point averages; more classes dropped; and higher rates of classes, assignments, exams, and social activities missed (DeRoma et al., 2009; Hysenbegasi et al., 2005). With more autistic students attending post-secondary institutions, there is a demonstrated need to understand the factors contributing to depressive symptoms in this population, as depressive symptoms can adversely impact school performance and socialization (Shattuck et al., 2020).

Objectives: The present study explored the mechanisms behind depressive symptoms in autistic students at the start of college, including self-esteem and feelings of loneliness.

Methods: 21 college students aged 18-20 (M=18.48, SD=0.68; 81% male) were included in the current analysis based on involvement in a college support program for autistic students. Program requisites include documentation of an autism diagnosis, enrollment as an undergraduate at the university, and student-expressed desire to participate. Students can enter the program at any point during their undergraduate career. In accordance with an ongoing program review process, students completed various self-report measures including the Center for Epidemiologic Studies-Depression Scale (CESD: Radloff, 1977), Rosenberg Self-Esteem Scale (RSES: Rosenberg, 1979), and Revised UCLA Loneliness Scale (Russell et al., 1980). De-identified data from the first month of entry into the program was requested by the research team for analysis.

Results: Bivariate Pearson correlation indicated that self-esteem was negatively correlated with depressive symptoms, (r(19)=-.590, p<.05). Loneliness was not significantly correlated with depressive symptoms, (r(19)=0.185, p>.05). Self-esteem was negatively correlated with loneliness, (r(19)=-0.381, p<.05). Multiple linear regression revealed that 35% of the variance in depressive symptoms can be accounted for by loneliness and self-esteem (R²=0.35, F(2,18)=4.85, p<.05). Using a two tailed test (a=0.05), self-esteem significantly predicted depressive symptoms (β=-0.61, t(18)=-2.96, p<.01). Loneliness was not a significant predictor of depressive symptoms (β=-0.05, t(18)=-0.23, p>.05).

Conclusions: Findings indicate that lower self-esteem is predictive of increased depressive symptoms in a sample of autistic college students. Notably, loneliness did not significantly correlate with or predict depression; however, loneliness was negatively correlated with self-esteem (i.e., more feelings of loneliness were associated with lower self-esteem). This analysis has implications for how to best support autistic college students who experience symptoms of depression when they first transition to university life. It appears that prioritizing autistic students’ self-concept and promoting confidence may be a more effective point of intervention than increasing amount of social contact. Relative to social interventions, there are myriad of possible neurodivergent-affirming avenues to increase self-esteem (e.g., strengths-based approaches, positive autistic identity development). Further, this study provides support for the integration of resources or exercises that increase autistic students’ self-assurance into college support programs. Future work will examine self-esteem and loneliness as predictors of depression at a later timepoint in the college support program, and after additional time on the university campus, to assess potential longitudinal changes.

420.011 (Poster) Predictors of Knowledge and Functional Skill Acquisition Using the “Teaching Model” in Adults with Profound Autism
Background:

Very few studies have examined intervention programs aimed at advancing academic and functional skills among adults with profound autism. Research in intellectual disability suggests possible progress in these domains even at older ages. In a previous study, we described an innovative intervention, the Teaching Model (TM), which transmits academic and functional skills to adults with profound autism in a classroom setting. We found the TM to be an effective continuing education intervention for both acquiring new knowledge and for improving functional skills consisting of social communication, adjusted behaviors, and independent skills related to the classroom setting. Identifying factors that predict the outcome of this intervention was the focus of the current study.

Objectives:

- To identify predictors-including demographic variables (age, gender), autism severity, adaptive skills, and maladaptive behaviors-of better acquisition of new knowledge through using the TM, among adults with profound autism.
- To identify predictors from among the previously mentioned variables of better acquisition of functional skills.

Methods:

The study included 86 participants (males=61; females=25) with an age range of 22.6-57.6 years (M=34.8, SD=8.7 years). The participants were previously diagnosed with autism based on their medical records, and currently live and work in sheltered frameworks for adults with profound autism. All the participants were evaluated for autism severity utilizing the Social Responsiveness Score (SRS), and for adaptive skills and maladaptive behaviors utilizing the Vineland Adaptive Behavior Scales (VABS). The participants were enrolled in TM courses on the topics of music, photography, recognizing emotions, gardening, and geography. Topics and functional skills were taught and practiced in small groups of 2-4 participants for one hour twice a week for four months using applied behavior analysis strategies. Outcomes of the TM were assessed by two measures designed for this research, including knowledge examination of the teaching topics and assessment of functional skills. Data were collected before (T1) and after the TM intervention (T2).

Results:

To identify predictors of better acquisition of new knowledge and functional skills through using the TM, two hierarchical linear regression analyses were performed. Age, gender, autism severity (SRS subscale scores), adaptive skills and maladaptive behaviors (VABS), were used as the independent variables. For better acquisition of functional skills (T2-T1), the model explained 21.1% of the variance. Better acquisition of functional skills was associated with low SRS social communication and interaction subscale scores (β=-.43, p<.001), older age (β=.25, p<.05), and male gender (β=.23, p<.05). For better acquisition of new knowledge (T2-T1), the model was not found significant. Nevertheless, age was the only independent variable that correlated significantly with better acquisition of new knowledge (r=0.25, p<.01).

Conclusions:

Less severe social communication impairments, older age, and male gender predicted better outcomes in functional skill acquisition. In addition, there was a significant correlation between age and knowledge acquisition. The major role of age in both outcome measures raises the possibility of the compensation age theory described in the intellectual disability field. This suggests there may be a window of opportunity for learning new skills even at older ages among those with profound autism.

420.012 (Poster) Prevalence of Anticholinergic Medication Use in Middle-Aged and Older Autistic Adults and Associations with Self-Reported Memory Problems and Self-Reported Cognitive Decline

Background: Anticholinergic (AC) medications block action of acetylcholine at cholinergic receptors in the central and peripheral nervous systems. Many commonly used prescription and over-the-counter medicines have potent AC effects. Among older adults, AC medication use is associated with acute and chronic cognitive impairment, and elevated risk for delirium, dementia, mild cognitive impairment, and Alzheimer’s Disease. Collectively, associations of AC medications with cognitive problems are referred to as anticholinergic cognitive burden (ACB). Because of high rates of co-occurring medical and psychiatric conditions across the lifespan, autistic individuals may...
have high AC exposure, and thus, may experience elevated risk for ACB. Nevertheless, no research has characterized AC exposure or examined its associations with cognitive outcomes in autistic adults.

Objectives: Characterize AC medications; Document concurrent associations between AC medications and self-reported memory complaints; and Examine if AC medications at Time (T1) predict self-reported cognitive decline at T2 in middle-aged and older autistic adults.

Methods: Autistic adults (40-83y) were recruited via SPARK’s Research Match. At T1, 415 participants reported their current prescription and over-the-counter medication. Medications were coded using the CRIDECO Anticholinergic Load Scale, which classifies AC potency as follows: 1=low, 2=moderate, 3=high. ACB was characterized in two ways: total ACB score, and ACB≥3, a cut-off identified as clinically meaningful. 382 participants self-reported memory problems via the Prospective and Retrospective Memory Questionnaire (PRMQ). Two hierarchical linear regression models examined associations of ACB with PRMQ total score, with birth-sex and age entered in the first step, and either ACB total score or ACB≥3 entered in the second step. At T2, a subset (N=197) of T1 participants self-reported on cognitive decline via the Eight-item Interview to Differentiate Aging and Dementia (AD8). Logistic regression models were run using the AD8 cut-off of ≥1 (recommended cut-off for the self-report AD8) and separately ≥2 (a conservative cut-off) as dependent variables, with birth-sex and T1-age entered in the first step, and either ACB total score or ACB≥3 in the second step.

Results: Table 1 presents sample characteristics. A high proportion (62.7%) of autistic adults reported taking at least one AC medication. This contrasts with ~20-50% of U.S. adults >65y taking at least one AC medication. Further, 26% of autistic adults reported ACB≥3. Hierarchical regression modeling revealed that after controlling for age and birth-sex, both concurrent total ACB and ACB≥3 predicted more self-reported memory problems (Table 2). Logistic regression modeling showed that, after controlling for age and birth-sex, higher total ACB at T1 predicted self-reported cognitive decline at T2 using the AD8≥1 cut-off.

Conclusions: This is the first study, to our knowledge, to characterize AC medications and associations with cognitive problems in autistic adults. Participants here (M=52.0y) were younger than those in most prior ACB studies of non-autistic adults (>65y). AC use and vulnerability to the negative effects of AC medicines increases with age; thus, high AC medication rates and associations with cognitive problems in this relatively young sample is concerning. Understanding ACB—including potentially earlier AC polypharmacy—and its impacts on cognition (e.g., dementia risk) in autistic adults is warranted.

420.013 (Poster) Prevalence of Common Medical Co-Morbidities of Adults with Autism Spectrum Disorders (ASD) at Selected Centers in Bangladesh

J. Shefa and F. Rahaman, (1)Bangabandhu Sheikh Mujib Medical University, Institute of Paediatric Neurodisorder & Autism (IPNA), Bangabandhu Sheikh Mujib Medical University, Dhaka, Bangladesh, (2)Bangabandhu Sheikh Mujib Medical University, Dhaka, Bangladesh

Background:

Autism spectrum disorder (ASD) encompasses a heterogeneous group of individuals with early childhood onset of deficits in social interaction and language development, a restricted repertoire of interests and activities, cognitive skills ranging from severe deficits to high functioning individuals. Medical conditions that have been shown to be significantly more prevalent in those with autism spectrum disorders than the general population.

Objectives:

General objective:

To observe the prevalence of different medical comorbidities among adult ASD persons at selected centers in Dhaka, Bangladesh.

Specific Objectives:

1. To evaluate present medical problems from parents by history taking, physical examination and personal medical records of particular ASD person.
2. To verify the status of medical problems by doing necessary investigations.
3. Evaluation of the Socio-economic & demographic condition of the family having diagnosed ASD adult with comorbidities.

Methods: This was a cross sectional study. Data were collected from selected centers of Dhaka, where adult ASD (age range: 18-47 years) persons regularly visit for vocational training, therapies and intervention of Autism. 44 participants were included in this study.
Results:
There were different kinds of medical co-morbidities present among the participants. Hypercholesterolemia was present in most (25%), followed by anemia in 13.8%, Diabetes Mellitus in 9.1%, Seizure disorder in 9.1%, insomnia in 6.8% and hypertension in 2.3%

Conclusions:
There were multiple medical co-morbidities present among adult ASD persons. But very limited researches were done about that. It would be necessary to find out the medical co-morbidities among them. There are limited data on medical co-morbidities among adults with ASD. Further large scale multi-center study will be needed to find out the cause and plan for the treatment.

420.014 (Poster) Psychological and Behavioral Profiles in Autistic Adults Who Self-Identify As Gender- and Neurodivergent

H. Voulgarakis and J. Scher Lisa\textsuperscript{1}, (1)St. Joseph's University, New York, NY, NY, (2)St. Joseph University, NY, NY

Background: Autism and related conditions have continued to rise in recent years as have the number of people who identify as gender-divergent. Those who are autistic/neurodivergent and gender-divergent are underrepresented, and less is known regarding the diagnostic complexities associated with gender diversity in the autistic population.

Objectives: The purpose of the current study is to better understand psychological/behavioral profiles in autistic adults who identify as neurodivergent alongside different aspects of gender identity. Specifically, we sought to identify factors related to cognition, social functioning and behavior, psychopathology, and sensory symptoms alongside gender constructs.

Methods: Data collection is ongoing (target \( N = 50 \)) however the current study provides a preliminary report on 11 adults who identify as autistic and gender-divergent between 18 and 35. Participants were adminisetred the Autism Quotient (AQ), the Genderqueer Indentity (GQI) scale, the Camouflaging Autistic Traits Questionnaire (CAT-Q), the Adult Repetitive Behaviour Questionnaire-2A (RBQ-2A), the Millon Clinical Multiaxial Inventory- Fourth Edition (MCMI-IV), the Adult/Adolescent Sensory Profile (A/ASP), and the Reynolds Intellectual Assessment Scales, Second Edition (RIAS-2).

Results: Of the preliminary sample (\( N = 11 \)), ten were assigned female at birth and one was assigned male. Six participants identified as non-binary, three female, and two selected “other/prefer not to say.” The subscales on the GQI including Social Construction, Gender Fluidity, Challenging the Binary, and Theoretical Awareness were all significant for associations with autistic symptoms. The mean AQ score (M=34.81, SD= 4.54) of the sample group was above the score threshold observed in those with clinical features of autism. The CAT-Q Compensation, Masking, and Assimilation scales were above the neurotypical score cutoff, as were RBQ-2A scores across both Repetitive Sensory-Motor Behaviors and Insistence on Sameness. RIAS-2 scores for verbal abilities (M=117.54, SD=4.99) were elevated in the sample as compared to non-verbal abilities (M=107.92, SD=11.2) and overall Composite IQ (M=113.99, SD=9.99). On the A/ASP, the sample reported significance on the Sensory Sensitivity and Sensory Avoiding subscales. Elevations on the MCMI-IV included Avoidant (M= 77.27, SD=22.00) and Anxious scales (M=80.36, SD 12.58).

Conclusions: The results of the current study are suggestive of diagnostic complexities associated with the female and gender diverse populations. There is clinical need for awareness of the distinguishing ASD factors within these populations, including sensory challenges, social behaviors such as camouflaging, anxious, and potentially avoidant behaviors. While these results should be considered within the small sample size, they help support our understanding of diagnostic tools and their detection and utility.

420.015 (Poster) Quality of Life and Coping Strategies for Activities of the Daily Life Among Young Adults with Autism Spectrum Disorders: A Mixed-Methods Study

M. S. Burrone\textsuperscript{1}, M. T. Solis-Soto\textsuperscript{1}, C. Cortés\textsuperscript{1}, M. Gonzalez\textsuperscript{1}, T. Galdames\textsuperscript{1}, L. Rojas\textsuperscript{1}, A. Basagoitia\textsuperscript{1} and P. Valenzuela\textsuperscript{2}, (1)Institute of Health Sciences, Universidad de O’Higgins, Rancagua, Chile, (2)Universidad de O’Higgins, Rancagua, Chile

Background:
Quality of life is a multidimensional construct that includes the domains of emotional well-being, interpersonal relationships, material well-being, personal development, physical well-being, self-determination, social inclusion, and rights, including work. Several studies have reported a lower quality of life in people with Autism Spectrum Disorder (ASD) compared to those without ASD, especially in the domains related to social relationships and integration. Thus, lower employment rates have also been reported in this group. There is little literature regarding coping strategies in young adults used for activities of daily living, including work, and their relationship with quality of life.

Objectives:
To explore the perception of quality of life and its relationship with coping strategies used by young adults (16-30 years) with ASD for activities of daily living, including work.

Methods:

A qualitative and quantitative study design is being conducted to analyze barriers and facilitators of labor inclusion and factors associated with employment rates in young adults with ASD. In this study, we analyzed a subset of data, in two regions of Chile, through a mixed methods design. For the quantitative analysis, questions from the disability and health module of the Chilean National Health Survey 2016-2017 were analyzed (n=22). Descriptive statistics were used to summarize data points.

Additionally, we conducted 25 in-depth interviews with subjects diagnosed with ASD. For this, all the information collected was digitalized and transcribed, creating a unique corpus of data. Then, an open coding process was conducted, using ATLAS.ti, enabling the assignment of units of meaning to the information and the construction of categories. During the analysis process, the principles of Glaser and Strauss’s Grounded Theory.

The ethics committee of the Universidad de O'Higgins approved the project. All safeguards were considered to guarantee confidentiality in the handling of information.

Results:

Information from 22 young adults who completed the survey were analyzed, 50% women and a median age of 22 years (Range 18 to 28). Of them, 83% reported feeling good or very good about their life (with their work, family, well-being, health, and close relationships). Most (81%) reported not having problems with personal care; however, 62% had difficulties performing their usual activities, including working, and a high percentage referred to requiring any level of support (41%). By triangulating this information with the qualitative analysis categories, it is observed that the participants developed coping strategies that allow them to face the difficulties of daily life, such as acting strategies for everyday life, and preparing scenarios and routines.

Conclusions:

It seems that the quality of life of the study participants was not worsened despite reporting difficulties in activities of daily living and requiring support, which might be related with personal coping strategies or working with the help of professionals from early stages of life. The results suggest that in young adults with ASD, the support received is valued positively and facilitates integration into school and workspaces.

420.016 (Poster) Repetitive Thinking in Relation to Cognitive Flexibility and Processing Speed

E. Avila, C. Cucchiara, E. Sotrah and K. O. Gotham, (1)Rowan University, Vineland, NJ, (2)Department of Psychology, Rowan University, Glassboro, NJ, (3)Psychology, Rowan University, Glassboro, NJ

Background: Repetitive thinking has been associated with depressive symptoms in autistic adults (Gotham et al., 2018), just as it is in the general population, and may represent a treatment target for improving mental health interventions for autistic adults. Repetitive thinking may be a form of autistic repetitive behavior related to cognitive inflexibility, as both constructs share an element of difficulty shifting cognitive focus. Autistic stakeholders who agreed to review our study design in a community engagement group stated that they believed their repetitive thinking functioned to make sense of information in the context of slower cognitive processing speeds.

Objectives: The present study investigates the associations between self-reported repetitive thinking – both that which is actively focused on meaning-making (reflective), as well as passive, negatively-focused brooding – and cognitive flexibility and processing speed. We hypothesize that participants who report greater passive brooding will display lower cognitive flexibility on a National Institute of Health (NIH) Toolbox iPad task, and those who report greater reflective repetitive thinking will display lower processing speed on a related Toolbox iPad task.

Methods: Our sample included N=130 adults aged 18-45 (M=26.85, SD=7.35), including autistic (n=57), non-autistic depressed (n=33), and adults with no history of autism or depression (n=40). Our sample identified as 34.6% men, 52.3% women, 8.5% non-binary/other, with the remainder choosing not to respond. We used the Ruminative Response Scale (RRS) Brooding and Reflection subscales (Treynor et al., 2003) to operationalize repetitive thinking variables, and standard scores from the NIH Toolbox.
Response to Conversational Bids in Autistic, Loss of ASD Diagnosis, and Neurotypical Individuals: Latency and Perceived Quality

Background: Conversation entails a complex range of skills, including openings, topic maintenance and shifting, and turn-taking. Autistic individuals tend to produce higher rates of “empty turns” (i.e., lack of responses where responses are expected; Eales, 1993), and take fewer conversational turns than neurotypical (NT) peers (Paul et al., 2009). Delays in turn-taking can elicit negative emotions in conversational partners (Kroodenburg, Postmes & Gordijn, 2013). Much of the existing literature on turn-taking in autism spectrum disorder (ASD) examines the frequency of conversational turns; less work has explored qualitative features of turn-taking such as latency between a conversational bid and a response. One study reported longer turn-taking gaps during the ADOS-2 in Japanese-speaking autistic males compared to NT peers (Ochi et al., 2019), apparently impacting social impressions. Some individuals diagnosed with ASD in childhood do not meet diagnostic criteria by adolescence; they have “lost the ASD diagnosis” (LAD; Fein et al., 2013). Our group has extensively characterized language skills in LAD.

Objectives: The current study assessed latency and perceived quality of responses to conversational bids in LAD, autistic, and NT adolescents and adults.

Methods: Graduate clinicians assessed fifty-two participants from LAD, ASD, and NT groups with age-appropriate cognitive and language skills using the ADOS-2, Module 4 in an online protocol (Eigsti et al., 2022); Table 1. Examiners presented 3-4 overly-vague conversational bids (“I saw a great movie last week”). Coders naïve to diagnosis calculated response latency as the interval from bid offset to the participant’s response, and assigned a quality rating using a 1-4 rating scale, based on nonverbal behaviors and perceived interest and sincerity of response. Coders reached 80% or better reliability on all variables.

Results: There were no group differences in latency. The NT group’s responses received a higher quality rating than for the autistic group; the LAD group’s rating did not differ from either group. A generalized linear model (GzLM) suggested that latency was unrelated to group, age, or verbal IQ; Table 2. Similarly, a GzLM examining quality ratings suggested no effects of group, age, or verbal IQ. Latency approached significance as a predictor of response quality in a GLM. Latency and response quality were significantly and negatively correlated (Spearman’s $\rho = -.31, p = .03$), such that longer delay before a response was associated with a lower response quality rating. ADOS-2 total scores were negatively correlated with quality ratings (Spearman’s $\rho = .53, p < .001$).

Conclusions: Response latency (approximately 1 second) to conversational bids during the ADOS-2 was equivalent across ASD, LAD, and NT youth. The LAD group’s perceived response quality did not differ from either group, suggesting they may have a social style that is intermediate between the ASD and NT groups, though the range was small. Although latency did not differ across groups, results suggest that longer latency is associated with poorer perceived quality of social responses. Next steps are to investigate the specific contributors to perceived quality of conversational bids (i.e., facial expressions, gestures), and how these behaviors differ across groups.
**420.018 (Poster) Resting Heart Rate Variability and Camouflaging As Predictors of Sensory Function in Autism Spectrum Disorder**

**Background:**

Autism spectrum disorder (ASD) is characterized by impaired social communication and repetitive/stereotyped behaviors. Often, individuals with ASD engage in camouflaging to compensate for or mask autistic characteristics during social interactions to minimize the visibility of their autism in social situations. Additionally, atypical sensory function and anxiety are often observed in ASD. Changes in heart rate variability (HRV), or the normal variation of time between consecutive heartbeats, have been linked to anxiety as well as social and communication impairments seen in ASD. However, the relationship between camouflaging and these other aspects is not known. Understanding the relationship between camouflaging and HRV to predict sensory function may better inform diagnostics and treatment of those with ASD.

**Objectives:**

This study explored how resting HRV or/and camouflaging predict sensory function in ASD. We hypothesized that resting HRV variables and camouflaging would correlate with sensory function score in ASD.

**Methods:**

Twelve young adults aged 19-26 with a diagnosis of ASD participated in the study. Time- and frequency-domain HRV was calculated from five minute resting electrocardiogram recordings. Sensory function was assessed in four domains: low registration, sensation seeking, sensory sensitivity, and sensation avoiding, as assessed by the Adult Sensory Profile (ASP). The Camouflaging Autistic Traits Questionnaire (CAT-Q) was used to assess three camouflaging domains: compensation, masking and assimilation. Multiple linear regression analyses were performed with GraphPad Prism 5.0. The correlation was considered to be significant at \(p<0.05\).

**Results:**

HRV in the frequency domain (VLF Power) and camouflaging (compensation and assimilation) were significantly positively correlated with sensory function. Furthermore, the compensation scores on the CAT-Q were significantly positively associated with sensory sensitivity on the ASP, while assimilation scores on the CAT-Q and VLF power (HRV) were significantly positively associated with sensation avoiding on the ASP.

**Conclusions:**

Among the HRV variables, the frequency domain variables (VLF Power) markers of arousal states and camouflaging were found to correlate with sensory function in ASD. One potential explanation is that VLF rhythm activity is generated by the heart intrinsically due to physical activity and anxiety that modulate its frequency and amplitude. Therefore, this may represent a marker for a relationship between anxiety and camouflaging. Furthermore, sensory function aspects (sensory sensitivity and sensation avoiding) were associated with camouflaging (compensation and assimilation), respectively. Subsequent work will need to explore the mechanisms by which increased sensory reactivity are associated with camouflaging. Our results suggest that sensory function, arousal, and camouflaging are interrelated in ASD. Future work is needed to better understand these relationships.

**420.019 (Poster) Restricted Repetitive Behaviors Among Adults from the SPARK Cohort: Rates and Correlates**

*E. Fombonne, B. J. O’Roak, and S. Mastel*, (1)Department of Psychiatry, Oregon Health & Science University, Portland, OR, (2)Molecular and Medical Genetics, Oregon Health & Science University, Portland, OR, (3)Institute on Development and Disability, Oregon Health and Science University, Portland, OR

**Background:** Restricted and repetitive behaviors (RRB) are one of the two core domains that define autism spectrum disorders (ASD). Yet, they have been relatively understudied, especially among adults.

**Objectives:** 1) to provide descriptive data on the prevalence of RRBs in a large sample of adults with ASD recruited in the SPARK national research cohort; 2) to examine correlates of RRBs in this large sample.
Methods: We used the SPARK data released in June 2022 by SFARI (https://www.sfari.org/resource/spark/). RBS-R data were available on 2,764 dependent adult participants, ages 18 to 32 (78.0% males; mean age: 22.2 years (SD=3.64)), and had been completed by their caregivers. Data on socio-demographic, medical, psychiatric, developmental, clinical correlates were extracted from other questionnaires completed at registration in SPARK by the caregivers.

Results: Almost two thirds (63.5%) of participants received their diagnosis before age 6, and a negligible fraction (4.4%) at or after age 18; 31.1% were minimally verbal. Almost half (46.2%) the sample had been diagnosed in his lifetime with intellectual disability (ID). Persistent language deficits were reported in 31.2% of the sample. Prevalence of comorbid psychiatric disorders was high (anxiety disorders: 42.1%; ADHD: 39.8%). The prevalence of the 43 RRB problems (of any severity level) ranged from 10.6% to 81.8% (median: 42.0%), and 21 items showed significant sex differences. Items more prevalent in males mapped on the Stereotyped and Restricted Behavior Subscale with 4 from the 6 items showing significantly higher scores in males. Items more prevalent in females loaded on the Self-Injurious Behavior subscale (with 4 from its 8 items showing higher scores in females) and the Sameness Behavior scale (with 5 of its 11 items showing higher scores in females). However, there was no significant sex difference for the RBS-R total score (p=.12). Increasing age was associated with a significant decline in 4 subscale and the total RBS-R scores. In bivariate analyses using the total RBS-R score as the dependent variable, socio-demographic (participant’s age, sex, race and ethnicity, maternal education, household annual income) and clinical/developmental characteristics (lifetime diagnosis of cognitive impairment, presence of a birth defect, prematurity at birth, prior language regression, current language level, comorbid ADHD, comorbid anxiety disorder, sibling recurrence of ASD) were associated with significant (p<.05) differences in mean RBS-R score in adulthood. Multiple regression analysis yielded a significant model (F=40.4, df=10; p<.001) with all aforementioned predictors significantly explaining variance in the RBS-R scores, with the exception of sibling recurrence, and after adjustment on socio-demographic background factors. The most significant predictors were current language deficits, a co-occurring diagnosis of anxiety and of intellectual disability.

Conclusions: In this large sample of dependent adults, RRBs were highly prevalent, slightly decreasing with older age and showing no consistent sex difference. Predictors of RRBs were current severity of ASD (as indexed by language and cognitive delays), psychiatric comorbidity (especially anxiety), and indicators of early abnormal prenatal and perinatal development (birth defects and prematurity). Our next step is to examine if levels and types of RRBs map onto specific genetic variation using SPARK exome sequencing data.

420.020 (Poster) Risk of Somatic Conditions and Mortality in Autistic Adults
A. Ly, V. Ahlqvist, M. Lundberg, J. Underwood, P. Madley-Dowd, E. Stergiakouli, C. Dalman, B. K. Lee, J. Heron, D. Rai and C. Magnusson. (1)Population Health Sciences, Bristol Medical School, MRC Integrative Epidemiology Unit, Bristol, United Kingdom, (2)Global Public Health, Karolinska Institutet, Stockholm, Sweden, (3)Department of Public Health, Karolinska Institutet, Stockholm, Sweden, (4)Neuroscience and Mental Health Innovation Institute, Cardiff University, Cardiff, United Kingdom, (5)University of Bristol, Bristol, United Kingdom, (6)MRC Integrative Epidemiology Unit, Bristol Medical School, University of Bristol, Bristol, United Kingdom, (7)Department of Public Health Sciences, Karolinska Institutet, Stockholm, Sweden, (8)Epidemiology and Biostatistics, Drexel University, Philadelphia, PA, (9)Population Health Sciences, Bristol Medical School, Centre for Academic Mental Health, Bristol, United Kingdom, (10)Population Health Sciences, Bristol Medical School, University of Bristol, Bristol, UNITED KINGDOM, (11)Karolinska Institutet, Stockholm, SWEDEN

Background:

Autistic adults are at increased risk of various health conditions and premature mortality. However, there are few population-based studies and most prior studies have employed a cross-sectional study design, which cannot ascertain direction of effects and may have inadequately adjusted for confounding. This current research focuses on somatic conditions of major public concern across the adult lifecourse. We used nationwide longitudinal data and employed population-based cohort and sibling study designs.

Objectives:

1. To assess the relationships between autism and major somatic conditions and premature mortality
2. To assess sex differences and differences by presence of intellectual disability in these relationships
3. To account for the influence of potential unobserved confounding using a sibling study design
4. To estimate absolute risks for public health utility

Methods:

Individuals born between 1940-1990 were selected with entry into the follow-up period (1969-2016) from 18 years of age. Data were from the Swedish Patient, Cause of Death, and Cancer registers. Exposures were: autism diagnosis (versus no autism), autism +/- intellectual disability (ID, vs no autism or ID). The ten outcomes of interest were: dementia, Parkinson’s disease, epilepsy, ischaemic heart disease, stroke, type 2 diabetes mellitus (T2DM), colorectal cancer, lung cancer, fractures and all-cause mortality. Covariates were: birth year, sex and parental educational level. Statistical analysis involved multivariable Cox regression. We repeated analyses, stratifying by sex and using the autism +/- ID exposure. Cox regression with stratification by family id was performed for the sibling analysis, with the autism diagnosis exposure. We used Royston-Parmar survival models to estimate absolute risks and risk differences at age 50.
Results:

There were 4,854,032 individuals in the national cohort analysis, with 26,707 (0.55%) individuals with an autism diagnosis. In the sibling analysis 46,988 individuals were included, with 18,197 autistic individuals. Autism was associated with elevated risks of dementia, epilepsy, Parkinson’s disease, stroke, T2DM, fractures and all-cause mortality (aHR range: 1.25-7.71). The largest effect sizes were for neurological diseases. Sibling analysis estimates were similar in direction and magnitude of effects, indicating little effects from unobserved confounders not shared by siblings (aHR range: 1.23-6.75). There was increased risk of epilepsy, fractures, and all-cause mortality in those autism + ID. Regarding sex differences, there was increased risk for autistic females compared to autistic males for fractures, T2DM and all-cause mortality. While the risks of neurological disorders (e.g. dementia and Parkinson’s disease) were higher for autistic adults, these conditions were reasonably rare in absolute terms. Fractures, T2DM and epilepsy were common in autistic adults, but also common in non-autistic adults. Risk differences at age 50 were generally small in absolute terms, where observed.

Conclusions:

Applying robust study designs and longitudinal analytic methods to nationwide Swedish data, we find that autistic adults compared to non-autistic adults are at higher risk of many somatic health outcomes and mortality in adulthood. Differences by sex and ID status were also uncovered. This information could help researchers and clinicians understand the healthcare needs of autistic adults.

420.021  (Poster) Robust Decline in Self-Reported Autistic Traits Levels Among Autistic University Students – a Yearlong Longitudinal Study

G. Zukerman, G. Yahav and E. Ben-Itzchak, (1)Communication Disorders, Ariel University, Ariel, Israel, (2)Ariel University, Ariel, Israel, (3)Bruckner Center for Research in Autism, Communication Disorder, Ariel University, Ariel, Israel

Background: Growing numbers of autistic university students have motivated more research examining the effects of attending university on this population. Previous research primarily examined well-being and functional indices (such as anxiety/depression or adaptive behavior) among autistic students enrolling in specialized support programs. However, changes in autistic characteristics were not examined

Objectives: In this study, we evaluated, over the course of an academic year, changes in university student autistic trait levels, considered a stable measure of phenotypic expression of autism, using the Autism Spectrum Quotient (AQ, Baron-Cohen et al, 2001). Additionally, changes in psychiatric symptoms (state/trait anxiety, social anxiety, depression, and obsessive-compulsive symptoms) were also studied

Methods: This longitudinal study included 24 neurotypically developed (ND) students with high levels of social anxiety symptoms (High SA), 30 ND students with low levels of social anxiety symptoms (Low SA), and 41 autistic students residing with an ND student peer mentor as part of participating in the university's integration support program. Self-report data were collected during the first semester of two consecutive academic years (T1, T2).

Results: The findings indicated a significant interaction between Group and Time, denoting a significant robust decline (2.9 SD) in AQ total score (overall level) of autistic traits at T2 from T1 among the autistic group and a moderate (.5 SD) decline in AQ total score at T2 among the high SA group. While autistic students reported a sharp decline at T2 from T1 across all AQ domains, the most prominent decline was in attention switching (see Figure 1). Among all three groups, a significant but relatively moderate reduction in state/trait anxiety (< .30 SD) was found, but no significant associations were evidenced between participants’ baseline (T1) levels of anxiety or depression and decreased AQ scores at T2. Only for autistic students were more compulsive symptoms at T1 associated with a lesser decline in AQ scores at T2, and their decreased AQ at T2 was negatively correlated with their year-end grade point average.

Conclusions:

These findings suggest that the autistic university students’ subjective experience of their autism traits may undergo a profound change when attending post-secondary education, and that autism traits, as tapped into by the AQ, may be more malleable than originally thought. Considering the sharp decline in attention switching found in this study, a possible interpretation is that elevated levels of social interaction elicited during one year’s participation in the university's integration program demanded more attention switching and, consequently, was followed by improvement in this attentional ability. Although changes in AQ levels were previously found to be positively correlated with altered anxiety levels among ND students (Kitazoe et al, 2015), this study finding suggests that a decline in AQ scores cannot be explained solely by a reduction in anxiety.

420.022  (Poster) Stress and Well-Being in Autistic Adults: Exploring the Moderating Role of Coping

M. Muniandy, A. L. Richdale and L. P. Lawson, (1)Olga Tennison Autism Research Centre, La Trobe University, Melbourne, VIC, Australia, (2)Department of Psychology, Counselling & Therapy, La Trobe University, Melbourne, VIC, AUSTRALIA
Background: Emerging studies have alluded to high levels of stress and frequent stressful encounters in the autistic adult population. The wider stress literature suggests negative associations between stress and psychological well-being, which is particularly relevant for autistic adults given the poor mental health and well-being frequently reported in this population. The use of approach-oriented (e.g., engagement coping) and avoidance-oriented (e.g., disengagement coping) coping strategies has been related to improved and reduced well-being respectively in autistic and non-autistic adult samples. However, a more in-depth examination of the role of these coping strategies in autistic adults, and the extent to which they may moderate the relationship between stress and well-being remains unknown.

Objectives: The aims of the study were to: 1) explore associations between perceived stress and well-being, and 2) examine the potential moderating (i.e., buffering or exacerbating) role of coping strategies on the relationship between perceived stress and well-being in a sample of autistic adults.

Methods: The sample consisted of 86 Australian-based autistic adults, aged 19-74 years, recruited through an online study. Using a multidimensional approach, perceived stress was measured using a composite stress score, an aggregate of broader general perceived stress (Perceived Stress Scale; PSS) and more specific stress over daily hassles (Daily Hassles Inventory; DSI). Correlation analysis was conducted to explore the associations between stress and well-being (Warwick Edinburgh Mental Well-being Scale; WEMWBS), while two moderation analyses were run to determine whether the stress-well-being relationship was moderated by use of engagement coping and disengagement coping strategies (Brief COPE).

Results: Stress was strongly negatively associated with well-being ($p < .01$). The first moderation analysis revealed that engagement coping had a significant effect on well-being both directly ($b = 0.57, p < 0.01$) and indirectly, through an interaction with stress ($b = 0.21, p < 0.05$). The second moderation analysis showed that disengagement coping only had a significant direct effect on well-being ($b = -0.76, p < 0.01$), with its indirect effect not reaching statistical significance ($p > .5$).

Conclusions: In addition to stress being inversely associated with well-being, we also found that only engagement coping was a significant moderator in the relationship between stress and well-being in our sample of autistic adults. These results suggest differential mechanisms under which engagement and disengagement coping strategies operate in the stress-well-being relationship. Specifically, engagement coping may have both a promotive (direct) and stress-buffering (indirect) role, while disengagement coping may have a risk (direct) role only. Implications in the design of coping supports include a focus on honing engagement coping strategies in autistic adults, where its stress-buffering role may be especially beneficial in the context of high stress. Relatedly, identifying both autistic adults currently experiencing high stress, as well as situations likely to invoke high levels of stress in this population would also be pertinent.

420.023 (Poster) What Autistic Adults Living in a Residential Facility Consider As Important Factors for Their Well-Being?

A. M. Nader$^{1,2,3}$, E. St-Jean$^1$, M. Charette$^4$, B. Forgeot d'Arc$^4$, I. Courcy$^4$, V. Lasalle$^4$ and R. Godbout$^4$, (1)Psychiatry, Université de Montréal, Montréal, QC, Canada, (2)CIUSSS Nord-de-l'Île-de-Montréal, Montréal, QC, Canada, (3)Occupational Therapy, Université du Québec à Trois-Rivières, Trois-Rivières, QC, Canada, (4)Faculty of Design, Université de Montréal, Montréal, QC, Canada

Background: Few autistic adults live independently and most live either with their family or in some form of residential care. Although the built and social living environment are important components of quality of life, few studies have focused on the experience of autistic adults living in group home. Associated conditions are common in autism resulting in further challenges to understand their perspective about their well-being due to a lack of appropriate measures. Therefore, how can we use an inclusive approach to understand what autistic adults currently experiencing well-being due to a lack of appropriate measures. Furthermore, how can we use an inclusive approach to understand what autistic adults currently experiencing high stress, as well as situations likely to invoke high levels of stress in this population would also be pertinent.

Objectives: The purpose of this study is to capture first-person perspective of autistic adults with intellectual and language disability about their well-being in a specifically designed group home environment. Through an inclusive method, this project aims to understand the relationship between autistic’s well-being and the physical/social components of the living environment.

Methods: This study is currently conducted (data collection: September-November 2022) with 14 autistic adults (21-55 years; 8F:6M) living in an autistic-specific residential home. All participants have an intellectual disability (mild to moderate) and significant language limitations (from minimally verbal to understanding/using short sentences). Participants took part individually in 1) a walking interview in which each adult selected and commented 3 significant spaces of their home, followed by 2) a complemented semi-structured interview using visual support (e.g., pictures) and different output modalities (e.g. card-sorting). Walking and semi-structured interview focusses on 4 major domains: physical space, relational/social environment, emotional well-being, occupation/social participation. Coding scheme was used to capture verbal and non-verbal communicative acts (e.g. gaze orientation). A mixed (inductive and deductive) descriptive qualitative analysis of the content was done following a person-environment interaction model.

Results: Overall, the combined method (walking and complementary semi-structured interview) allows participants to share their experience, including for adults who are minimally verbal. Being in the home environment to contextualize questions/answers, using pictures and objects as well as different output modalities are all helpful methods to support understanding and answering. So far, 7 preliminary relevant key themes are identified by participants: 1) positive/negative appreciation of living spaces is strongly related to individual experience (e.g. activities/mood in the space); 2) more importance given to what the environment offers and less to the intrinsic characteristics (e.g. architectural features, furniture); 3) feeling safe at home (e.g. access to an individual secure place), 4) sensory issues, 5)
Social/relational environment (e.g. significant relationships with staff and co-residents); 6) social and emotional regulation (e.g. possibility of being alone or choosing who one is with); 7) individual specific interest as a lever for social participation.

**Conclusions:** This study is one of the first to highlight what autistic adults with intellectual and language disability consider to be important factors associated with their well-being in the context of living facilities, showing that physical, social and occupational components are important. This study shows that it is not only possible but imperative to consider autistic individuals views and experiences for designing homes with and for autistic adults.

**420.024 (Poster) Self-Determination Trajectories in High School and Post-School Community Participation in Autistic Young Adults**

1. Frank Porter Graham Child Development Institute, University of North Carolina at Chapel Hill, TEACCH Autism Program, Chapel Hill, NC, 2) Special Education, San Diego State University, San Diego, CA, 3) Frank Porter Graham Child Development Institute, University of North Carolina at Chapel Hill, Chapel Hill, NC, 4) University of Wisconsin-Madison Waisman Center, Madison, WI, 5) University of Central Florida, Orlando, FL, 6) School of Education, University of North Carolina - Chapel Hill, Chapel Hill, NC, 7) Frank Porter Graham Child Development Institute, University of North Carolina at Chapel Hill, San Diego, CA

Background: Self-determination refers to an individual's causal agency in their lives. Self-determined individuals set and take action to achieve goals based on their interests and values. Opportunities to develop self-determination during the transition to adulthood are critical (Shogren & Wehmeyer, 2017). Promoting self-determination during transition has been found to support more positive post-school outcomes in adults with disabilities, such as employment and community participation (Shogren et al., 2015; Test et al., 2009). Few studies have examined longitudinal studies of self-determination and its impact on community participation from the perspective of autistic individuals.

Objectives: The present study examined trajectories of self-determination in autistic transition-aged youth from adolescence to young adulthood and relationships to community participation after high school.

Methods: Participants included 144 autistic adolescents and young adults (Mean age = 20.1 years, SD = 1.5 years). Self-Determination capacity and opportunity were measured using the AIR Self-Determination Scale Student and Parent reports across three-time points during high school and one post-high school time point (Wolman et al., 1994). Autistic young adults and parents completed the Adolescent and Young Adult Activity Card Sort (Berg et al., 2015) at the post-high school time point. The card sort directly assesses young adults' self-reported and informant-reported current and desired participation in educational, vocational, daily living skills, and social and recreational activities, and barriers for any desired activities. Parents also reported whether or not the autistic adult had a job or educational experience ever since exiting high school and completed the Scales of Independent Behavior-Revised as a measure of adaptive behavior. All growth models were estimated using MPlus Version 8. Fixed effects for linear and quadratic growth models were estimated for self-determination.

Results: A linear growth model best fit the data. At entry into the study, participants, on average, rated their self-determination capacity and opportunities as a 3.6, SE = .05. On average, participants reported a significant increase in self-determination over time. Specifically, students reported a .05-point increase in self-determination scores per year across the five-year data period (β = .52, p = .02). Self-determination trajectories were significantly associated with community participation in vocational activities. Having a higher self-determination score at entry into the study was significantly associated with the young autistic adult having a vocational experience at all since exiting high school (β = .35, p = .01). Autistic young adults who reported more significant gains in self-determination over time reported that they were currently participating in more vocational activities (β = .44, p = .02). Self-determination at entry in the study also significantly predicted parent-reported vocational skills as measured by the SIB-R (β = .28, p = .03). Self-determination trajectories were not associated with educational, daily living skills, or social and recreational activities.

Conclusions: Autistic self-reports of self-determination at entry into the study and gains in self-determination skills over time were associated with vocational activity participation and work-related adaptive behavior skills. Findings suggest that targeting self-determination in high school and earlier may support autistic transition-aged youth participating in vocational activities after they exit high school.

**420.025 (Poster) Sex Differences in Anxiety and Autism Symptom Severity Among Adolescents and Young Adults**

1) TEACCH Autism Program, TEACCH Autism Program, UNC Chapel Hill, Chapel Hill, NC, 2) Psychiatry, TEACCH Autism Program, UNC Chapel Hill, Chapel Hill, NC, 3) Frank Porter Graham Child Development Institute, University of North Carolina at Chapel Hill, TEACCH Autism Program, Chapel Hill, NC, 4) TEACCH Autism Program, Psychiatry, UNC TEACCH Autism Program, Chapel Hill, NC

Background: Autistic individuals are at higher risk of developing a co-occurring anxiety disorder or experiencing anxiety symptoms than non-autistic individuals (White et al., 2009). Current research is conflicted on if higher or lower autism symptom severity is associated with an increased risk of experiencing anxiety (Eussen et al., 2013; Oswald et al., 2016). In non-autistic populations, women experience greater anxiety than men (Gao, Ping, & Liu, 2020). In autistic samples, sex differences in anxiety have not been demonstrated in adolescents.
Sex Differences in Service Utilization and Internalizing Behaviors Among Adults with Autism in Latin America during the COVID-19 Pandemic

Objectives: The primary aim of this study is to examine sex differences in anxiety symptoms among autistic adolescents and young adults. We also examined whether the association between anxiety and autism symptom severity differed for transition-aged autistic males and females.

Methods: Participants (N=180, 72% male, 28% female) were individuals with a prior diagnosis of autism, ages 16-21 (average age = 18.4 years), who participated in a transition to adulthood intervention program (TEACCH School Transition to Employment and Post-Secondary Education Program; T-STEP). Prior to the intervention, participants completed the self-report State-Trait Anxiety Inventory, Trait Scale (STAI-T) and caregivers completed the Social Responsiveness Scale-2 (SRS-2). A linear regression was conducted to assess the moderating effect of autism symptom severity on the association between sex and anxiety in this sample.

Results: Levels of anxiety were high for both autistic males and females—on average, females reported anxiety in the 83rd percentile, and males reported anxiety in the 79th percentile. Multiple linear regression predicting rates of anxiety with sex and autism symptoms was significant (F(3, 176)=4.69, p<.004; Table 1). The R2 for the overall model was 7.4%, with an adjusted R2 of 5.8%. There were significant main effects of sex (b=.19, t(176)=2.55, p=.012) and SRS-2 Total Raw Score (b=.21, t(176)=2.44, p=.016), with females and individuals with higher autism symptom severity reporting higher levels of anxiety. The interaction between sex and SRS-2 was not significant (b=.10, t(176)=1.09, p=.28). These results indicate that in autistic transition-age youth, both sex and autism symptom severity uniquely predict anxiety (Figure 1).

Conclusions: Consistent with our predictions, transition-age autistic females experienced greater levels of anxiety than autistic males. Both males and females experienced high levels of anxiety, averaging in the 81st percentile. Across the sample of autistic transition-age youth, elevated autism symptoms were associated with increased levels of anxiety. Sex differences were not moderated by autism symptom severity. While the scatterplot of anxiety symptoms by autism symptoms (Figure 1) displays a potential interaction between sex and autism symptom severity on anxiety, it is not significant, which may be due to the smaller sample size in females. To better understand how to support autistic transition-age youth experiencing anxiety, future research is needed to explore sex differences in anxiety and the potential effects of autism symptom severity on anxiety levels in males.
There was an almost equal distribution of females (53.6%, n=30) and males (46.4, n=26). More than half of the sample (71.4%) had a diagnosis of Asperger syndrome, while 14.3% reported a diagnosis of autism spectrum disorder (ASD). There were no statistical differences between males and females regarding the type of diagnosis, country of residence, or age. The most commonly used service was medication (26%), with almost half of them (41.8%) maintaining the same medication plan. On the contrary, the least used services were speech therapy and sensory integration (1.8%). During the pandemic, 21.4% suspended services, 48.2% reported significant setbacks, 57.1% experienced an increase in negative mood, and 62.5% increased anxiety compared to pre pandemic. However, there were no statistical differences between males and females for any of these variables.

Conclusions:

Autistic adults living in Latin American countries experienced a significant increment in their internalizing behaviors (e.g., anxiety, mood, and regression) during the pandemic and decreased service utilization and medication. These results highlight the systemic and individual barriers to accessing therapeutic services in Latin America and, at the same time, shed light on how the pandemic has affected autistic adults in this region. In addition, we found no sex differences in internalizing and externalizing behaviors of autistic adults in Latin America during the COVID-19 pandemic, which supports previous reports of a similar prevalence of co-occurring disorders among autistic adults across sexes.

420.027 (Poster) Sexuality and Affective Life in Young People and Adults Diagnosed with Autism in Argentina. Descriptive Study Based in an Online Survey.

Background: Sexuality and intimacy are developmentally important and influence the health and quality of life of all people, including those with autism spectrum disorders (ASD). Research on how young people and adults with ASD perceive sexual and romantic relationships is scarce in Argentina and the Latin American region. This information is of great importance to help clinicians and families to make decisions regarding the need for supports and for risk prevention.

Objectives: To describe the supports, needs, and challenges regarding affective and sexual life in young people and adults with autism spectrum disorders in Argentina based on an online survey.

Methods:

An online survey was designed to investigate about affective life and sexuality in people with autism over 16 years of age living in Argentina.

The survey was structured into the following categories: 1) gender identity and sexual orientation; 2) access to information; 3) interest in social and romantic relationships; 4) Sexual and romantic experiences; 4) Barriers to access sexuality.

An exploratory analysis of the data was performed. Descriptive statistics such as mean values, standard deviation, and frequencies (absolute, percentage, and cumulative) were obtained. The responses were analyzed using Statistical Package Social Science, version 23.00 (SPSS 23.00)

Results:

156 people with a diagnosis of ASD between 16 and 55 years old (M = 30.76; SD = 9.23) completed the survey (66% female biological sex). 46.8% identified themselves as female, 32.7% male, 9% non-binary, and 2.6% transgender. Regarding sexual orientation, 47.4% defined themselves as heterosexual, 12.2% asexual, 12.2% bisexual, 8.3% pansexual, and 5.1% homosexual. Of the total number of respondents, 94% stated that they had social relationships, 77% reported having had at least one love relationship and 80.1% some sexual practice. Differences were observed in the proportion of responses by biological sex: 87.4% of female-biological-sex respondents reported having had an affair compared to 56.6% of the male biological sex.

The most relevant results are related to barriers: 75.7% of female respondents revealed having experienced a situation of risk or abuse, while among males it represented 35.8%. 78.6% of females reported that their sensory profile interfered with their affective or sexual relationships, while among males it represented 50.9%. In addition 61% of the whole sample indicated using "not very useful" strategies to approach other people in search of a love relationship.

Conclusions:
Sexuality and affective life in people with autism have not been systematically studied in Argentina. Our results are consistent with previous international studies regarding the report of positive sexual functioning and the desire to have social and loving relationships (Byers, 2013 et al.; Gilmour, et al., 2012), and the greater risk of sexual abuse and victimization in women within the spectrum (Sevlever, et al. 2013).

These preliminar results are relevant to guide future research that systematically explores sexuality in this population in Argentina. It is essential to count on reliable information to guide public policies to improve the quality of life of young people and adults with autism.

### 420.028 (Poster) Social Anxiety Symptoms in Autistic Young Adults: Comparing the Cognitive, Emotional, and Physiological Components of Emotion Regulation

**S. A. Lehman**, E. J. Adler, A. D. Haendel, N. S. Gordon and A. V. Van Hecke, (1)Psychology, Marquette University, Milwaukee, WI, (2)Department of Psychology, Marquette University, Milwaukee, WI, (3)Speech-Language Pathology, Concordia University Wisconsin, Mequon, WI

Background: Research suggests that autistic people engage in adaptive emotion regulation strategies less frequently (Samson et al., 2014), identity emotions less readily (Kinnaird et al., 2019), and exhibit increased physiological arousal (i.e., low HRV) (Cheng et al., 2020) compared to their neurotypical counterparts, all of which have been associated with anxiety symptoms (Cai et al., 2018; Moskowitz et al., 2013; Oakley et al., 2020). Prior research has primarily focused on autistic children or adolescents, and commonly relied on one method (i.e., self-report) to capture the multifaceted construct of emotion regulation (Conner et al., 2020). Additional multi-method research with autistic young adults is necessary for understanding how emotion dysregulation results in the manifestation of social anxiety during this critical transition period. The prevalence of social anxiety in the autistic population underscores the importance of this work (Spain et al., 2018).

Objectives: The present study utilized cognitive (i.e., use of suppression and use of reappraisal), emotional (i.e., alexithymia traits), and physiological (i.e., respiratory sinus arrhythmia (RSA) and heart period (HP)) measures to ascertain whether components of emotion dysregulation contribute to social anxiety in autistic young adults.

Methods: 63 autistic young adults ages 17-29 (M= 20; 18% female) completed self-report measures assessing usage of specific emotion regulation strategies (i.e., suppression and reappraisal) (ERQ; Gross & John, 2003), alexithymia traits (TAQ; Bagby et al., 1994) and symptoms of social anxiety (LSAS; Fresco et al., 2001). Physiological data were collected using a BIOPAC ambulatory heart rate monitor and electrocardiogram (ECG) electrodes. Participants sat quietly for three minutes to obtain baseline heart data. To calculate RSA, the Porges’ method was implemented with the CardioEdit and CardioBatch programs utilizing data from the frequency band representing spontaneous breathing in adults (i.e., .12-.40 Hz) (Porges, 1985; Riniolo & Porges, 2000). To calculate HP, successive interbeat intervals were averaged. Covariates of age and gender were included.

Results: Social anxiety symptoms were positively correlated with suppression (r(63)=0.39, p<.01) and alexithymia (r(63)=0.49, p<.001). Social anxiety was not correlated with reappraisal, RSA, HP, age, or gender. Backwards hierarchical regression revealed that suppression (β1=0.34, t(61)=3.07, p<.01), reappraisal (β2=0.35, t(61)=3.33, p<.001), and alexithymia (β3=0.42, t(61)=3.92, p<.001) significantly predicted social anxiety symptoms. This model accounted for 40.8% of the variance in social anxiety symptoms (R²=0.408, F(3,59)=13.58, p<.001).

Conclusions: Findings indicate that greater usage of suppression, less usage of reappraisal, and alexithymia traits are predictive of increased social anxiety symptomatology in autistic young adults. Notably, RSA and HP did not significantly correlate with or predict social anxiety symptoms. Possible explanations include the usage of baseline heart rate data or a small sample size. This multi-method research highlights the importance of the cognitive and emotional aspects of emotion regulation in the manifestation of social anxiety in autism. This study provides preliminary support for the prioritization of cognitive and emotion-focused therapies with a neurodivergent-affirming provider to support autistic young adults with social anxiety. Future research is needed to clarify the significance of the physiological aspect of emotion regulation for autistic young adults who experience social anxiety.

### 420.029 (Poster) Steering Control Differences Emerge during Curve Negotiation Based on Autistic Traits and Attention

**G. M. Sherrod**, R. K. Kana, H. M. Bednarz, A. M. Svancara, B. McManus, S. Mrug and D. Stavrinos; (1)Department of Psychology, University of Alabama at Birmingham, Birmingham, AL, (2)University of Alabama, Tuscaloosa, AL, (3)University of Alabama at Birmingham, Birmingham, AL

Background: Negotiating horizontal curves safely and effectively requires adept control of steering adjustment, speed, and lane positioning, as well as accurate perception of road segment curvature and adjustment to proprioceptive cues. As such, this maneuver requires heightened use of cognitive resources such as attention and executive function. Prior research has revealed differential performance in these cognitive functions in autistic individuals, as well in driving maneuvers involving steering and turning. This suggests that autistic drivers may differ in their curve negotiation strategies relative to their non-autistic counterparts.
Objectives: To examine the effects of dimensional autism symptoms and executive functioning on steering behavior during curve negotiation in a driving simulator environment.

Methods: Thirty-one licensed adolescent and emerging adult drivers ($N_{ASD} = 13$, $N_{TD} = 18$) matched on age ($M = 20.00; SD = 2.75$), gender ($N_{female} = 19$, $N_{male} = 12$), and IQ ($M = 105.97; SD = 16.12$) were recruited. Participants completed a 13-mile experimental drive containing one right curve and one left curve in a high-fidelity driving simulator. The Autism Spectrum Quotient (AQ) was used as a continuous measure of traits related to autism in both groups. Further, participants completed various measures of executive functioning (EF). For analysis, EF scores were reduced using a Principal Components Analysis (PCA). Generalized Estimating Equations (GEE) using a Poisson distribution were used to estimate the number of lane exceedances and steering reversals across curve segments for each curve individually. Predictor variables included AQ Sum Score and EF component scores, with driving experience as a covariate.

Results: PCA yielded 2 component scores, titled Inhibition and Information Processing and Selective and Divided Attention. Drivers who endorsed more autistic traits demonstrated greater difficulties in steering recovery and compensatory maneuvering compared those reporting fewer traits. Poorer attention capacity was related to increased likelihood of lane exceedances during typical curve negotiation, as well as reduced likelihood of using corrective steering maneuvers (i.e., fewer steering reversals) when needed.

Conclusions: Drivers who endorsed more autistic traits demonstrated greater difficulties in steering recovery and compensatory maneuvering compared those reporting fewer traits. Increased steering reversals and lane exceedances may put autistic drivers at a higher risk for run off road crashes during challenging curves. Findings have the potential to inform targeted driver education protocols for this population, as these data suggest that steering control may be largely implicated in challenges experienced by autistic drivers. Additional investigation is needed to discern if difficulties navigating complex driving situations are a function of challenges with motor planning and execution, differences in gaze patterns, visuomotor integration difficulties, and/or other underlying processes, as well as the extent to which degrees and types of complexity affect driving behavior among autistic individuals.

420.030 (Poster) Suicidal Ideation and Behavior Mediates the Relationship between Executive Functioning and Quality of Life for Transition-Age Autistic Youth

Background: Autistic advocates identify quality of life and mental health as leading research and clinical priorities. Many autistic teens and young adults report a lower quality of life and elevated rates of suicidal ideation and behavior (SIB). Scientists have identified executive functioning as a predictor of quality of life for autistic people. However, this literature has not addressed the possibility that observed relationships are in fact mediated by other key factors – in particular, SIB. In non-autistic populations, suicidal ideation and behavior are associated with both executive function and quality of life. SIB may be a critical driver of quality of life independent from executive functioning skills, or it may mediate the relationship. Illuminating how SIB interplays with executive function on quality of life outcomes is vital for determining which factors the field needs to intervene upon to improve patient-centered outcomes, such as quality of life.

Objectives: To determine the association between executive functioning and SIB with subjective quality of life ratings for transition-age autistic youth.

Methods: Participants included 161 autistic adolescents without an intellectual disability diagnosis (ages 16-19 years) who enrolled in an online study about independent transportation and driving. All caregivers completed a broad psychiatric screener that included items about executive functioning and SIB (Behavior Assessment System for Children, 3rd Edition), and adolescents completed the NIH PROMIS Global Quality of Life scale (7 questions). We conducted two path analysis models (executive function$\rightarrow$suicidal behavior$\rightarrow$quality of life; suicidal behavior$\rightarrow$executive function$\rightarrow$quality of life) and one model of two independent direct effects (executive function$\rightarrow$quality of life; suicidal behavior$\rightarrow$quality of life) with maximum likelihood estimation (Figure 1). Significance testing of mediation effects were complemented with estimates of indirect effect sizes using a 95% bootstrapped confidence interval (CI) based on 20,000 bootstrapped samples. CIs that do not contain zero indicate significant mediation.

Results: 22% of the sample endorsed SIB. SIB significantly mediated the relationship between executive function and quality of life ($p<0.001$, CI does not contain 0), but executive function did not significantly mediate the relationship between SIB and quality of life ($p=0.287$, CI contains 0). The model of two independent direct effects was also significant, but a lesser fit than the mediation model (Table 1).

Conclusions: This study meets the call of the autistic community to illuminate paths that contribute to lower quality of life in transition-age youth. Here, we establish that executive functioning only has an indirect effect on quality of life, and that SIB has the direct effect. These findings emphasize the importance of SIB on quality of life and the potential role that executive functioning may play in the SIB of autistic
Background: Research suggests that autistic adults are vulnerable to age-related cognitive decline (Pagni et al., 2022), co-occurring mood conditions (Lever & Geurts, 2017), ongoing social challenges (Walsh et al., 2019), and attenuated quality of life (Braden et al., 2022). Despite this, supports for autistic adults beyond young adulthood are exceptionally limited.

Objectives: 1) To describe protocol development for the Strengthening Skills Program (SSP), a multi-component program for autistic adults of all ages that aims to empower participants to improve their quality of life. 2) To examine and compare feasibility and acceptability of SSP and an adapted version of the PEERS social skills program.

Methods:

Development and iterative revision of the protocol was based on focused interviews with stakeholders and feasibility and acceptability data from a pilot RCT comparing SSP and PEERS (Fig. 1). The study team included an autistic doctoral student and autistic consultants provided feedback on program content. Focused interviews included 5 autistic adults (30-68 years; 3 male) and 4 stakeholders selected by the autistic adults (e.g., family/friend). Separate 90-minute interviews were conducted with autistic adults and stakeholders to identify priorities and solicit feedback and suggestions regarding topics and format of SSP.

Pilot RCT participants included 42 adults (Age=41.43±13.99 years; 59.5% male) who met criteria on the ADOS-2 and up to one program partner of each participant (i.e., family/friend). Across two cohorts (Fall 2021, Spring 2022) participants were randomly distributed across three groups: SSP (n = 14), PEERS (active comparator; n = 14), or delayed treatment control (DTC) (n = 14). Random assignment was stratified by age, gender, and presence of a program partner.

Both programs were delivered through Zoom during the pandemic. SSP participants attended weekly 3-hour group meetings that included discussion of cognitive compensation skills (e.g., habit formation; external memory aids), mindfulness-based strategies, and strategies adapted from the PEERS social skills program for young adults. PEERS participants attended weekly 90-minute group meetings. Feasibility and acceptability were assessed by examining fidelity of implementation checklist data and quantitative and qualitative responses on a post-program participant satisfaction questionnaire.

Results: Fidelity of implementation ranged from 94-100% for SSP (M=99%) and 85-100% (M=97%) for PEERS. Descriptive statistics and themes identified from qualitative responses on the post-program participant satisfaction survey are reported in Table 1. Composite acceptability scores on the participant satisfaction survey for SSP participants were significantly higher than PEERS participants (t(19) = 2.21, p = .04).

Conclusions: Iterative development of SSP resulted in a program that has promising feasibility and acceptability. Attrition was higher in the SSP group (36%) relative to PEERS (14%), which may indicate reduced feasibility of a 3-hour program relative to a 90-minute program. Acceptability composite scores indicated that SSP had higher acceptability than PEERS. Although there was considerable overlap in qualitative themes across the two programs, limitations of PEERS were related to program content and method, whereas limitations of SSP were related to program format. Delivery of the revised program protocol with DTC participants is ongoing; future research will examine effectiveness of SSP.

Background: Interpersonal synchrony, or the temporal coordination of one’s own behaviors with the behaviors of others, mediates social exchange to establish natural interactions and facilitate rapport. However, interpersonal synchrony is often attenuated between autistic individuals and their interaction partners (Georgescu et al., 2020). It is not yet clear whether this attenuation stems from issues with motor production or difficulties in perceiving the timing of others’ behaviors. Little research has investigated how interpersonal synchrony is perceived in autism; thus, the contribution of perception warrants investigation.
Objectives: Approaching this gap from a participant’s perspective, the present study aims to clarify how interpersonal synchrony is behaviorally perceived in individuals with and without autism, as well as parsing features of the interaction that may influence interpersonal synchrony perception formation.

Methods: 33 autistic (11 women, age M(SD) = 35.16(10.52) years) and 29 non-autistic (11 women, age M(SD) = 34.31(11.68) years) individuals participated in two 10-minute conversational tasks with a non-autistic stranger, who was a research assistant naïve to the participant’s diagnostic status. Videos of the interaction were recorded and analyzed with Motion Energy Analysis to assess nonverbal movement synchrony between partners. Participants also reported how synchronous they perceived the interaction to be and their experience of rapport (e.g., likeness of the partner) with the partner. Linear models and linear mixed effects models were used to analyze the data.

Results: In line with previous work, dyads including an autistic individual produced less movement synchrony than dyads of two non-autistic individuals. Moreover, autistic participants reported perceiving the interaction as less synchronous than non-autistic participants. Interestingly, there was no effect of movement synchrony production on synchrony perception or rapport. However, there was an effect of rapport on reported synchrony perception.

Conclusions: Our findings suggest that behavioral synchrony perception may be altered in autism, and hints that access may be limited to the low conscious processing of synchronous behaviors, wherein rapport may instead guide behavioral synchrony perception formation.

420.033 (Poster) The Driving Profile of Individuals with Autism Spectrum Disorder

A. Mercier, G. M. Sherrod and D. Stavrinos, (1)Psychology, The University of Alabama at Birmingham, Birmingham, AL, (2)Department of Psychology, University of Alabama at Birmingham, Birmingham, AL.

Background: A major developmental milestone facilitating the transition into adulthood, by increasing functional status and quality of life, is the ability to drive; however, only 1 in 3 individuals with ASD obtain licensure by age 21 (Curry et al., 2021). Evidence suggests that autistic drivers are not generally at greater risk of negative driving outcomes, but face unique challenges based on skills needed in specific driving contexts. By understanding the differential needs of autistic drivers, researchers can develop and implement effective and adapted interventions to increase this population’s driving skills and, thus, quality of life.

Objectives: Identify, systematically organize, and critically evaluate driving behaviors and impairments related to the safe operation of a motor vehicle to determine a comprehensive understanding of the driving profile of autistic individuals.

Methods: Data was systematically (PRISMA, 2009) extracted by two independent reviewers from articles that met pre-specified inclusion criteria: published in English between 2000 and 2021, peer reviewed, included a sample of people with ASD or people working with those with ASD. Methodology used in studies examining autistic drivers included: 18 simulators, 11 qualitative reports, 4 computers, 3 on-road observations, 1 mixed methods. Results were extracted and driving skills were organized and evaluated at the strategical (planning the drive), operational (operating the vehicle), and tactical (maneuvering the vehicle within the environment) levels of driving based on the theoretical framework proposed by Michon’s Hierarchal Model of Driving (Michon, 1985).

Results: The 37 qualifying articles included a comprehensive sample of studies with a wide range of sample size (N=7-609) and driver age (15-60 years). 89.7% ASD drivers who obtain their permit later obtain their license, although time between permit and license is 9.2 months longer than that of non-autistic drivers.

The social and cognitive impairments commonly associated with ASD impact the driving experience. To compensate, autistic drivers adapt their driving behavior and environment within the strategical level of driving to increase predictability and consistency within their driving environment. At the operational level of driving, autistic drivers exhibited challenges in driving simulators, but qualitative reports by both parents and driving instructors as well as on road performance show less underperformance in these skills. The biggest challenges faced by autistic drivers are at the tactical level of driving (e.g., multitasking, response to the driving environment, reaction to unpredictable situations). Despite the challenge of tactical skills, autistic drivers show similar to lower rates of adverse driving outcomes, including crashes, violations and suspensions on-road compared to typically developing drivers.

Conclusions: Autistic drivers report challenges and display deficits in driving skills particularly in self-report or in a driving simulator, but these impairments do not directly translate to on-road driving. Autistic drivers place restrictions on themselves to increase safe driving behavior and experienced autistic drivers show fewer driving skill deficits. Continued research focused on autistic drivers is needed to provide a comprehensive understanding of their driving behaviors and advocate for implementation of strategies to increase licensure amongst safe drivers, thereby increasing quality of life throughout adulthood.

420.034 (Poster) The Experiences of Autistic Medical Students: A Phenomenological Study
Background: Increasing recognition of autism, and particularly late-diagnosed autistic adults, is reflected in the growing awareness of autistic healthcare providers. Regulatory bodies including the UK General Medical Council and the UK Medical Schools Council have published guidance that actively fosters inclusion. Little is known about the numbers of autistic students studying medicine. The total number of students at English universities identifying as autistic more than doubled between 2014/15 and 2020/21. Medicine and dentistry have relatively lower proportion of students identifying as disabled compared to other disciplines, although numbers had risen from 8.3% in 2014/15 to 11.1% by 2018/19. Whilst many autistic doctors and students are thriving, most do not disclose their diagnosis unless difficulties arise, which unfortunately perpetuates stereotypes.

Objectives: No studies have explored the experiences of autistic medical students. We aimed to fill this void.

Methods: This was an interpretive phenomenological study by an autistic-led research team. Phenomenology is a qualitative methodology grounded in social constructionism, which strives to explore the ‘lived experiences’ of participants, while interpretive phenomenology also embraces the subjective experiences and beliefs of the researcher. As such, this study design is well suited to teams including insider researchers. This was an important consideration, as our research team includes two autistic doctors. Autistic medical students were recruited using Facebook announcements. Those who consented to participate underwent audio-recorded, loosely structured interviews. Recordings were transcribed and underwent an interpretive phenomenological analysis.

Results: Five participated from five different UK medical schools. Themes included: autistic profiles and stereotypes; sensory processing, the learning environment and its impacts; diagnosis, identities and masking; peers, socialising, isolation and role models; seeking help, reasonable adjustments and medical school processes. Participants reported a variety of strengths and challenges. They all agreed that being autistic carried strengths which could benefit the profession. In fact, the ability to help autistic people provided an incentive to persevere with their studies with one participant describing a desire “to figure myself out and help others like me”. Common challenges centred around uncertainty, social concerns, and a lack of structure or routine. Communication was a strength and a challenge, dependent on context. The well-defined social roles within patient interactions facilitated ease and skill. As one participant explained, “I’m a lot better with patients than I am with my peers, with staff, which is hard for a lot of people to understand.” All had disclosed being autistic to their medical schools. Some had disclosed to clinical supervisors, with varying degrees of success.

Conclusions: Participants longed for understanding and support, but reported experiences of isolation, bullying and anxiety. Most felt themselves to be victims of the system; expected to adapt themselves to appear non-autistic. When participants reported difficulties, most were advised to take time out. None were offered personalised adjustments. All reported strengths associated with being autistic, including attention to detail, a methodical approach, and heightened empathy. This supports the idea that autistic individuals can be safe, effective, and skilled doctors.

420.035 (Poster) The Impact of COVID-19 on the Mental Health and Socioeconomic Outcomes of Autistic Adults in the United Kingdom: A Prospective 12-Month Follow-up Study. J. Findon, R. A. Hoekstra, M. Cella, and F. Cotier, (1)Department of Psychology, Institute of Psychiatry, Psychology and Neuroscience, King’s College London, London, United Kingdom, (2)Department of Psychology, Institute of Psychiatry, Psychology and Neuroscience, King’s College London, London, UNITED KINGDOM

Background: The COVID-19 pandemic has had a significant impact on mental health and socioeconomic outcomes. Autistic adults, who are already at increased risk of poor mental health are likely to have been disproportionately affected. Understanding the experiences of autistic adults across the course of the pandemic is crucial to ensure targeted support in the post pandemic age.

Objectives: The current study aims to explore the mental health and socioeconomic impact of the COVID-19 pandemic on autistic adults in the UK over a 12-month period using a longitudinal design.

Methods: A total of 3614 participants (Mage = 52.67(12.4), Female = 87.4%) completed an online survey between 8th April and 11th May 2020. Participants self-reported on symptoms of anxiety (Generalized Anxiety Disorder-7 [GAD-7]) and depression (Patient Health Questionnaire-9 [PHQ-9]) and their experiences of the pandemic. At baseline we included two versions of the GAD-7 and PHQ-9 – one assessed retrospective symptoms (T0) before the onset of the pandemic, the other assessed current symptoms (T1). The sample included 133 adults who declared a clinical diagnosis of an autism spectrum disorder (ASD). Participants also responded at +3Months (T2; n=2312), +6months (T3; n=1774) and +12Months (T4; n=1911).

Results:

At all time points symptoms of anxiety and depression were higher among autistic adults compared to non-autistic adults. In both groups there were significant (p<.001) and large increases in anxiety and depression symptoms from T0 to T1. Symptoms of anxiety gradually
declined from T2-T4 and returned to baseline levels by T4 in both groups. However, while depression symptoms gradually declined in the control group, they remained high in the ASD group. A mixed model ANOVA revealed a significant group*time interaction indicating that the difference in PHQ scores widened between T3 and T4 (f=6.39, p<.05). Autistic adults reported more frequent socio-economic impacts than controls across a range of domains including being unable to do paid work (ASD: 34.1%, control: 19.3%), being unable to access medication (ASD: 22%, controls: 8.1) or essential services (ASD: 46.3%, controls: 27.2%; see also Table 1). Multiple regression analysis predicting depression scores at T4 indicated significant effects of autism diagnosis (β=3.7), lack of access to services (β=2.7), lack of access to paid work (β=1.1) and lack of access to medication (β=3.9).

Conclusions: Our findings reveal that the COVID-19 pandemic has had a significant long-term impact on the mental health and socioeconomic outcomes of autistic adults. Furthermore, autistic adults have been disproportionately impacted compared to non-autistic adults, widening existing inequalities. Autistic adults reported greater socioeconomic impacts, and these impacts in turn predicted enduring depression symptoms. These findings highlight the need for targeted support for autistic adults to address barriers in service access and to support their long-term mental health.

420.036  (Poster) The Impact of Cognitive Impairment on Service Utilization Among Transition-Aged Youth with ASD
C. C. Bradley, A. D. Boan and L. Carpenter, (1)Developmental-Behavioral Pediatrics, Medical University of SC-Developmental Pediatrics, Charleston, SC, (2)Medical University of South Carolina, Charleston, SC

Background: Transition from adolescence to adulthood is a critical period for individuals with autism spectrum disorder (ASD). While transition outcomes for youth with ASD have been previously described, few studies have evaluated the service utilization patterns of youth and young adults with ASD and ID leading up to and including transition years.

Objectives: The goal of this study was to describe and compare service access and utilization by young adults with ASD (with and without ID), ID alone, and population controls (PC) during the specific period of transition from childhood to adulthood (ages 17-23).

Methods: Using record linkages with state agency datasets and a cohort of individuals with ASD and/or ID identified via the South Carolina Autism and Developmental Disabilities Monitoring Network (SC ADDM), transition-period service utilization and access was analyzed for transition-aged youth ranging in age from 17 to 23 years. Four groups were compared: ASD-only (n=315), ASD+ID (n=291), ID-only (n=1,271), and PCs identified via birth certificate records frequency matched 5:1 to ASD cases (n=2973). Generalized linear mixed model derived estimates were used for pair-wise comparisons with covariate and multiple-comparison adjustments.

Results: Those with ID-only were more likely to have received mental health services than PC, and all 3 disability groups had more mental health encounters than PC. ASD+ID were more likely to be eligible for state disability-specific services, and among those eligible, were more likely than individuals with ASD-only to utilize these services. Fewer than half of those eligible actually utilized disability-specific services regardless of group. Youth with ASD+ID were far more likely than the other three groups to have out of home placements. Those with ASD+ID were also more likely than those with ASD-only or ID-only to qualify for Medicaid and to have outpatient medical encounters. These participants had more healthcare providers, and were more likely to be prescribed psychotropic medications. Those with disabilities were more likely than PCs to receive therapeutic interventions during the transition period, but rates were low across all three disability groups (less than 1/3). Those with ASD+ID were also far more likely to be enrolled in school during the transition period.

Conclusions: Results indicate that participants with ASD+ID represent a distinct group with higher service utilization during the transition years than those with ASD or ID alone. Those with ASD+ID were more likely to receive physical health, mental health, and educational services during the transition period. They were also more likely to qualify for disability-specific insurance benefits during the transition years than those with ASD or ID alone. These results indicate that those with ASD or ID alone may be “under-treated”. Although many are eligible for services, relatively few, particularly within the ASD-only and ID-only groups, are receiving services during this key transition time period, representing the need for early and targeted interventions to ensure that patients are able to access necessary supports and services during the critical period of transition from adolescent to adulthood.

420.037  (Poster) “I Live in Extremes”: Understanding Autistic Adults’ Phenomenological Experiences of Inertial Rest and Motion
H. Rapaport, H. Clapham, J. Adams, K. Porayska-Pomsta, W. Lawson and E. Pellicano, (1)Macquarie School of Education, Macquarie University, Macquarie University, NSW, Australia, (2)UCL Institute of Education, University College London, London, United Kingdom, (3)Macquarie School of Education, Macquarie University, Sydney, NSW, Australia, (4)Department of Clinical, Educational and Health Psychology, University College London, London, United Kingdom

Background: The term ‘inertia’ was adopted by the Autistic community several decades ago to refer to the seemingly common experience of remaining in a mental and physical state of rest or motion until there is some form of intervention. Although ‘Autistic inertia’ is now part of the Autistic community’s everyday lexicon, the condition has received scant attention in the scholarly literature. The little attention it has received has narrowly focused on ‘inertial rest’ (i.e., difficulties with initiating tasks), with minimal exploration of ‘inertial motion’ (i.e., difficulties with stopping).
Objectives: Here, we sought to investigate Autistic people’s phenomenological experiences of inertial rest and motion. Furthermore, we aimed to identify underlying mechanisms and moderators of inertia, and the everyday impact of Autistic inertia.

Methods: We adopted a participatory approach in which Autistic and non-autistic researchers worked together as a team to design and implement this study. Twenty-four Autistic adults (Mage = 44.3 years, range: 19 – 71 years; 11 women, 7 men, 4 non-binary, 2 other) agreed to take part in in-depth semi-structured interviews over Zoom, conducted by an Autistic or non-autistic researcher. Participants were asked about their difficulties with starting and stopping tasks, including how these experiences made them feel, the duration and frequency of these experiences, their perceived causes, what helps, and the impact of starting and stopping difficulties on their everyday lives. We followed Braun and Clarke’s method for reflexive thematic analysis to analyse the data using an inductive (bottom-up) approach within a critical realist framework.

Results: We identified four themes relating to Autistic experiences of starting and stopping everyday tasks. Themes and associated subthemes are summarised in the figure below. Interviewees spoke in-depth of their inertial “difficulties moving from one state to another” (Theme 1) and described how these challenges pervade “every single day” (Theme 2). While inertia was described as “the single most disabling part of being Autistic” (Theme 3), interviewees also described some effective ways to respond to it (Theme 4), including taking pleasure in states of flow, when they could become completely “engrossed” in a task.

Conclusions: While participants’ emphasised that inertial difficulties are “very human problems”, our findings reveal the often-extreme nature of these difficulties for Autistic people. Our findings also contribute to a more holistic characterisation of inertia as both a disabling and enabling condition. We discuss these findings within the context of predictive coding models of autism and propose divergent precision weighting as one possible mechanism underlying Autistic inertia. Specifically, we suggest inertia may be the product of a neural system that ascribes relatively high salience to prediction error signals, irrespective of context.

**420.038 (Poster)** Within-Family Differences in Autistic Traits and Young Adults’ Sibling Relationship Quality

*A. Jensen* and *M. A. Brown*, *(1)Brigham Young University, Provo, UT, (2)School of Family Life, Brigham Young University, Provo, UT*

**Background:**

Research highlights that those with autism spectrum disorder (ASD) have lower sibling relationship quality compared to those with other disorders such as Down syndrome (Aksoy & Yildirim, 2008; Pollard et al., 2013) and intellectual disability (Tomeny et al., 2017; Travers et al., 2020). Among those with ASD, a higher level of autistic traits (AT) is also linked to poorer sibling relationship quality (Hastings & Petelas, 2014; Orsmond et al., 2009). Each of these studies, however, makes comparisons between families. Between-family comparisons mask the potential of the role within-family differences in AT may play in shaping sibling relationship quality in families with more than two children. For example, although siblings are typically similar in AT (Hoekstra et al., 2007), a young adult may develop a better relationship with a sibling who has fewer AT than other sibling(s) in the family.

**Objectives:**

Examine within-family differences in AT among siblings as linked with seven dimensions of sibling relationship quality: closeness, conflict, ill-wishes, upward comparison, parent-mediated relationships, contact, and desired contact.

**Methods:**

Data come from 490 young adults, with at least two siblings, living in the United States (reporting on 1215 sibling relationships). Participants ranged between 18 and 29 years old (Mage = 25.38, SD = 2.52). The sample was mostly female (57%) and Caucasian (73%). Participants reported each of their siblings’ AT using the Autism Spectrum Quotient questionnaire (Baron-Cohen et al., 2001) and their relationship quality with each sibling using the Emerging Adults’ Relationships with Siblings Scale (Jensen et al., 2022). Data were collected via Amazon Mechanical Turk.

**Results:**

Analysis was conducted in separate multilevel models for each relationship quality variable, controlling for important demographic variables. Each dependent variable was modeled as the deviation from the family mean. We included the average of the AT among all siblings in the family and the sibling’s deviation from the family mean.

Results revealed (see Table 1) that young adults who perceive a sibling to be higher in AT relative to other siblings in their family report comparatively less closeness (b = -.01, se = .01), less upward comparison (b = -.01, se = .00), less parent mediation (b = -.02, se = .00), more contact (b = .04, se = .01), and a greater desire for contact (b = .04, se = .02).
Conclusions:

Overall, these results suggest young adults’ relationships with siblings who are higher in AT than other siblings in the family are multifaceted. On one hand, they feel less close to and engage in less comparison with those siblings. On the other hand, they engage in more contact, want more contact, and rely less on parents to maintain their relationship. It is possible that young adults are more proactive in connecting with their sibling highest in AT as a means of supporting them, even if they feel less close. These findings highlight the potential role of differences between siblings in shaping the nature of young adults’ sibling relationships.

420.039 (Poster) The Relationship between Autism and Suicide: Risk Factors and Potential Mitigation Strategies

D. Su and T. L. Procyshyn, (1)University of California, Los Angeles, Los Angeles, CA, (2)Autism Research Centre, Department of Psychiatry, University of Cambridge, Cambridge, United Kingdom

Background:

Suicide is a global problem, and individuals with autism may be at particular risk due to risk factors such as comorbidities with mental illnesses, poor self-esteem, social isolation, lack of supportive relationships, and psychosocial stressors. Suicidality among autistic people is an emerging area of research. To understand risk factors unique to autistic people, the Interpersonal-Psychological Theory of Suicide (IPTS) model for the general population was modified by Pelton and Cassidy (2017) to include predictors for suicide based on autistic traits. However, there is a lack of understanding of factors related to suicidality among young autistic adults without intellectual disability. Thus, there is a pressing need for a psychological theoretical model to analyse suicidality risks in this population.

Objectives:

1. To summarise the current literature surrounding suicidality for young autistic adults without intellectual disability.
2. To expand upon the IPTS model of suicide, as modified by Pelton and Cassidy (2017).

Methods:

This scoping review was conducted using Google Scholar. It focused on scientific articles published in peer-reviewed journals from 1994 to 2022, with an emphasis on those that sampled young autistic adults without intellectual disability. The search included the key words “autism”, “suicide”, “risk factors”, “comorbidities”, and “suicide prevention”. Articles were included in the synthesis even if they contained samples of non-autistic suicidal young adults, as the findings were still potentially pertinent to the research objectives. The final number of articles included was 55.

Results:

The findings suggest that existing suicide support mechanisms, such as peer support groups, therapy, and safety planning, for young adults with autism without intellectual disability fit into the main components of the IPTS model—perceived burdensomeness, thwarted belonging, and capability for suicide, respectively. There appear to be gaps in the literature pertaining to suicide support mechanisms catered to young autistic adults without intellectual disability, which is a particularly vulnerable group (e.g. Hannon and Taylor, 2013). Based on the literature review, we propose a new dimension of the IPTS model (Figure 1): the intersection between perceived burdensomeness and thwarted belonging, as the existing model does not capture all aspects of perceived burdensomeness and thwarted belonging, and that not every autistic trait falls neatly into one category or another. Potential interventions that target the new dimension of the model would include vocational education groups for employment and modified therapeutic approaches.

Conclusions:

Areas for further improvement of existing suicide support mechanisms include adapting the models to accommodate autistic people and including autistic people in the field of suicide research. While the research surrounding suicidality for autistic adults is emerging, there appears to be gaps in breadth and depth. The IPTS model for autistic traits states that three factors contribute towards suicidality. This may be improved to apply to young autistic adults by including the overlap between perceived burdensomeness and thwarted belonging. Areas for future research include interdisciplinary collaboration between the autistic community and researchers to identify the causes of suicide, implementation of autism-specific risk assessment and prevention tools, and education of clinicians and the general public about autism and suicide.

420.040 (Poster) The Reliability and Validity of a Novel Autistic Burnout Measure Among Neurodiverse College Students

Background: Autistic burnout (ABO) is a recently-described phenomenon characterized by periods of exhaustion, social withdrawal, poorer executive functioning and quality of life, and more, which putatively occurs in autistic individuals after exposure to prolonged stressors such as social and sensory burdens (e.g. Raymaker et al., 2020). Despite ABO’s hypothetical role in pathways to depression and suicidality in autistic people, few studies have explicitly attempted to investigate it. ABO has not been fully operationalized or quantitatively measured in the peer-reviewed literature, nor has its association with mental health been explored quantitatively.

Objectives: The present study sought to (a) evaluate the internal consistency of a novel measure attempting to operationalize ABO, and (b) explore whether ABO exhibits convergent and discriminant validity with theoretically-related and unrelated variables. ABO was hypothesized to be positively associated with autistic traits, depression, anxiety, stress, social anxiety, repetitive thinking, and repetitive behavior, as well as gender, birth sex, and sexual orientation (since sexual and gender minorities often report higher levels of internalizing symptoms), and negatively correlated with engagement in passionate interests and availability of friendships. Age, race, ethnicity, and university one attends were hypothesized to have no correlation with ABO.

Methods: First-semester college students (N=62) completed a survey battery at the end of the fall 2021 semester as part of a larger longitudinal study (Table 1). Participants either reported a formal diagnosis of autism (n=8), suspected undiagnosed autism (n=19), or were non-autistic (n=35). Autism was measured dimensionally using the Social Responsiveness Scale, 2nd Edition (SRS-2; Constantino & Gruber, 2005). Reliability of a novel 8-item ABO survey was assessed using Cronbach’s Alpha. Cross-sectional Pearson correlations and one-way ANOVAs were used to determine ABO’s convergent and discriminant validity via its associations with mental health and demographic variables.

Results: The ABO scale items exhibited high internal consistency (α=.91). Participants did not differ on ABO scores by self-reported autism status (Table 1), but dimensional autistic traits (SRS-2) exhibited a large positive correlation with ABO scores (Table 2). ABO was positively associated with all hypothesized variables but, contrary to hypotheses, not associated with levels of engagement with passionate interests and friendships. As expected, ABO was not associated with age, race, ethnicity, or university.

Conclusions: A new measure of ABO demonstrated strong internal consistency. Hypothesized correlations largely support the ABO measure's convergent validity, while hypothesized nonsignificant correlations (i.e., age, race, ethnicity, university) support its discriminant validity. These results affirm ABO’s potential ties with symptoms of depression and anxiety, stress, and repetitive thinking and with sex/gender. However, it remains unclear whether a measure of ABO can distinguish burnout as an autism-specific phenomenon. Further efforts are needed to establish if ABO is autism-specific and how ABO may fit into the time course and etiology of mental health concerns, namely depression and suicidality, in autism.

420.041 (Poster) What Do Autistic Adults Need to Attain Employment Fast? L. K. Fung1, M. Gavartin1, C. Matta2 and L. Mohamed2, (1)Psychiatry and Behavioral Sciences, Stanford University, Stanford, CA, (2)Stanford University, Palo Alto, CA

Background:

About 80% of autistic adults are unemployed or under-employed. Although the general employment outcomes are known to be poor, little is known about factors driving attainment of job opportunities and the duration of job search needed to achievement employment.

Objectives:

This study is part of a larger on-going investigation in determining the effects of a specialized employment program (a psychosocial intervention) on job retention and quality of life. In this presentation, we focus on the participants’ baseline data and their employment outcomes. We hypothesize that participants with higher level of social skills knowledge will attain employment sooner.

Methods:

Eligibility criteria for participating in the study include: (1) documented diagnosis of autism, (2) age 18 to 55 years, (3) IQ >59, and (4) current job seekers. Participants received support in preparation of their interviews. Investigators negotiated with employers on accommodations that can reduce participants’ level of anxiety. Employers also received training on awareness of neurodiversity and best practices in recruiting autistic adults. Demographic information as well as behavioral measures (Autism Spectrum Quotient (AQ), Test of Young Adult Social Skills Knowledge (TYASSK), Rosenberg’s Self-Esteem Scale (RSES)) were collected at baseline. Descriptive
Background: Initial research has identified a higher co-occurrence of transgender identity among autistic individuals than among the general population. Some transgender individuals access gender-affirming healthcare through gender dysphoria diagnoses. While gender dysphoria is a condition stemming from incongruence with gender identity and sex assigned at birth, the diagnosis is often a politically fraught requirement to receive healthcare. Claims data has never been used to examine trends and demographics of transgender autistic individuals receiving gender dysphoria diagnoses. Medicaid is a major insurer of both autistic and transgender patients, especially as both populations are at increased vulnerability to poverty. Recent speculation proposes that this population is growing. Currently in the U.S., state laws dictate whether and how gender-affirming care can be covered under Medicaid. However, we do not yet know how this state-by-state healthcare provision impacts autistic patients. National data from systems delivering services to autistic transgender youth and adults is needed to describe necessary service and system improvements.

Objectives: This study used Medicaid claims data to 1. understand the general demographic trends among the Medicaid patient population receiving both ASD and GD diagnoses, and 2. Analyze state policies to better contextualize these rates.

Methods: Descriptive statistics were calculated for demographic and Medicaid enrollment characteristics. Two groups were defined: 1. An autism claims group (N = 467,321). 2. A control group (N = 1,730,686) representing a random sample of 3.5 million Medicaid beneficiaries with no ASD nor intellectual disability (ID) claim. We compared the ASD and control groups using t-test for age, and χ² tests for all other categorical variables.

Results: The prevalence of enrollees with GD claims was higher among the ASD sample than the control sample, with .34% or 340 per 100,000 having both GD and ASD claims as compared to .04% or 39 per 100,000 GD claims in the non-ASD control sample. The estimated GD prevalence per 100,000 autism claims for those 9 years increased from 9 per 100,000 in 2008 to 150 per 100,000 in 2016. Comparatively, the GD prevalence among the control sample increased from 6.5 per 100,000 claims in 2008 to 47 per 100,000 claims in 2016. Most enrollees with both claims were children, which was similar to the control group. However, more racial diversity and enrollees who were assigned female at birth were present in the ASD group versus control. There was substantial variation by state that reflected state laws, but also indicated the presence of major gender clinics was important for states without explicit laws.

Conclusions: The Medicaid population receiving both autism and gender dysphoria claims is growing – faster than the general population – and is less white, male, or young than the previous literature suggests. We offer this data to specifically discern the characteristics of this population to help better support them, and argue for more integration of Medicaid claims to understand the impact of state policy on healthcare.
The Wider Experiences and Contexts of Camouflaging for Autistic and Non-Autistic Individuals

H. L. Moore, J. Baggaley, S. A. Cassidy and J. Rodgers, (1)Newcastle University, Newcastle upon Tyne, UNITED KINGDOM, (2)School of Psychology, Newcastle University, Newcastle upon Tyne, United Kingdom, (3)School of Psychology, University of Nottingham, Nottingham, UNITED KINGDOM, (4)Population Health Sciences Institute, Newcastle University, Newcastle upon Tyne, United Kingdom

Background:

There is a wealth of literature surrounding the causes and consequences of camouflaging for autistic individuals. Research is limited about the wider contexts affecting camouflaging behaviours and also the decisions to camouflage. There is also no in-depth research to date to understand the camouflaging experience for non-autistic individuals.

Objectives:

To understand the wider experience of camouflaging for autistic and non-autistic individuals.

Methods:

Participants were recruited through volunteer databases and social media. Data were available for 478 autistic 175 non-autistic adults, all of whom identified as camouflaging in their daily lives. Among other measures relevant to the wider study, participants completed an online survey about the reasons for, and positive and negative consequences of camouflaging, as well as contexts in which individuals camouflage. This research analyses the free text responses from participants using an inductive, semantic, thematic analysis. Two coders individually coded the data using a critical realist approach, and met regularly to compare coding and themes.

Results:

Five themes were identified: 1) Awareness of camouflaging; 2) Impressions; 3) Transactions; 4) Mental Health; and 5) Context. Awareness of camouflaging describes how individuals either consciously or unconsciously camouflage, and whether the decision to camouflage is automatic vs. intentional. Some individuals described a transition in their awareness of and participation in camouflaging behaviours, as a result of greater awareness of autism and/or camouflaging as a construct. Impressions describes those self-imposed by the individual, through ideas about how people should behave and the impression they want to give, as well as external factors such as judgement from others. Participants also described resulting damage to self-identity, fears about identity management if contexts mixed, and concerns about perceptions by others if they were discovered. Participants described camouflaging as transactional, to further goals such as career, friendships, avoid negative consequences, or even to reduce conversation length. For many, there were mental health implications attached to camouflaging. This varied between participants, with some camouflaging to hide mental health difficulties, while others experienced mental health difficulties as a consequence of either camouflaging or not camouflaging. Context described how an individual or a place could influence whether an individual felt the need to camouflage, due to factors such as feeling safe or accepted. Longstanding relationships, trust in the individual, and shared experience were described as individual factors, as well as being at home or alone as safe places. Differences in experience of autistic and non-autistic individuals will be discussed, where relevant.

Conclusions:

Camouflaging is a very individual experience with different participants citing different causes, consequences, and circumstances in which they are comfortable to be themselves. While the literature and our own findings show that camouflaging has negative consequences, it has a very important purpose. We need to understand more about how to create environments where people feel comfortable to present as their non-camouflaging selves.
Objectives: The overall aim of this was to explore the strengths and challenges of intersectional experiences and healthcare needs of adults who identified as autistic and gender diverse.

Methods: Twelve gender-diverse autistic adults (mean age= 27 years, SD= 9). Participants described their gender as: non-binary (n=5), transmasculine (n=3), non-binary female (n=1), non-binary/agender (n=1), genderqueer (n=1), and genderqueer woman (n=1). Participants completed an online semi-structured interview (n=2) or an open-ended survey (n=10). Reflexive thematic analysis was used to analyse the data, following the six phases of analysis (Braun and Clarke, 2013;2022).

Results: Three key themes were generated from this data: (1) navigating a gender journey - participants felt they understood gender differently from neurotypical cisgender individuals and emphasised the importance of self-authenticity. (2) The impact of social context on self – participants discussed both increased discrimination and invalidation, but also facilitative relationships founded in commonality. (3) Provision of healthcare – participants stated that healthcare professionals lack awareness of the co-occurrence of autism and gender diversity which limits the support they receive and reflects a lack of training. Participants discussed the negative experiences they had faced more generally when accessing healthcare but also identified ways in which autistic gender-diverse adults could be better supported.

Conclusions: This study builds on recommendations from previous research that qualitative research must better understand the experiences and needs of this under-served community. Here we extend knowledge in this area by capturing the experiences of the intersection of autism and gender diversity in adulthood. The findings demonstrate the intersection of being both an autistic and gender-diverse adult can present individualised challenges but can also be a positive experience. Results also highlight the difficulties that autistic gender-diverse participants experienced when trying to access support. This study contributes to this limited evidence base by provide novel and important insights on the intersection of autism and gender diversity in adulthood and has important implications for clinicians and healthcare provisions.

420.045 (Poster) Trait Anxiety, Camouflaging and Adjustment to College in Women with and without Autism Symptomatology
D. Davidson and D. Morales; (1)Psychology, Loyola University Chicago, Chicago, IL, (2)Loyola University Chicago, Chicago, IL

Background:

Females may express autism symptomatology differently than males and therefore may be less likely to be diagnosed (Loomes et al., 2017). For example, females may engage in more camouflaging behaviors during social situations (e.g., making eye contact) than autistic males (Hull et al., 2020; Lai et al., 2015). Although potentially beneficial, camouflaging behaviors are associated with increased anxiety (Halsall et al., 2021). In conjunction with high rates of trait anxiety (Jolliffe et al., 2022), this can make adjustment to college difficult.

Objectives:

Objectives were: (1) to explore group differences in trait anxiety, camouflaging and adjustment to college in women with and without autism symptomatology and (2) to examine the unique contributions of autism symptomatology, trait anxiety and camouflaging behaviors on adjustment to college.

Methods:

Participants were 102 female college students attending a university in the U. S. (Midwest region). Table 1 provides demographic information for the sample. Following informed consent, students completed these online measures: autism symptomatology (Social Responsiveness Scale-2; Constantino & Gruber, 2012), trait anxiety (trait subscale, State-Trait Anxiety Scale; Spielberger et al., 1993), camouflaging (Camouflaging of Autistic Traits; Hull et al., 2019), and adjustment to college (Student Adaptation to College Questionnaire-SACQ; Baker & Siryk, 1999). SACQ adjustment subscales assessed for this study were academic (managing of academic demands), social (integration into social settings) and personal-emotional (psychological and physical well-being). On the SRS-2, a raw score cutpoint value of 70 or greater can be indicative of autism symptomatology (Constantino & Gruber, 2012). Cronbach alphas were good to excellent (α = .88-.94) on all measures.

Results:

Table 1 presents group comparisons on the study variables including t, p, and d values, and means and standard deviations. Females with autism symptomatology reported significantly higher camouflaging behaviors and trait anxiety, and lower academic, social and personal-emotional adjustment to college, than those without autism symptomatology. Pearson correlation analyses showed that camouflaging behaviors were related to increased trait anxiety and negatively related to adjustment types, p’s < .05. Linear regression analyses showed that autism symptomatology and trait anxiety were significant predictors of academic adjustment to college, whereas only trait anxiety was a significant predictor of social and personal-emotional adjustment. Autism symptomatology approached, but was not significant for social adjustment. Camouflaging was not a significant predictor of adjustment (see Table 2).
Conclusions:

Results showed that women with autism symptomatology experience more trait anxiety, camouflaging behaviors and less adjustment to college than those without autism symptomatology. Autism symptomatology and trait anxiety were significant predictors of academic adjustment, suggesting that both affect the student’s ability to manage the academic demands of school. In contrast, only trait anxiety was a significant predictor of social adjustment (i.e., social integration) and personal-emotional adjustment, or students’ mental (e.g., psychological distress) and physical (e.g., sleep) well-being. Although camouflaging was not a significant predictor of adjustment, camouflaging was negatively related to adjustment scales. Camouflaging was also related to higher trait anxiety. Study findings suggest that college support programs targeting anxiety in women with autism symptomatology—regardless of formal diagnostic status—may be particularly beneficial.

420.046 (Poster) Transdiagnostic Approaches to Supporting Mental Health of Autistic Adults.

Background: Co-occurring psychiatric conditions are common in autistic adults, with many experiencing multiple anxiety and mood disorders (Joshi et al., 2013; Jadav et al., 2022). This suggests transdiagnostic approaches targeting symptoms across conditions may be beneficial. Brief and problem-focused interventions to support individuals through periods of distress (e.g., postsecondary transition; COVID-19 pandemic) and treatments that teach strategies that can be applied to a variety of situations that cause or maintain depression or anxiety are needed.

Objectives: To describe the development of two transdiagnostic approaches to support the mental health of autistic adults:

1) Self-guided Emotional Safety Plan (ESP-S), a brief telehealth and mobile intervention, modeled after suicide safety plans (Brown & Stanley, 2012), designed to help autistic adults anticipate and prepare for distressing situations;

2) Group Behavioral Activation Therapy (GBAT, Chu et al., 2009), a 10-week group designed to treat non-autistic youth was adapted for telehealth for autistic adults with depression, anxiety or anger.

Methods:

ESP-S: Written and video-based instructions and materials to support ESP-S creation were developed by a team of autistic and non-autistic students and faculty. Six college students provided feedback immediately after creating their ESP-S and after 14 weeks (NCT04926090).

GBAT-A: GBAT was adapted to improve appropriateness for adults. Five autistic adults completed GBAT-A (NCT04788212). Based on feedback, autistic and non-autistic adult collaborators are further adapting GBAT-A to enhance content relevance and engagement to boost participation and skill generalization; enhanced GBAT-A is currently being tested with two additional groups (n=10; NCT05512221).

Results:

ESP-S: On a scale of 1-3, students indicated that materials to support creation of ESP-S were all somewhat (2) or very helpful (3) (M=2.25-3) and creation of the ESP-S was neutral (3)-to-very easy (5; M=3.7). Some indicated it would have been more helpful to have someone walk them through the process than do it on their own. After 14-weeks, ratings were neutral-to-positive regarding how helpful the self-guided intervention was for them (Fig.1). One participant felt the ESP-S had not had a positive impact on them because their therapy had covered this information, but that the ESP-S may be helpful to someone who did not already have coping strategies in place. Self-rated Emotion Dysregulation Inventory (Mazefsky, personal communication) showed some improvement (d=.457).

GBAT-A: In the original GBAT-A group, on a scale of 1-4, overall quality was rated as Good to Excellent (M=1.5), participants endorsed being Mostly to Very Satisfied with the help they received (M=1.25). Feedback highlighted a need for individual sessions and activities to allow more practice and personalized supports to increase generalizability of the lessons. Individual sessions added to the groups, as well as video-based educational materials and additional activities to personalize content are currently being developed and tested. Self-reported adaptive behavior, depressive and anxiety symptoms showed improvement (Fig.2).

Conclusions: Preliminary results support further efforts to refine both the ESP-S and GBAT-A. Discussion will center around how autistic engagement at different levels (participant feedback, consultants and co-developers) and stages of each project has critically informed
adaptation and development of these interventions.

**420.047 (Poster) Exploring Friendships between College Students with and without Intellectual and Developmental Disabilities**

*L. S. Athamanah, Educator Preparation & Leadership, University of Missouri - St. Louis, Saint Louis, MO*

**Background:** Despite nearly 25 years of federally mandated transition services, youth with intellectual and developmental disabilities (IDD), including autism spectrum disorders, still experience poor post-school outcomes compared to their peers without disabilities (Bouck, 2012). Inclusive postsecondary education (IPSE) programs for students with IDD have been created and housed at colleges and universities nationwide to produce better post-school outcomes. Higher education provides a unique context for students with and without IDD to build friendships, engage in the campus community, and build social networks (Author et al., 2020; Bumble et al., 2019; Gibbons et al., 2018).

**Objectives:** While IPSE programs have developed rapidly over the past ten years, this growth demands a response by researchers to help identify best practices for promoting an equitable and inclusive campus community for those with and without IDD. Social peer programs allow students to learn and work together in supportive and inclusive educational environments. Thus, this study aimed to explore the insight and experiences of participants in a social peer program. This study was guided by the following research question: *How was your experience in the Social Peers program?*

**Methods:** Using a qualitative case study design, this study focused on the inclusive experiences of four participants, two students without IDD and two students with IDD. Data were collected through pre- and post-program individual semi-structured interviews with each participant, and students without IDD participated in two focus groups during the program. Data are analyzed by reading the transcripts and then conducting a thematic analysis with a triadic coding scheme (Strauss & Corbin, 1998) to identify the main themes and topics that emerge from the data.

**Results:** Two preliminary themes have emerged from the data: (1) **Missed Opportunities for Friendship** and (2) **Potential Campus Community Benefits**.

**Missed Opportunities for Friendship.** Students enjoyed the Social Peers program and were pleased to see a program like this on a college campus. They felt the program provided an opportunity to meet and get to know college students they may not have met had the program not existed. Several participants expressed dismay that they were not exposed to a program like this earlier in their schooling because they missed out on potential friendships.

**Potential Campus Community Benefits.** While the Social Peers program was small, students discussed how this program could potentially change the campus community for the better. They felt that the more students saw students with and without IDD together on campus and in familiar places (e.g., dining hall, classrooms), the inclusion of students with IDD would become “normal” and provide equitable opportunities to interact with each other in a typical social space.

**Conclusions:** IPSE programs are crucial in providing equitable college experiences for students with IDD. An essential part of attending college is developing friendships, which can be complicated for these students. Thus, programs like the Social Peers program can provide an opportunity for students with and without IDD to socialize in supportive and integrated environments.

**420.048 (Poster) Transportation Use and Barriers for Employed and Unemployed Autistic Adults**

**Background:** Autistic adults are significantly unemployed or underemployed even compared to other disability groups. Employment is a social determinant that, when satisfied, closely influences health-related quality of life. For autistic adults, limited transportation options are a primary barrier to employment and independence as it limits employment opportunities. This study provides a closer examination of the association between transportation use and employment status.

**Objectives:** To examine the use of different types of transportation and barriers to public transit by employed and unemployed autistic adults.

**Methods:** The data was from a large, statewide study conducted between May 2017 and June 2018 using the Pennsylvania Autism Needs Assessment (PANA), in which information about employment and transportation use was obtained from autistic adults who were residents of Pennsylvania. The study sample included 1120 autistic adults (Mage=28.03 years, SD=9.84; 70% men; 82% non-Hispanic white).
Results: Participants who were employed were more likely to drive themselves than those who were unemployed (45% vs. 21%, p<0.001), while they were less likely to take rides from others (62% vs. 75%, p<0.001) or use service transportation (11% vs. 18%, p=0.001). For barriers to public transit, identified that employed participants reported fewer barriers to public transportation than unemployed participants with a small effect size (1.98 vs. 2.54, d=0.22).

Conclusions: Employed autistic adults exercise more transportation independence. Unemployed autistic adults report more barriers to participation and less ability to independently use public transportation. Future transportation and employment studies are necessary.

420.049 (Poster) Treatment of Menopausal Vasomotor Symptoms (VMS) and Sensory Issues: A Case-Based Approach in a 53-Year-Old Caucasian Autistic Woman
A. Rynkiewicz1, N. Hadijkhani1, R. Moseley1, J. M. Turner-Cobb1, A. Ossolińska2 and I. Lucka2; (1)Department of Psychiatry, College of Medical Sciences, University of Rzeszow, Rzeszow, POLAND, (2)Center for Diagnosis, Therapy and Education SPECTRUM ASC-MED, Gdansk, Poland, (3)Gillberg Neuropsychiatry Center, Gothenburg University, Gothenburg, Sweden, (4)MGH, Martinos Center for Biomedical Imaging, Harvard Medical School, Charlestown, MA, Sweden, (5)Department of Psychology, Bournemouth University, Poole, United Kingdom, (6)Students Research Club, Department of Psychiatry, College of Medical Sciences, University of Rzeszow, Rzeszow, Poland, (7)Department of Developmental Psychiatry, Psychotic and Geriatric Disorders, Medical University of Gdansk, Gdansk, Poland

Background: Adult autistic women are still under-recognized (Rynkiewicz et al. 2019). Of more than one billion women aged 50 and over, it is unknown how many are autistic and experiencing menopause. Still considered a taboo topic in many societies, little research exists on how menopause affects autistic women’s health and well-being. Existing studies suggest this often-difficult transition period is associated with many unmet health needs, a frustrating lack of knowledge and support from healthcare professionals, and an absence of resources dedicated to this population (Karavidas &Visser 2022; Rynkiewicz et al. 2022; Moseley et al., 2021). Menopausal vasomotor symptoms (VMS), or hot flashes and night sweats, are cardinal symptoms of menopause. While VMS are experienced by the majority of women during menopause, in autistic women such symptoms may intensify and worsen sensory sensitivities (Groenman et al. 2022).

Recently, more adult women without intellectual disability have pursued a formal autism diagnosis to define their own autistic identity. This often helps them learn to more effectively recognize warning signs of sensory difficulties and meltdowns, and can lead to the self-discovery of unexpected strength, resilience, and confidence in advocating for their needs.

Objectives: to investigate menopausal VMS experienced by an autistic woman and examine whether symptoms are linked to autistic traits and sensory issues.

Methods: This case-study describes a 53-year-old Caucasian autistic woman without intellectual disability, diagnosed at age 43 by a trained psychiatrist, and currently experiencing menopausal symptoms. Anxiety and depression were previously recorded and treated pharmacologically, but she currently has no other comorbidities or somatic illnesses, and was not taking medication at the start of recording. Tests completed include: the ADOS-2 (Module 4) and ADI-R; a modified version of the Girls Questionnaire for Autism Spectrum Condition for adult women (Brown et al. 2020), focusing on sensory difficulties and profile; the Social Communication Questionnaire (Lifetime scale); the Autism-spectrum Quotient; and the Menopause-Specific Quality of Life Questionnaire, measuring vasomotor, physical, psychosocial, and sexual menopausal symptoms. Gynecologic and hormonal lab testing were also conducted. Hormone replacement therapy (HRT) was introduced to ameliorate symptoms of estradiol and progesterone deficiency.

Results: Over a period of 7 months after HRT implementation, hot flashes, night sweats, foggy thinking, vaginal dryness, mood swings and anxiety decreased. Strong sensory issues were linked to more severe VMS. A healthy Mediterranean diet, physical outdoor exercise and mindfulness practice were implemented in the patient’s daily routine for potential positive effects on well-being. Standardized assessments confirmed ASD diagnosis and the presence of sensory difficulties.

Conclusions: Intensity of VMS symptoms were observed in relation to strength of sensory issues, as found by Groenman et al. (2022). Sensory perception and intellectual processing appear to influence how VMS symptoms are interpreted, labeled, and reported. Since gynecologists often lack fundamental knowledge on ASD, this highlights the need for further research to inform treatment plans, including HRT and non-pharmacologic approaches that could be offered to autistic women during menopause.

S. M. Bury1, R. Jellett2, A. Haschek2, M. Wenzel2, J. R. Spoor3 and D. Hedley4; (1)Olga Tennison Autism Research Centre, La Trobe University, Melbourne, VIC, Australia, (2)Swinburne University of Technology, Melbourne, VIC, Australia, (3)Olga Tennison Autism Research Centre, La Trobe University, Bundoora, VIC, Australia, (4)Flinders University, Adelaide, VIC, Australia, (5)Department of Management & Marketing, La Trobe University, Melbourne, VIC, Australia, (6)Olga Tennison Autism Research Centre, La Trobe University OTARC, Melbourne, VIC, Australia

Background: Prior research has tabulated preferences for identity- or person-first language amongst persons with an autism diagnosis (e.g., Kenny et al., 2016). The current study differs from this previous body of research by examining quantitative predictors of language preferences. Utilising a social identity theoretical approach (SIA, Dirth & Branscombe, 2018), the current research investigates whether the centrality of an autism identity to the person reported in qualitative literature (e.g., Botha et al., 2020) leads to participants embracing terms
that prioritizes their identity (e.g., identity-first terms) and reject terms that distance their self from the diagnosis (e.g., person-first terms). Additionally, within SIA approaches, threats (e.g., stigma, discrimination) to minority group identity can lead to attempts by ingroup members to distance themselves from or hide aspects of their identity (Barreto & Ellemers, 2011). Thus, greater experiences or internalisation of stigma may lead participants distance themselves from their threatened minority groups status, by preferring terms that downplay autism (e.g., person-first terms). Finally, qualitative research suggests that how and where one learns about autism and the quality and nature of information provided, can be an important part of how one develops and expresses an autism identity (MacLeod et al., 2013; Riccio et al., 2021). Thus, we would posit that those who have more accurate and less stigmatised autism knowledge, would be more immune to negative autism stereotypes, and express this through the endorsement of identity-first language.

Objectives: This current study investigated psychological and social factors that might underlie language use and preference within the autistic community, specifically whether autism knowledge, internalised stigma, and autism identity predict participants preference for, or the offensiveness of autism labels.

Methods: 198 Australian adults with a formal diagnosis of autism ($M_{age}$=34.89; 29.3% male; 56.1% female, 14.6% non-binary) were recruited to an online survey via email and social media. Participants rated on a 7-point Likert scale their preference for, and the offensiveness of, four person-first (Person with Autism, Person on the Autism Spectrum, Person with ASD, and Person with ASC) and two identity-first autism terms (Autistic, Autistic Person). Participants also completed measures of autism knowledge (Gillespie-Lynch et al., 2015), experiences of stigma (Ritsher et al., 2003), and autism identity (Leach et al., 2008), as well as demographic variables.

Results: Regression results (Table 1) indicated a stronger autism identity was associated with a greater preference for identity-first terms and finding these terms less offensive. Contrastingly, stigma was associated with finding identity-first language less favourable and more offensive. Interestingly, a more recent diagnosis was associated with finding identity-first terms less offensive. Preferences for or offensiveness of person-first terms was not explained by the autism knowledge, internalised stigma, and autism identity variables.

Conclusions: These findings add to the discussion about language preferences in autism. Findings suggest decision making around identity-first language is influenced by a strong sense of autistic identity, experiences of stigma, and timing of when participants received their diagnosis.

420.051 (Poster) Understanding Motivation Regulations to Physical Activity in Young Adults with Autistic Traits

D. Morales and D. Davidson; (1)Loyola University Chicago, Chicago, IL, (2)Psychology, Loyola University Chicago, Chicago, IL

Background:

Individuals with autism spectrum disorder (ASD) are often less physically active and engage in more sedentary behaviors than their peers without autism (Kuo et al, 2014; Soden et al, 2012). Specifically, individuals with ASD engage in physical activity (PA) less frequently and at lower intensity and duration levels than their neurotypical peers (Gehricke et al., 2020; Hillier et al. 2020; Stanish et al., 2017). Self-determination theory (SDT; Deci & Ryan, 1985) provides a lens to examine the different motivations behind why a person does, or does not, engage in a behavior. As such, SDT is appropriate for understanding the motivations behind PA engagement (Hamm & Kim, 2018).

Objectives:

Motivation to engage in PA was examined quantitatively and qualitatively in young adults with autistic traits. Giving a voice and first-hand account to young adults with autistic traits can result in deeper understanding of the motives behind PA engagement.

Methods:

Thirty young adults (43% white, 67% identified as female) participated in an online survey. Table 1 has all demographics. Participants completed the Social Responsiveness Scale-2 (SRS-2, Constantino & Gruber, 2012) to assess for the presence of autism traits. This sample was taken from a larger study and only included participants scoring above threshold on the SRS-2. SRS-2 raw scores above 69 can be used clinically to recommend screening for autism and has been previously used in underdiagnosed populations (e.g., females; Hull et al., 2020; Lai et al., 2017). Additional measures included the Behavioral Regulations in Exercise Questionnaire – 3 (BREQ-3; Cid et al., 2018) used to assess self-determination across amotivation, external, introjected, integrated, and intrinsic regulation subscales, and self-reported physical activity frequency, duration, and intensity (see Table 2). An open-ended question was also provided: “What motivates you to engage in physical activity?”

Results:

Young adults with autistic traits engaged in PA on average 3 days per week, for 40-minute intervals, and at moderate intensities (Table 1). In addition, this sample showed higher introjected and identified self-motivation regulations and were less motivated by amotivation and
external regulations (Tables 1 & 2). Qualitative analysis of the open-ended question validated the BREQ-3: young adults (39%) provided anecdotes of being motivated by identified regulations. However, an additional theme emerged that suggested motivation was rather multi-faceted and was dependent on context and situation (Table 2).

Conclusions:

The findings underline the need to assess the various factors which motivate an individual with autism traits to engage in PA. PA behaviors in adults with autistic traits are on par with meeting PA guidelines (at least 150 minutes/week of moderate-vigorous PA). Both the BREQ-3 scores and qualitative responses suggest that young adults with autism traits are highly motivated by identified regulations. Identified regulations are based on conscious values that are personally important. Results suggest that identifying the benefits and positive outcomes of PA (i.e., mental and physical health benefits) may be more likely to motivate a person with autism traits to participate in PA than to gain an external reward or avoid a punishment (i.e., external regulation).

420.052 (Poster) Self and Caregiver-Reported Changes in Positive Affect during the Transition to Adulthood Among Male and Female Autistic Adults

J. B. McCauley, H. K. Schiltz, E. B. Clarke and C. Lord, (1)Saint Mary's College of California, Moraga, CA, (2)UCLA, Los Angeles, CA, (3)CART, UCLA, Los Angeles, CA, (4)UCLA Semel Institute for Neuroscience and Human Behavior, Los Angeles, CA

Background: The transition to adulthood is a period of uncertainty for many autistic individuals. They frequently experience challenges in obtaining and maintaining normative adult outcomes such as employment (Clarke et al., 2021) and independent living (Dudley et al., 2019), and report high rates of loneliness (Schiltz et al., 2021) and internalizing symptoms (Hollocks et al., 2021), with evidence that autistic females may experience adulthood differently than males (Taylor & DaWalt, 2020). To better promote positive transitions, characterizing happiness and well-being during adolescence and adulthood is an essential pursuit.

Few studies have examined caregiver- and self-reported internal states across time in this population from a strengths-based perspective (see Pelicano et al., 2022). As autistic individuals are increasing their relative independence during the transition to adulthood, we aim to examine the consistency in patterns of positive affect across reporters for men and women on the spectrum.

Objectives: The current study explored 1) concordance between self- and caregiver-report positive affect during the transition to adulthood, (ages 15-29), 2) change in self-reported and caregiver-reported positive affect in autistic individuals and 3) changes across time by participant gender.

Methods: Participants (n = 42; 21% female) were drawn from a longitudinal cohort followed from age 2 through adulthood. Participants and their primary caregivers (reporting on participants) completed the Positive and Negative Affect Scale (PANAS; Watson et al., 1988) up to five times (ages 15, 20, 23, 25, 29). Correlations were used to examine associations across reporters at multiple ages, and multilevel modeling was used to examine PANAS positive subscale composite score across time and by gender.

Results: Correlations between caregiver-reports and self-reports on positive affect revealed varying patterns of associations across time. Between 15 and 19 years old, self-report and caregiver report agreement was low (r = 0.12). However, there was significant agreement between ages 19 and 21 (r = 0.30**), 21-24 (r = 0.42***), and 24 and 30 (r = 0.23**).

Multilevel modeling revealed a significant main effect of age, indicating a negative slope in self-reported positive affect from age 15 to 30. There was also a significant interaction effect of gender and age, which indicated the slope for female participants (b = -1.10) to be steeper than the slope for male participants (b = -0.31).

Using caregiver-reported data, we found only a marginal main effect of age, and a significant interaction with gender. Simple slopes revealed a small negative slope for male participants across time (b = -0.19), but a significant positive slope for female participants across time (b = 0.53).

Conclusions: We found declines in positive affect over time using both self- and caregiver-reports. Despite our small sample size, we found moderate concordance between self- and caregiver-report positive affect which varied as a function of participant age during adulthood. We identified divergent patterns of change across time for autistic women by reporter, with self-report indicating more negative slopes than men, and caregiver-report indicating positive slopes. Findings indicate a need to consider the experiences and perspectives of autistic women during the transition to adulthood.

420.053 (Poster) The Role of Social Competence in Achieving Normative Adult Outcomes

E. B. Clarke and C. Lord, (1)CART, UCLA, Los Angeles, CA, (2)UCLA Semel Institute for Neuroscience and Human Behavior, Los Angeles, CA
Background: An autism diagnosis does not preclude the ability to engage in meaningful, adaptive social behaviors. Though some socially-impairing aspects of ASD—such as narrative skills, prosody, and eye contact—may be resistant to change, individuals with autism can display social competence through other behaviors such as sharing, cooperation, and use of emotional coping skills. Strengths in aspects of social functioning not directly associated with core features of autism could promote positive developmental cascades for autistic individuals. However, little work has replicated longitudinal findings from the general population that adolescent social competence predicts positive adult outcomes in ASD. The current project sought to characterize social competence in ASD and examine associations between adolescent social competence and normative adult outcomes.

Objectives: 1) Characterize social competence trajectories as measured by VABS social age equivalence (AE) scores from ages 2-26, 2) examine convergence between VABS social-AE trajectories with two measures of social competence collected in early adolescence—the Social Skills Questionnaire (SSQ), and the prosocial domain of the Strengths and Difficulties Questionnaire (SDQ), and 3) examine the utility of scores from age 14 for all three social competence measures in predicting work, friendship, and romantic outcomes in adulthood.

Methods: 253 adults with ASD were drawn from an ongoing longitudinal study. The VABS was administered 8 times from ages 2-26. The parent- and self-report SSQ and teacher-report SDQ were administered at approximately age 14. Employment, friendship, and romantic relationship data were compiled from self- and parent-report demographic forms. Group-based trajectory modeling was used to identify trajectories in social competence development as measured by the VABS social domain. Multilevel modeling was used to investigate convergence between SSQ and SDQ scores from adolescence and VABS social-AE trajectories. Logistic regressions were used to examine the predictive validity of VABS, SSQ, and SDQ scores from age 14 for normative adult outcomes.

Results: We identified two patterns of social competence development: a low trajectory characterized by slow linear gains throughout childhood and plateauing in adulthood, and a high trajectory characterized by steeper linear gains in childhood followed by decline in adulthood. Multilevel modeling indicated that caregiver-report and self-report SSQ scores from adolescence and non-verbal IQ at age 9 were associated with faster growth in Vineland Social-AE scores for the High Social-AE trajectory group. In contrast, teacher-report SDQ prosocial scores from adolescence were associated with faster growth in Vineland Social-AE scores in all participants, regardless of trajectory group. Regression models indicated Vineland Social-AE scores significantly predicted employment and friendships in adulthood. SSQ total and SDQ prosocial scores also significantly predicted friendship in adulthood. Only non-verbal IQ at 9 predicted the likelihood of having ever had a romantic relationship.

Conclusions: These findings highlight the role of social competence in atypical and typical development and suggest day-to-day social behaviors may be distinct from the core social deficits traditionally associated with ASD. Future studies should continue to move towards a worthwhile definition of social competence in ASD and should leverage strengths-based approaches to define and examine meaningful adult outcomes in this population.

420.054 (Poster) The Understanding of Wrongfulness By Autistic Individuals When Interacting with the Criminal Judicial System
R. L. Young, M. Kernahan, N. Weber, and A. Lim; (1)Flinders University, Adelaide, Australia, (2)Flinders University, Adelaide, SA, Australia, (3)Flinders University, Adelaide, SA, Australia

Background:

Upon being arrested after engaging in criminal activity, either willfully or naively, autistic individuals have shown an inability to reason about the wrongfulness of their conduct. It has been argued that this inability to reason may reflect an inability to think about the impact one’s behaviour has on others, or appreciate that they had in some way been manipulated. This inability to appreciate the thoughts, feelings, and intentions of others – often referred to as poor Theory of Mind (ToM) – is thought to underpin many of the difficulties faced by autistic people and may lead to poor reasoning about wrongful behaviour.

Objectives:

The present study investigated the effect of autism, and theory of mind, on reasoning ability, and whether this effect was weakened when explicit information was given about the intentionality behind, and harmful outcome of, a behaviour. It was hypothesised that when explicit intent and harm information were absent, ToM would mediate the autism and reasoning ability relationship.

Methods:

The reasoning ability and ToM of 37 autistic and 48 non-autistic participants was assessed. To test reasoning ability, participants read criminal scenarios with intent and harm information absent or present and reasoned why the behaviour was/was not ‘wrong’. Participants’ reasons were then scored by the level of intent and harm information used in their responses.

Results:
Although autistic individuals scored lower for reasoning ability than non-autistic individuals, ToM did not mediate this relationship when information about intent and harm was not provided. The estimated difference in reasoning ability was smaller between the groups when harm information (harm-only and harm & intent) was present compared to when it was absent (intent-only and neither).

Conclusions:

The poorer reasoning ability of autistic people suggests they may not readily think about the intent or potential harm to others when engaging in illegal behaviours or confronted with wrongful situations. However, if informed about the potential harm and intent, the difficulties experienced by autistic people are reduced suggesting that anticipating the potential outcome may not be intuitive for some autistic people and education is required for the autistic person, as well as non-autistic persons who may be involved in making judgements in such matters.

420.055 (Poster) The Influence of Remorse on How Autistic People Are Perceived and Punished in the Criminal Judicial System

R. L. Young, L. Burleigh, N. Weber and A. Lim, (1)Flinders University, Adelaide, Australia, (2)Flinders University, Adelaide, SA, Australia, (3)Flinders University, Adelaide, SA, Australia

Background:

Research indicates that individuals with autism spectrum disorder receive harsher penalties when charged with the same crime as their non-autistic peers. e search also indicates that diagnostic features of autism such as flat affect, inappropriate emotional reactions, and poorly integrated verbal and nonverbal communication may reduce one’s ability to either feel remorse or if felt, convey that emotion. Given remorse plays a key role in sentencing, of interest in the present study was whether autistic individuals on the were perceived as demonstrating less remorse than their non-autistic peers when accused of the same crime, and whether this led to harsher penalties.

Objectives:

The aim of this study was to determine whether non-autistic participants would apply harsher penalties to autistic defendants and whether this relationship was affected by the amount of remorse shown. Also considered was whether education would mediate any observed relationship between penalty harshness and perceptions of remorse.

Methods:

Five autistic and five non-autistic individuals took part in video recordings and were instructed to convey remorse for two proposed crimes. Non-autistic participants (N = 195) were then randomly allocated one autistic video and one non-autistic video and asked to indicate how remorseful they perceived each individual to be and the degree to which each person should be penalised. Education was then administered, informing participants of autistic characteristics, and participants were given the option to re-rate perceived remorse and penalty harshness.

Results:

Results revealed that perceived remorse mediated the relationship between autism diagnosis and penalty harshness. Further, education resulted in a reduction on the harshness of the penalty imposed, through improving perceptions of remorse.

Conclusions:

These results provide evidence that autistic individuals may be unfairly disadvantaged within the forensic setting due to difficulties or differences in displaying remorse. However, the administration of education regarding autism may negate these adverse outcomes, thus highlighting the importance of educating decision makers on potential differences in autistic presentation.

420.056 (Poster) “I Can’t Relate to It”: Exploring Autistic and Neurotypical Adults’ Perceptions of the Australian Physical Activity and Sedentary Behaviour Guidelines

C. Thompson, J. McVeigh, T. Gorey, G. Watson, B. Wells and T. Lawler, (1)School of Occupational Therapy, Social Work and Speech Pathology, Curtin University, Perth, WA, Australia, (2)School of Occupational Therapy, Social Work and Speech Pathology, Curtin University, Curtin University, Perth, WA, Australia, (3)Curtin University, Bentley, Western Australia, Australia

Background: Despite sufficient participation in physical activity being strongly associated with better health outcomes, 56 per cent of the Australian population do not meet the Australian Physical Activity and Sedentary Behaviour Guidelines (the Guidelines). These Guidelines are available in the Make Your Move - Sit Less, Be Active for Life! brochure, and were designed to educate the public about the recommended levels of weekly activity needed for health benefits. Autistic adults have poorer health outcomes and participate in even
lower levels of physical activity when compared to neurotypical adults. The perceptions of the *Guidelines* by the Australian neurotypical and autistic population is unknown.

**Objectives:** The objective of the current study was to explore and compare autistic and neurotypical adults’ perceptions of the *Australian Physical Activity and Sedentary Behaviour Guidelines*.

**Methods:** The current study used a qualitative research design, interviewing 15 autistic and 20 neurotypical adults. An interpretative phenomenological analysis approach was used to collect and analyse the interview data.

**Results:** The findings between the two groups were largely similar and data were combined. Four themes were identified during data analysis. These included: 1) **Lack of Awareness and Engagement with the brochure containing the Guidelines**, whereby the participants were unaware of the existence of the material, and found the information not engaging. 2) **Misinterpretation of Key Terms and Concepts**, whereby participants misunderstood the terms related to different levels of physical activity. 3) **Relevance and Relatability of the Brochure and Guidelines**, whereby participants did not feel the material was relevant to them because of the illustrations used. 4) **Lack of Inclusivity**, whereby participants noted the guides were written from an ablest perspective.

**Conclusions:** The findings of the two groups were largely similar and they suggest that health promotion materials would be more visible, clear, inclusive and engaging for neurotypical and autistic Australians. The public’s perception of the *Guidelines* should be considered in the future development of health promotion materials. This study has implications for considering how to improve the number of people meeting the *Guidelines*. To the authors knowledge, this is the first study to consider how autistic adults perceive the health promotion Guidelines. The autistic participants advocated for the use of more inclusive messaging to create more relatable health promotional content. The study’s findings suggest the brochure needs to remove ableist language and include information and examples relevant to adults with an impairment. Further research is needed to evaluate how differences in interpretations impact the application of the *Guidelines* and how this could be used to foster sufficient participation in physical activity.

**420.057 (Poster) The Impact of Physical Activity on Mood for Autistic Adults**

**C. Thompson, M. Anwar, N. Clifford, F. Doi, S. Docker and J. McVeigh, (1)School of Occupational Therapy, Social Work and Speech Pathology, Curtin University, Perth, WA, Australia, (2)Curtin University, Bentley, Western Australia, Australia, (3)School of Occupational Therapy, Social Work and Speech Pathology. Curtin University, Curtin University, Perth, WA, Australia**

**Background:**

Autistic adults appear to be at greater risk of experiencing mental health comorbidities than that of their non-autistic peers. Depression and anxiety are among the most prominent mental health conditions within the autistic community. There is robust evidence purporting the benefits of physical activity on mood for the non-autistic population. Consequently, physical activity is often suggested as an early intervention or preventative strategy for non-autistic adults. However, there is limited evidence outlining the impact of physical activity for autistic adults.

**Objectives:**

The objective of this study was to explore the experience and impact of physical activity on mood for autistic adults.

**Methods:**

This study was conducted using semi structured interviews in an Interpretative Phenomenological Analysis (IPA). The IPA research process has been demonstrated to be effective in the autistic population and is suited to small samples. A total of 11 individuals participated in the study, six females and four males (one person did not disclose their gender). Semi-structured interviews were conducted online. Interview topics included preferred types of physical activity, the influence of physical activity on mood, their sleep and eating patterns, as well as sensory and environmental preferences. Interview questions were reviewed by an autistic research reference group prior to the study to ensure suitability for the target population. The interview transcripts were analysed using the seven stage IPA framework.

**Results:**

Four themes being identified: 1) **The right physical activity has a purpose**, participants noted that completing physical activity provided them with a sense of achievement. 2) **Exercising with people can make a difference**, participants acknowledge that when completing social sports where they were surrounded by people with similar interests, was motivating and encouraging. 3) **Fitting physical activity into everyday routine**, the routine of physical activity was identified as a common idea expressed by the participants that would impact their mood towards physical activity and the reason why they engaged in it. 4) **The body and mind’s response to physical activity**, participants commented that they do not like “sweating”, “being out of breath”, “red in the face” or “in pain” following exercise. These preferences affected the intensity of their physical activity as these physiological responses would significantly influence their emotional state.
Conclusions:

These findings highlight that physical activity can improve mood for autistic adults. However, the impact of physical activity on the mood for autistic adults appeared to be dependent on their perception of ‘having a good or bad day’ and the type of physical activity completed. Positive effects on mood from engaging in physical activity on a perceived good day were reported by participants. This resulted in feelings of accomplishment and purpose, social opportunities provided and increasing motivation. Conversely, physical activity was not reported as having a significant impact on mood during self-perceived bad days. These findings can provide insight into how mood can impact autistic adults and would benefit from further research investigating and supporting the mental health of the autistic community.

**420.058 (Poster) Seeking and Receiving Support for Mental Health and Suicidal Behavior: A Qualitative Study of the Experiences of Autistic Adults in Australia**

D. Hedley, J. Wilson, S. M. Hayward, S. M. Bury, C. Dissanayake, D. B. Nicholas and M. A. Stokes, (1)Olga Tennison Autism Research Centre, La Trobe University OTARC, Melbourne, VIC, Australia, (2)Olga Tennison Autism Research Centre, La Trobe University, Melbourne, VIC, Australia, (3)School of Social and Political Sciences, The University of Melbourne, Melbourne, VIC, Australia, (4)Olga Tennison Autism Research Centre, Olga Tennison Autism Research Centre, Melbourne, VIC, Australia, (5)University of Calgary, Edmonton, AB, Canada, (6)Deakin University, Burwood, VIC, Australia

Background: Autistic adults experience high rates of co-occurring mental illness, including major depressive disorder, anxiety disorders, self-harm and suicidal behavior, with risk of death by suicide about three-times that of the general population (Santomauro et al., 2022). Effective support for mental health is therefore a priority for the autistic population (Gotham et al., 2015). To date only a few studies have examined the experience of autistic adults seeking support for their mental health concerns. In this study, we interviewed autistic adults living in Australia who had all experienced significant mental health challenges associated with suicide, about their experiences seeking support for their mental health.

Objectives: To examine participants’ experiences seeking and accessing support for mental health, supports and coping strategies, including for when they were feeling suicidal, quality of care (what worked, what did not), and recommendations for improving services.

Methods: Ethics approval for the study was received from the La Trobe University Human Research Ethics Committee. The research methodology we adopted was based on an integrated co-design approach (Kerr et al., 2022). Thirty-three (16 women, 14 men, 3 nonbinary) autistic adults aged 21–68 years ($M_{age}=41.72, SD=11.49$ years) participated in a phenomenologically informed one-to-one semi-structured interview conducted over Zoom. Interviews lasted up to 60 minutes ($M=46.53, SD=10.03$ minutes, $Range=22–67$). All individuals had previously participated in a longitudinal study and had consented to be contacted; all provided informed consent prior to commencing the interviews. We utilized a targeted strategy to recruit participants with a higher likelihood of having accessed mental health services or of seeking support for their mental health associated with suicidal behavior. We achieved this by inviting participants based on prior responses to the Columbia-Suicide Severity Rating Scale (C-SSRS; Posner et al., 2011) or Suicidal Behaviors Questionnaire-Revised (SBQ-R; Osman et al., 2001). We analyzed interview data using applied thematic analysis (Guest et al., 2012).

Results: Twenty-five (76%) participants reported a history of suicidal behavior (i.e., C-SSRS actual, interrupted, or aborted attempt, preparation) and a lifetime history of suicide plan or attempt (i.e., SBQ-R, item 1). Thematic analysis revealed three main themes: Barriers to accessing services (including financial barriers, finding appropriate services as an adult, and gate-keeping of services preventing access); Difficulty in finding services that were understanding of the autistic context and autistic lived experience (e.g., assumed incompetence in activities of daily life, disregarding individualization and lived experience when formulating treatment or safety plans, lack of sensory accommodations); and Difficulties in finding a “good fit” for both mental health clinician/s and therapies (e.g., a perceived high level of clinician knowledge of autism but a low level of understanding of the impact of autism on communication and on the effectiveness of therapies, clinicians recommending a symptomology-based “one-size-fits-all” approach, therapies “not working like they do for other people”).

Conclusions: Our findings demonstrate an urgent need for improvement in both access to mental health services and service provision for autistic adults. We provide specific recommendations based on the insights gained from examining the lived experience of autistic people.

**420.059 (Poster) Transitioning Autistic Adults into the Workforce: Economic Impact and Implementation of a Workplace-Based Health and Wellbeing Support Program**

D. Hedley, S. M. Bury, E. Walkowiak, C. Dissanayake and J. R. Spoor, (1)Olga Tennison Autism Research Centre, La Trobe University OTARC, Melbourne, VIC, Australia, (2)Olga Tennison Autism Research Centre, La Trobe University, Melbourne, VIC, Australia, (3)Department of Accounting, Data Analytics, Economics and Finance, La Trobe University, Melbourne, VIC, Australia, (4)Olga Tennison Autism Research Centre, Olga Tennison Autism Research Centre, Melbourne, VIC, Australia, (5)Department of Management & Marketing, La Trobe University, Melbourne, VIC, Australia

Background: Autistic people experience poor outcomes in adulthood. Two significant transition “cliffs” have been identified post-secondary school and higher education. Autistic people transitioning into the workforce have difficulty finding employment, particularly employment matched to their skills, interests, and level of education. This results in broad costs to society associated with lost revenue, or
low return on investment (e.g., associated with education investment). Recently, various industries have instigated autism targeted employment programs which support transition to work. Research is required to evaluate the viability and sustainability of these programs, as well as potential impacts on program participants.

Objectives: To a) quantify the economic impact of supported employment programs, b) identify impacts on individuals participating in these programs, and c) introduce a novel autism workplace-based health and wellbeing support program.

Methods: We examined data from 56 autistic adults ($M_{age}=25.28, SD=8.36$ years) participating in a competitive entry 3-year government and private enterprise collaborative supported employment program. These data were used to develop a cost-benefit analysis (CBA) modelling savings to the government. Participants were followed-up at the conclusion of the program and optimal outcomes (i.e., transition into open employment) were evaluated. Based on follow-up data from 43 autistic adults ($M_{age}=27.50, SD=9.63$ years) participating in the program, we report changes over 12-months to daily living, social support, job satisfaction, depression, anxiety, and well-being.

Results: The unemployment rate prior to entering the program was 66%. Retention in the program over year 1 was >98%. Follow-up revealed 49 (87.5%) participants had transitioned into open or alternative employment post-program, reflecting an unemployment rate of 16%. Net benefits of the program to government equated to AUD$34,927 per participant after 3-years, and AUD$618,151 cumulative benefit per participant after 20-years. In terms of health and wellbeing outcomes, there was a small but significant increase in daily living skills, $t(35)=-1.96$, BcA 95%CI [-1.78, -0.114], $d=0.31$ [-0.15, 0.78], and slight decrease in job satisfaction, $t(35)=2.11$, [0.243, 5.36], $d=-0.40$ [-0.87, 0.07]. No significant changes over 12-months were identified for any other mental health or wellbeing measure.

Conclusions: Our findings demonstrate the feasibility and benefits, both to the individual and society, of a supported employment program for autistic adults operating within the private and government sector. Specifically, we found that the program was reasonably successful in transitioning young, educated, but mostly unemployed or under-employed autistic adults into the workforce. Following 3-years, most participants had secured open employment, crediting the program with providing them a ‘stepping-stone’ into the workforce. This shift provided substantive savings to government, associated with avoided costs administering and funding programs, higher education loan repayment, income tax contributions, and reductions in pensions or unemployment benefits. Nonetheless, we did not see clear improvements to health and wellbeing, leading to the development of a new training program aimed at supporting autistic employees in the workforce. This program is currently being evaluated in a Randomized Control Trial (RCT) across various workplaces.

Animal Models

**POSTER SESSION — ANIMAL MODELS**

**408 - Animal Models**

**408.001 (Poster) A Novel Approach to Measure Emotional Empathy in Rats through Playback of Ultrasonic Vocalizations**

*E. Bartsoen1,2 and M. Wöhr1,3,4*  
(1)Faculty of Psychology and Educational Sciences, Research Unit Brain and Cognition, Laboratory of Biological Psychology, Social and Affective Neuroscience Research Group, KU Leuven, Leuven, Belgium, (2)Leuven Brain Institute, KU Leuven, Leuven, Belgium, (3)Behavioral Neuroscience, Experimental and Biological Psychology, Philipps-University of Marburg, Marburg, Germany, (4)Center for Mind, Brain and Behavior, Philipps-University of Marburg, Marburg, Germany

**Background:** Difficulties in responding to and understanding the emotions of others, known as empathy, is characteristic of Autism Spectrum Disorder (ASD). Rodent models have been crucial in identifying neurobiological mechanisms underlying ASD. Despite their importance, the translatability of findings on treatments from rodent to human studies has been daunting. This is partly due to the often exclusive use of basic social tests that do not do justice to the complex behavioral expression of ASD.

**Objectives:** For these reasons, we developed a novel test of emotional empathy (i.e. mimicking the affective state of a conspecific) in rats. Rats are highly social and communicate via ultrasonic vocalizations (USV). In aversive situations (e.g. predator exposure), rats emit 22-kHz USV that presumably reflect a negative affective state. These USV serve as "alarm calls" and, in response, rats freeze or hide. In appetitive situations (e.g. social play), rats emit 50-kHz USV that presumably reflect a positive affective state. They serve as "social contact calls" and elicit approach behavior from the receiving rat. Hence, 22-kHz and 50-kHz USV are believed to induce a negative and positive affective state in the receiver, respectively. Our new empathy protocol builds on the distinct affect-inducing properties of USV and combines it with the acoustic startle response test. The acoustic startle response is a reflexive contraction of the body muscles in response to a loud noise burst and its intensity depends on the animal's affective state - i.e. intensified at a negative affective state and reduced at a positive affective state. Therefore, we tested whether playback of both USV types can alter the acoustic startle response bidirectionally – i.e. enhanced and reduced by 22-kHz and 50-kHz USV playback, respectively.
Methods: Juvenile male Sprague-Dawley rats (N = 16) were subjected to the acoustic startle response test on four subsequent days. On each day, playback of 22-kHz USV, 50-kHz USV, or their acoustic control stimulus was presented (order counterbalanced between rats). The effect of USV type on the maximum startle response was compared to their acoustic control stimulus within rats.

Results: Our results indicated that playback of 50-kHz USV significantly decreased the acoustic startle response by 37.91 – 52.17 % compared to its acoustic control across several startle stimulus intensities, suggesting that the rats successfully mimicked the positive affective state of the caller. Playback of 22-kHz USV did not significantly increase the acoustic startle response compared to its acoustic control possibly due to insufficient sound pressure levels.

Conclusions: We have developed a novel protocol that can measure positive emotional empathy in rats. The protocol differs from previous ones not only because of its focus on bidirectional modulation of empathy, but also because it does not require learning since it uses ethologically relevant stimuli (i.e. USV). Furthermore, because the protocol is not labor-intensive, it can easily be added to a standard social test battery for genetic rat models of ASD. This will help us understand the complex psychological mechanisms underlying the core symptoms of ASD and aid in the development of optimized treatment approaches.

408.002 (Poster) Abnormal CYP11A Metabolic Pathway and Offspring ASD Development and Vitamin D Intervention Study

J. Xie, H. Yin, Z. Qiu and W. Xu, (1)The ministry of science and education, South West Jin Tong University, Chengdu 3rd People’s Hospital, chengdu, China, (2)The Third People’s Hospital of Chengdu, Affiliated Hospital of Southwest Jin Tong University, Chengdu,Sichuan, Chengdu, China, (3)West China Second University Hospital,Sichuan University,Chengdu,Sichuan, Chengdu, China

Background: Our previous results suggest that abnormal upregulation of CYP11A gene in placental trophoblast cells directly leads to overloading of mitochondrial biosynthesis and excessive peroxide (ROS), thereby inducing mitochondrial damage and apoptosis. Furthermore, we found that aberrant upregulation of CYP11A gene can lead to changes in the local microenvironment of trophoblast cells as well as the release of inflammatory factors, thereby indirectly damaging neural stem cells and inhibiting their proliferation; These results suggest that abnormal up-regulation of CYP11A1 gene in trophoblast cells may affect the development of fetal nervous system. In the course of the study, we also found that moderate vitamin D 3 intervention can effectively inhibit and reverse the damage of trophoblast cells, so as to rescue and restore the function of neural stem cells.

Objectives: To determine whether overexpression of CYP11A during pregnancy affects the neurodevelopment of the offspring and the development of autistic spectrum disorder (ASD). And we also aimed to investigate the effect of vitamin D supplementation during pregnancy on the intervention of ASD in the offspring and wish to provide a basis for the early prevention of clinical ASD.

Methods: Pregnancy overexpression CYP11A animal model (creation of mouse Cyp11a1 knockdown protein at the H11 locus in C57BL/6N mice by CRISPR/cas-mediated genome engineering) was constructed and validated at protein level. Vitamin D feeds (1000 IU/KG, 5000 IU/KG, 10000 IU/KG) were prepared. Maternal CYP11A(KI) overexpressing mothers were fed with different doses of vitamin D supplementation from the first day of bolus pick-up after cage ensainment; WT mothers fed with vitamin D supplementation at a dose of 1000 IU/KG as the control. The vitamin D diet was fed until the pregnant mice gave birth and the offspring were tested behaviorally at 6-8 w to detect the effect of vitamin D supplementation during pregnancy on the treatment of autistic spectrum disorder.

Results: Social competence was tested in the first phase of a three-box social behaviour experiment. Compared to exposure to an empty metal frame, WT submice (1000IU/KG) preferred contact with unfamiliar mice compared to KI submice (1000IU/KG) (WT:p=0.0093; KI(1000IU/KG):p=0.4442), while social behaviour of submice improved after the VD intervention during pregnancy (WT:p=0.0001; KI(1000IU/KG):p=0.0001). improved (KI(5000 IU/KG):p<0.0001; KI(10000 IU/KG):p<0.0001), and social novelty preference was tested in the second stage, with WT submice (1000 IU/KG) preferring to socialize with unfamiliar mice compared to exposure to familiar mice (WT:p=0.0248; KI(1000IU/KG):p=0.0616), whereas the social novelty preference of submice improved after the VD intervention during pregnancy (KI(5000IU/KG):p=0.0089; KI(10000IU/KG):p=0.5784). In the elevated cross experiment, anxiety was evident in KI subrats (1000 IU/KG) compared to the WT group (p=0.0355) and reduced after the VD intervention during pregnancy (KI(5000 IU/KG):p>0.9999; KI(10000 IU/KG):p=0.9067).

Conclusions: Abnormal up-regulation of CYP11A1 gene expression can lead to autistic behaviours in offspring compared to healthy controls, and appropriate amount of vitamin D3 intervention during pregnancy can effectively improve social competence and social novelty preference and anxiety behaviours in offspring mice, and reduce the occurrence of autism. This will provide a new idea for the early prevention of autism.

408.003 (Poster) An Assessment of the Translational Validity of Sustained Attention Tasks between Rodents and Humans

C. Salmon, S. Li; E. L. Burrows and K. A. Johnson, (1)School of Psychological Sciences, The University of Melbourne, Parkville, VIC, Australia, (2)Florey Institute of Neuroscience and Mental Health, University of Melbourne, Parkville, VIC, Australia

Background: Our previous results suggest that abnormal upregulation of CYP11A gene in placental trophoblast cells directly leads to overloading of mitochondrial biosynthesis and excessive peroxide (ROS), thereby inducing mitochondrial damage and apoptosis. Furthermore, we found that aberrant upregulation of CYP11A gene can lead to changes in the local microenvironment of trophoblast cells as well as the release of inflammatory factors, thereby indirectly damaging neural stem cells and inhibiting their proliferation; These results suggest that abnormal up-regulation of CYP11A1 gene in trophoblast cells may affect the development of fetal nervous system. In the course of the study, we also found that moderate vitamin D 3 intervention can effectively inhibit and reverse the damage of trophoblast cells, so as to rescue and restore the function of neural stem cells.

Objectives: To determine whether overexpression of CYP11A during pregnancy affects the neurodevelopment of the offspring and the development of autistic spectrum disorder (ASD). And we also aimed to investigate the effect of vitamin D supplementation during pregnancy on the intervention of ASD in the offspring and wish to provide a basis for the early prevention of clinical ASD.

Methods: Pregnancy overexpression CYP11A animal model (creation of mouse Cyp11a1 knockdown protein at the H11 locus in C57BL/6N mice by CRISPR/cas-mediated genome engineering) was constructed and validated at protein level. Vitamin D feeds (1000 IU/KG, 5000 IU/KG, 10000 IU/KG) were prepared. Maternal CYP11A(KI) overexpressing mothers were fed with different doses of vitamin D supplementation from the first day of bolus pick-up after cage ensainment; WT mothers fed with vitamin D supplementation at a dose of 1000 IU/KG as the control. The vitamin D diet was fed until the pregnant mice gave birth and the offspring were tested behaviorally at 6-8 w to detect the effect of vitamin D supplementation during pregnancy on the treatment of autism.

Results: Social competence was tested in the first phase of a three-box social behaviour experiment. Compared to exposure to an empty metal frame, WT submice (1000IU/KG) preferred contact with unfamiliar mice compared to KI submice (1000IU/KG) (WT:p=0.0093; KI(1000IU/KG):p=0.4442), while social behaviour of submice improved after the VD intervention during pregnancy (WT:p=0.0001; KI(1000IU/KG):p=0.0001). improved (KI(5000 IU/KG):p<0.0001; KI(10000 IU/KG):p<0.0001), and social novelty preference was tested in the second stage, with WT submice (1000 IU/KG) preferring to socialize with unfamiliar mice compared to exposure to familiar mice (WT:p=0.0248; KI(1000IU/KG):p=0.0616), whereas the social novelty preference of submice improved after the VD intervention during pregnancy (KI(5000IU/KG):p=0.0089; KI(10000IU/KG):p=0.5784). In the elevated cross experiment, anxiety was evident in KI subrats (1000 IU/KG) compared to the WT group (p=0.0355) and reduced after the VD intervention during pregnancy (KI(5000 IU/KG):p>0.9999; KI(10000 IU/KG):p=0.9067).

Conclusions: Abnormal up-regulation of CYP11A1 gene expression can lead to autistic behaviours in offspring compared to healthy controls, and appropriate amount of vitamin D3 intervention during pregnancy can effectively improve social competence and social novelty preference and anxiety behaviours in offspring mice, and reduce the occurrence of autism. This will provide a new idea for the early prevention of autism.
Sustained attention is the ability to maintain focus over time, particularly to dull tasks. This cognitive ability underpins other more complex cognitive skills such as learning, planning, organizing, and working memory. These cognitive skills are often affected in autistics. Rodents can complete many neuropsychological tasks that have been designed for use with humans. Studies with rodents are very useful as they allow for the investigation of pharmacological, genetic, and neurobiological mechanisms that would be difficult or indeed impossible to study in humans. Sustained attention is commonly assessed in rodents using three tasks – the rodent Continuous Performance Task (rCPT), the Sustained Attention Task (SAT), and the five-choice CPT (5C-CPT). How well these rodent sustained attention tasks map to human sustained attention tasks was assessed.

Objectives:

The translatable of these three tasks between rodents and humans was assessed based on (1) methodological similarity between the rodent and human tasks, (2) similarity in performance across species, and (3) replication of results.

Methods:

A systematic review was conducted to find relevant rodent experimental papers on the rCPT, SAT, and 5C-CPT. Search terms were entered into EMBASE, Medline (R) ALL, and American Psychological Association PsychInfo databases on Ovid.

Results:

Included for review were 138 studies, including 21 with the rCPT, 90 with the SAT, and 27 with the 5C-CPT. The 5C-CPT was found to have high utility as a cross-species paradigm. The rCPT and SAT both require adaptation and further development to meet the high utility translatable benchmarks. The replication benchmark was difficult to assess due to the recent developments of the tasks, potential publication bias, and poor clarity in some reporting of results.

Conclusions:

The 5C-CPT is an excellent candidate for the measurement and analysis of sustained attention for cross-species research. This task would be ideal for sustained attention research with mice with autism-related gene mutations. In the future, improved data sharing, transparent results reporting, and standardization of research practices will promote translatability between rodent and human research, furthering our understanding of the neural mechanisms of sustained attention.

Animal Model of Autism Induced By Valproic Acid Combined with Maternal Deprivation: Effects on Inflammation and Oxidative Stress Parameters

Background: Autism spectrum disorder (ASD) etiology probably involves a complex interplay of both genetic and environmental risk factors, which includes pre- and perinatal exposure to environmental stressors. Indeed, rodents exposed prenatally to valproic acid (VPA) exhibit ASD-like behavior. Besides, recent studies have shown that maternal deprivation (MD), can interfere with the development of the central nervous system (CNS) and lead to biochemical and behavioral abnormalities compatible with ASD.

Objectives: This study aimed to analyze the effects of prenatal exposure to VPA, combined with MD, on locomotor and social behavior, oxidative stress parameters, and inflammatory state in the CNS and in the periphery.

Methods: Pregnant Wistar rats were injected with VPA (600 mg/kg) or saline (control group) on the gestational day 12.5. At birth, the VPA-exposed and SAL-exposed offspring were subdivided into two groups: MD and non-maternal deprivation, n=10-13/per group. MD occurred from the 1st to the 10th postnatal day (PND), where the litter was separated from their dams 3 h/day. On PND 30, male and female pups were tested for locomotor and social behavior; after, the animals were euthanized, and the brain tissues (cerebellum, posterior cortex, and prefrontal cortex) and blood were analyzed to inflammatory markers (tumoral necrosis factor-α (TNF-α), Interleukin (IL)-1, IL-6, IL-10) and enzymatic assays to evaluate the oxidative damage by carbonyl (Carb), dichlorofluorescein oxidation (DCF), nitric oxide (NO), and antioxidant defense by activity of glutathione (GSH), superoxide dismutase (SOD) and sulfhydryl concentration (SH).

Results: Young rats exposed only to VPA presented a lower social approach when compared to the control group. VPA+MD did not present the same deficit. No locomotor deficit was observed in any group tested. Regarding the inflammatory parameters, males exposed only to MD exhibited an increase in pro-inflammatory cytokines (TNF-α, IL-1, IL-6), both in the blood and in the cortex total. Females exposed only to VPA exhibited an increase in (TNF-α, IL-1, IL-6), both in the blood and in the cortex. On the other hand, animals exposed to VPA+MD showed only an increase in (TNF-α, IL-1, IL-6), in the blood (females) and IL-1 in the posterior cortex (males). Regarding
oxidative stress parameters, females exposed to VPA+MD presented an increase in DCF and/or NO and a decrease in antioxidant defense (SH or/and GSH or/and SOD) in all brain areas analyzed (cerebellum, posterior cortex, and prefrontal). On the other hand, males in the VPA and VPA+MD groups presented an increase in DCF and/or Carb and a decrease in GSH or SOD only in the cerebellum. Besides, exposition to MD or VPA alone promoted other small alterations sex- and brain area-specific. All analysis was made compared to the control group.

Conclusions: This study showed that while MD alters more inflammatory cytokines in males, VPA affects these same parameters in females. Combined exposition to VPA and MD could be toxic to female brains when we look at the oxidative stress parameters or protective to males when we look at the inflammatory response. In summary, this study shows sex differences responses in ASD at the molecular level.

408.005 (Poster) Blame Grandpa: Transgenerational Effects on Mouse Behavior Due to X Chromosome Epimutation

Background: Given that males are 4.2 times more likely to be diagnosed with Autism Spectrum Disorder (ASD) than females and that ASD individuals display impaired social interaction and restricted, repetitive behaviors, it is prudent to use animal models to investigate this male bias. The male bias in ASD has been proposed to be due to imprinted loci on the X chromosome and our lab possesses a transgenic mouse model of Xlr3, an imprinted gene on the mouse X chromosome. We have devised a breeding scheme whereby third generation male mice possess an epimutated X chromosome that is the direct result of impaired meiosis in their Xlr3 transgenic maternal grandfather. A cohort of 25, third-generation mice have been sent for behavioral testing at the UConn Murine Neurogenetics Behavioral Facility (MBNF). The tests selected correlate with ASD behaviors in humans.

Objectives: To determine if males with epimutated X chromosomes are behaviorally distinct from control animals. The presence of distinct behaviors would indicate that the epimutated X chromosome is responsible.

Methods: 10 outcross animals who have never been under the control of the Xlr3 transgene were selected as control animals. 15 animals were generated from the transgene containing strain and represent the experimental strain. Study animals were singly housed and transferred to the MBNF for behavior testing. The following behavioral tests were performed: Novel Object Recognition, Open Field, Tube Task, Water Escape, and Morris Water Maze. Statistical analyses were performed on the raw data using the program SPSS Statistics by IBM. Multivariate Analysis of Variance (ANOVA) was used to analyze Novel Object Recognition and Open Field tests while a univariate ANOVA was used for Tube Task and Water Escape tests. A repeated measures ANOVA was used for the Morris Water Maze. Data were graphed using GraphPad Prism 9 and are displayed as mean values using standard error of the means for error bars.

Results: In the Novel Object Recognition test, experimental animals spent more time interacting with the novel object than the control animals (p-value < .031). In the Open Field test, experimental animals moved faster in both the inner and outer rings than control animals (p-values .041 and .027, respectively). The Morris Water Maze was statistically significant across the 8 days of testing, whereby experimental mice were unable to find the hidden platform (p-value < .001). Experimental mice tended to win more challenges in the tube task than control animals (not significant). No differences were observed in the water escape task.

Conclusions: The novel object recognition results suggest that the experimental mice do not have cognitive and memory deficits as they are able to detect the novelty of an object. The experimental animals were more exploratory in the open field, suggesting they possess a low level of anxiety. The Morris Water Maze highlights spatial learning deficits for the experimental mice because they fail to learn the location of the hidden platform over the 8 days. Thus, epimutation of the X chromosome leads to experimental mice with behaviors that are discernibly different from control mice.

408.006 (Poster) Development of Social Preference in Zebrafish Larvae
D. Dreher Nabinger, P. Cronell and L. Westberg, (1)Pharmacology, University of Gothenburg, Gothenburg, Sweden, (2)Department of Pharmacology, University of Gothenburg, Gothenburg, Sweden

Background: Social abilities, like attention to faces, and joint attention are established very early in human infants. Children with autism display deficits in these abilities, often already at birth. Whereas sociability is difficult to investigate in mammals during early development the animal model zebrafish provides unique possibilities to explore the development of the social brain. Zebrafish larvae are hatched and exhibit basic locomotor and feeding behaviours already some days after fertilisation. However, they do not interact with each other until almost a month of age, providing the opportunity to use various experimental approaches to decipher the neurobiology underlying the development of social preference.

Objectives: To describe how social preference behaviour develops during the first weeks of age in zebrafish larvae, and to what extent this development is associated with levels of monoamines and oxytocin.
Methods: Social preference was investigated using a three-chambered test arena for sociability in >300 larval zebrafish larvae at approximately one to five weeks of age. Information about the developmental stages, and tissue for HPLC and QPCR were collected.

Results: The social preference behaviour was not present at the second week, appeared at the third week, and increased considerably at the fifth week of age. There was also a substantial increase in the levels of the monoamines dopamine and serotonin, but not noradrenaline, between the second and third week of age.

Conclusions: Our results suggest that zebrafish can be easily used to investigate the initiation and development of social preference. Since there is a large number of molecular and genetic tools available that can be used for investigations of the nervous system of zebrafish, this may have large impact on our future understanding of the pathophysiology of autism. So far, our data indicate that serotonin and dopamine may be involved in the early development of attention to social stimuli.

408.007 (Poster) Developmental Vitamin D-Deficiency Produces Autism-Relevant Behaviours and Gut-Health Associated Alterations in a Rat Model
M. K. Tamang¹, A. Ali¹, R. N. Pertile¹, X. Cui¹, S. Alexander¹, M. D. Nitert¹, C. Palmieri¹ and D. Eyles¹, (1)Queensland Brain Institute, The University of Queensland, Brisbane, QLD, Australia, (2)School of chemistry and molecular bioscience, The University of Queensland, Brisbane, QLD, Australia, (3)School of veterinary science, The University of Queensland, Brisbane, QLD, Australia

Background:

Vitamin D-deficiency during pregnancy (here we refer to as Developmental Vitamin D (DV D)-deficiency), is an epidemiologically established risk factor for autism. Studies have also shown alteration of gut microbiome and gut dysfunction in autistic children and in animal models of autism such as Maternal Immune Activation (MIA). Our lab was the first to develop a preclinical model of DVD-deficiency in rats to study the effect of vitamin D-deficiency on brain development and behaviour. Vitamin D has broad physiological effects in brain, gut and immune system. A recent study from our lab has shown some behavioural phenotypes and immune alterations related to autism. The current study is motivated by findings showing similar behavioural phenotypes and neurobiological implications of validated animal models of autism such as MIA and our DVD-deficiency rat model. Thus, the goal of our study is to generate data that could link behavioural deficits and gut health in our model relevant to autism.

Objectives:

The current study aims to examine a broad range of autism-relevant behavioural phenotypes and impacts on gut health/microbiome induced by DVD-deficiency.

Methods:

DVD-deficiency was induced by placing four-week-old outbred female Sprague-Dawley rats on standard casein AIN93G rodent chow without any added vitamin D (0 IU Cholecalciferol) or control diet (added 1000 IU Cholecalciferol) for six weeks. Then, the females were mated, with the resulting pregnant dams remaining on DVD-deficient diets or corresponding control diets throughout pregnancy, birth of pups and until weaning postnatal day 21 (P21). At weaning, dams were euthanized and the pups remained on their maternal diet until P35. Assessment of maternal care was conducted from P2-P6, pup ultrasonic vocalizations and pup retrieval task were measured at P7 and P9. Social play behaviour was assessed at P35 in adolescent rats. After social play behaviour, animals were euthanized and tissues collected for experiments.

Results:

DVD-deficient rat dams exhibited altered postnatal maternal care. DVD-deficient pups at P9 showed increased ultrasonic vocalizations and in adolescence (P35), decreased social play and increased repetitive self-grooming behaviour. There were significant impacts of DVD-deficiency on offspring gut health as demonstrated by altered microbiome composition and diversity, correlation of bacterial abundance with social play behaviour, decreased villi length, and increased ileal propionate levels.

Conclusions:

Our animal model of this epidemiologically validated risk exposure for autism shows an expanded range of autism-related behavioural phenotypes and now alterations in gut microbiome that correlate with social behaviour. This model remains informative for studying autism-relevant brain and gut mechanisms.

408.008 (Poster) Dissecting Cortical Circuits Driving Motor Deficits in a Mouse Model of DDX3X Syndrome
Background: Many individuals with autism spectrum disorder (ASD) present with motor problems, although the relationship between ASD and motor ability is poorly understood. DDX3X syndrome is a monogenic form of ASD that affects primarily females and presents with significant motor involvement, including hypotonia and/or hypertonia, abnormal gait, and movement disorder. DDX3X syndrome is caused by mutations in the X-linked RNA helicase DDX3X, known to regulate mRNA metabolism. DDX3X is key for the development of the neocortex and hindbrain, but how it impacts the formation and function of brain circuits is unknown. To date, the brain circuits underlying the motor phenotype in DDX3X syndrome have not been explored. Our lab generated a Ddx3x haploinsufficient mouse (Ddx3x+− females) with construct and face validity for loss-of-function mutations. Ddx3x+− females have motor delays and deficits, and a misplacement of subcerebral projection neurons (scPNs) in primary motor cortex, which are neurons important for motor function. One type of scPN that we believe is particularly vulnerable to Ddx3x mutations is the corticopontine projection neurons, a population critical for motor control as these neurons initiate the cortico-ponto-cerebellar pathway connecting the cortex with the cerebellum.

Objectives: My project seeks to identify the cortical circuits driving motor deficits in Ddx3x+− mice. My objective specifically is to use in vivo viral tracing and transcriptomics to identify the neural substrate of motor deficits at the circuit, cellular and molecular levels, with the goal of ameliorating motor deficits using chemogenetics. Understanding the role of DDX3X in motor circuits will help decipher the relationship between ID and motor function, while defining objective readouts for pre-clinical testing of novel therapeutics.

Methods: I first investigated corticopontine circuits by injecting a retrograde virus carrying GFP into the pontine nuclei, a region important for motor behavior and innervated by scPNs. I then performed rotared and balance beam motor tests and stained for the immediate early gene c-Fos to investigate whether the corticopontine neurons are activated by the tasks. I also performed developmental and adult motor tests on a forebrain-specific line (Emx1-Ddx3x) to determine the role of the cortex in motor function. Lastly, I perform RNA-sequencing and proteomic analyses on Fluorescence-Activated Cell Sorting (FACS) purified corticoponine neurons from Ddx3x+− mice and control mice.

Results: My results show that execution of skilled motor tasks elicited neural activity in the cortex of control mice, however, the c-Fos+ cells did not significantly overlap with corticopontine neurons. Additionally, Emx1-Ddx3x mutant mice show developmental delays and adult motor deficits. Transcriptomic and proteomic experiments are ongoing.

Conclusions: These deficits in cortical development in Ddx3x+− mice provide basis to dissect the neural substrates of motor deficits observed in DDX3X syndrome with primary emphasis on the cortex.

408.009 (Poster) Effects of a Gut-Selective Integrin-Targeted Therapy in Mice Exposed to Early Life Immunostimulation, a Model for the Study of Autism Spectrum Disorders
L. Ricceri1, A. Butera2, R. De Simone1, R. Potenza1, M. Armida1, F. Trenta1 and M. Boirivant1, (1)CSCSM, Istituto Superiore di Sanità, Rome, ITALY, (2)CNRVF, Istituto Superiore di Sanità, Rome, Italy, (3)CSCSM, Istituto Superiore di Sanità, Rome, Italy

Background: Inflammatory and immune changes are recognized as pivotal mechanisms in ASD, particularly those involved in gut mucosal immune response. Few data are so far available upon the selective contribution of mucosal immune dysfunction to behavioral and neuroinflammatory profiles in mouse models for the study of ASD.

Objectives: To clarify the role of gut mucosal immunity on behavioral and neuroinflammatory profile in ASD, we used the early-life immune activation (EIA) mouse model. It is a double-hit model, including both prenatal (Poly I:C, mimicking a gestational viral infection) and postnatal (LPS mimicking a bacterial infection) immune challenges.

Methods: In male C57BL6/J EIA adult male offspring we evaluated the effects of i.p. administration of a monoclonal antibody directed against the integrin alpha4 beta7 (DATK-32: rat antimouse-α4β7 Ab), responsible for lymphocyte trafficking in the gut mucosa. The anti-α4β7 Ab causes a selective blockade of gut-experienced lymphocyte traffic to intestinal lamina propria. The effects of the treatment were assessed on EIA behavioral and neuroinflammatory profile, and gut immune-inflammatory changes.

Results: EIA male mice show a significant increase of colonic tissue IL-17A mRNA content when compared with controls. Cytofluorimetric analyses of lymphocytes isolated from mesenteric lymph-nodes (MLN) and spleens show in EIA mice increased percentage of CD8-(CD4+) α4+β7+ IL-17+ lymphocytes in MLN and of CD8-(CD4+), α4+β7+ IL-17+ and IFN-γ+ lymphocytes in the spleens. Treatment with anti-α4β7 Ab was associated with colonic tissue IL-17mRNA content and percentage of CD8-(CD4+) IL-17+ and IFN-γ+ α4+β7+ lymphocytes comparable to control mice. The anti-α4β7 Ab treatment rescued the social novelty deficit shown by EIA male mice in the three-chamber tests and improves the EIA-male mice rotarod impairment. EIA behavioral effects were associated with a proinflammatory profile in the hippocampus and prefrontal cortex of male offspring (significant increase in the mRNA expression of the proinflammatory cytokine IL-6 and IL-1 β), not modified by anti-α4β7 Ab treatment.
Conclusions: Amelioration of the gut inflammatory status obtained by a pharmacological agent acting exclusively at gut level, ameliorates some ASD behavioral features (e.g., response to social novelty and motor coordination skills), not necessarily interfering with the neuroinflammatory status. Once confirmed, these results of a behavioral rescue following normalization of gut inflammation in a mouse model for ASD study, could pave the way for a therapeutic strategy against gut-immune activation in a subpopulation of ASD subjects (e.g. with peripheral increase of gut-derived (α4β7) lymphocytes expressing IFN-γ and/or IL-17).

408.010 (Poster) Human Induced Pluripotent Stem Cell-Based Treatment in a Valproic Acid Rat Model of Autism

P. Juarez, P. Knoepfler, D. Fioravante, B. Dufour and V. Martinez-Cerdeno, (1)Department of Pathology and Laboratory Medicine, UC Davis / Shriner's Hospital of Northern California, Sacramento, CA, (2)Cell Biology and Human Anatomy, University of California, Davis, Sacramento, CA, (3)Neurobiology, Physiology and Behavior Center for Neuroscience, University of California, Davis, Davis, CA, (4)Psychiatry and Behavioral Sciences, UC Davis / Shriner's Hospital of Northern California, Sacramento, CA, (5)Pathology & Laboratory Medicine, UC Davis, Sacramento, CA

Background: Autism Spectrum Disorder (ASD) is a neurodevelopmental disorder that is characterized by deficits in social interaction and stereotypical patterns of behavior. Abnormal gamma wave patterns in the brains of ASD patients suggest that there is an imbalance in the ratio between excitatory and inhibitory signaling (E/I). Our lab was the first to characterize a significant loss of Parvalbumin expressing (PV+) GABAergic interneurons in the prefrontal cortex (PFC) of ASD patients, and later in our Valproic Acid (VPA) rat model of ASD (50% and 30% loss, respectively). Deficits in the PV+ cell population is believed to cause hyper-excitability in cortical circuits which contributes to promoting the core behavioral deficits observed in ASD patients and in our VPA rat model of ASD.

Objectives: We speculate that substituting this lost population of PV+ cells in VPA rats improves behavioral deficits by improving E/I signaling through the formation of functional inhibitory synapsis with the endogenous rat circuitry. To address this hypothesis, we proposed a Human Induced Pluripotent Stem Cell (hiPSC)-based therapy that ameliorates core behavioral deficits in VPA rats through the transplantation of Medical Ganglion Emience (MGE) cells (PV+ GABA precursor cells) into the medial PFC.

Methods: We first reprogrammed hiPSC’s into MGE cells using a previously defined 21-day dual SMAD inhibition protocol. We then bilaterally transplanted the human derived MGE cells into the mPFC of 6-week-old rats. We have four groups: VPA+MGE rats, VPA+dead MGE rats, VPA Rats and non-treated rats (n=9-12/group). In addition to performing patch clamp recordings of MGE cells, behavioral assays were assessed 1-month post-transplant using tests designed to model core behavioral deficits seen in human ASD (Social Apparatus Test, Marble Bury Test, Elevated Plus Maze Test, and Open Field Test).

Results: Our human MGE cell grafts were able to survive, extend fibers away from the injection site, and express PV marker 2 months post-transplant. In the social preference test, VPA animals with MGE cell transplants had significantly more transitions into the chamber with the novel animal relative to the VPA animals with dead MGE cell transplants (12.5 vs 7.0, P=0.01). In the open field test, VPA animals with MGE cell transplants traveled significantly more distance relative to the VPA animals with dead MGE cell transplants (128.56 vs 98.2 meters, P=0.046). Lastly, VPA animals with MGE cell transplants buried less marbles than those with dead MGE cell transplants, although to a non-significant extent (14.71 vs 6, P=0.08). Patch clamp recordings 4 weeks after transplant showed that MGE cell transplants had immature action potential properties.

Conclusions: Our preliminary findings suggest that our hiPSC-derived MGE cells were able to survive and mature after transplant. Moreover, our transplanted cells were able to rescue social, anxiety, motor and repetitive behavioral deficits in VPA rats. Lastly, the cell transplants immature electrical properties suggest that they may form functional inhibitory synapsis with the endogenous circuitry. Collectively, the use of hiPSC’s in the context of our study is promising novel approach with translational value for establishing the framework for a personalized hiPSC-based ASD human clinical trial.

408.011 (Poster) Lack or Reduction of the Autism Candidate Gene Reelin in Somatostatin Inhibitory Cortical Neurons Alters Developmental Trajectories in Mouse Pups: A Pilot Study

L. Di Crescenzo1,2, E. Bartoens2, R. Moors3, L. Lim4 and M. Wöhr2,3, (1)Faculty of Psychology and Educational Sciences, Research Unit Brain and Cognition, Laboratory of Biological Psychology, Social and Affective Neuroscience Research Group, KU Leuven, Leuven, Belgium, (2)Leuven Brain Institute, KU Leuven, Leuven, Belgium, (3)VIB-KU Leuven Center for Brain & Disease Research, Leuven, Belgium, (4)Center for Mind, Brain and Behavior, Philips-University of Marburg, Marburg, Germany, (5)Behavioral Neuroscience, Experimental and Biological Psychology, Philipps-University of Marburg, Marburg, Germany

Background: Autism Spectrum Disorder (ASD) is among the most heritable neuropsychiatric dysfunctions and increasing evidence indicates that abnormal development of cortical inhibitory circuits and the disruption of excitation and inhibition balance are central to ASD pathogenesis. While available evidence points to a complex set of genetic factors, Reelin (RELN) has emerged as a key candidate gene. Yet the exact relationship of how genetic mutations relate to circuit formation and behavioral alterations relevant to ASD remains largely unknown. Due to the multifaceted functions of Reelin in different cell types, it is still unknown which cell type is most affected and drives changes in circuits and behaviors relevant to ASD. The lack of a clear (endo)phenotype significantly hinders the development of specific-target therapies. Here, we aimed at bridging this gap by interrogating the function of a prominent ASD-associated gene, RELN, in a
Objectives: As a first step, we sought to evaluate isolation-induced ultrasonic vocalizations (USV) in mouse pups carrying a mutation in the ASD candidate gene Reln specifically in SST+ inhibitory cortical neurons. Pup USV serve important communicative functions and are known to induce maternal caregiving behavior.

Methods: N=32 mouse pups with a reduction or a lack of Reln (SST+/−;Reln+− and SST−/−;Reln−−, respectively) and wildtype littermate controls (SST−/−;Reln−−) of both sexes were individually isolated from mother and littermates and repeatedly exposed (postnatal days 3, 6, 9, and 12) to one of two experimental social conditions, i.e. clean versus home cage bedding, by an experimenter blind to the genotype. Broadband high-frequency ultrasound recordings were performed, followed by a detailed spectrographic analysis.

Results: Our preliminary results indicate a slight tendency for SST−/−;Reln+− and SST−/−;Reln−− pups to emit fewer isolation-induced USV compared to wildtype littermate controls, particularly in clean bedding conditions. Sex appeared to play a modulatory role. We further obtained evidence for effects on body weight gain, with mutant pups weighing less than wildtype littermate controls, highlighting differences in developmental trajectories.

Conclusions: This pilot study may suggest that a lack or a reduction of Reln in SST+ inhibitory cortical neurons affects socio-affective communication during early development. In future experiments, it would thus be interesting to assess the interaction between mother and pup in order to see whether alterations in pup ultrasonic calling leads to reduced maternal caregiving behavior, ultimately affecting pup developmental milestones.

408.012 (Poster) Life-Long Social Isolation Decreases Activation of Oxytocin Neurons in Zebrafish
S. Shams1, L. Zentveld1 and L. Westberg2, (1)Pharmacology, University of Gothenburg, Gothenburg, (2)Pharmacology, University of Gothenburg, Gothenburg, Sweden

Background: Animal models of social isolation have been used as a tool to study various human neuropsychiatric disorders, including autism. Additionally, autistic individuals typically experience substantial social isolation, which may lead to more adverse effects on their brain development and social processing. Long-term behavioural and physiological effects of developmental social deprivation have already been well-established in rodents, songbirds, and primates, highlighting conserved physiological mechanisms that regulate social interaction in vertebrates. Social isolation in fish influences subsequent behaviour but less is known about how social networks in the zebrafish brain are affected by early social deprivation.

Objectives: Oxytocin is a neuropeptide involved in various social behaviours in vertebrates, including bonding, social interaction, and social anxiety. Zebrafish are a highly social vertebrate species that share 70-80% homology in molecular pathways and neural networks with humans, including the oxytocin system. Availability of sophisticated genetic manipulation in zebrafish further advances their utility as a model organism for studying neurodevelopmental disorders with strong heritability. As such, zebrafish has emerged as a promising model to study regulation of both typical and atypical behaviours relevant for better understanding of autism and other neuropsychological disorders. In particular, we investigated how social deprivation influences the function of oxytocin neurons in zebrafish.

Methods: Transgenic zebrafish, expressing fluorescent proteins in oxytocin-producing cells (oxtl:egfp), were either housed in isolation or in social groups, from larval stage to adulthood. Zebrafish from these two groups were either exposed to a brief social stimulation, non-social objects, or left undisturbed in their home tanks (n ≥ 8, for all groups; age-matched, mixed-sex). Subsequently, they were euthanized and the brains were prepared for immunohistochemical experiments using an antibody against phosphorylated S6 (pS6), an endogenous marker of neuronal activation. The number and size of eGFP-positive neurons and the intensity of the eGFP signal, here used as a proxy for oxytocin mRNA transcription, were analyzed by confocal microscopy (LSM770, Zeiss). The imaging analysis was performed using Fiji/ImageJ software.

Results: Compared to the socially-housed sibling control groups, zebrafish isolated throughout their lives had lower levels of activation in oxytocin neurons, as measured by pS6 immunoreactivity. There was no obvious effect of brief social or non-social stimulation on the number of activated oxytocin neurons in either isolated or socially housed animals.

Conclusions: Our results indicate that life-long social deprivation resulted in lower activation of the oxytocin neurons in adult zebrafish and that isolated zebrafish can be a valuable tool for studying the oxytocin system. Understanding oxytocin’s role will provide excellent insight into regulation of vertebrate socialization and into onset and aggravation of social abnormalities, seen in autism and other neuropsychiatric conditions.

408.013 (Poster) Multi-Compartmental & Prenatal Metabolic Exploration in a Rat Model of ASD
A. Bourdin Pintuelles1, P. Emond1, S. Bodard1, J. Busson1, A. Lefèvre1, F. Bonnet-Brilhault1, S. Mavel1 and L. Galineau1, (1)UMR iBrain 1253, Inserm, University of Tours, Tours, France, (2)UMR iBrain 1253, Inserm, University of Tours, TOURS, France
Background: autism spectrum disorder (ASD) is a group of neurodevelopmental disorders whose etiology remains unknown. ASD is thought to begin in utero, but there is still a lack of information regarding the early biological modifications related to its pathophysiological mechanisms.

Objectives: our objective was to explore the biochemical changes occurring prenatally in the fetal brain and its environment using a validated animal model of ASD, i.e. a prenatal exposure to valproic acid (VPA).

Methods: metabolomics was used to investigate the biochemical modifications in the rat fetal brain, placenta, and maternal plasma extracted at the 19th day of gestation (GD19) from Wistar pregnant dams prenatally exposed to an acute VPA (600 mg/kg i.p.) or saline injection at GD12.5 (n=9 and 10 litters for the saline and VPA groups, respectively).

Results: we showed that the VPA acute injection at GD12.5 induced metabolic modifications observed in the fetal brain, placenta and maternal plasma at GD19. These changes were sex-specific in the fetal brains, the number of the discriminant metabolites being significantly more important in female than in male samples. In the fetal brain and placental compartments, VPA samples were discriminated from controls based on changes in energy, nucleotides, vitamin, inflammatory and amino acids-related (arginine, beta-alanine, GABA metabolisms in the fetal brains along with the methionine metabolisms in the placenta) metabolisms. In the maternal plasma samples, significant changes mainly involved amino acid metabolisms (beta-alanine, histidine, methionine metabolisms), and significant increases in pro-inflammatory cytokines (IL-6, TNF-α and IFN-γ) in the maternal plasma from the VPA group vs controls. In addition, these metabolic changes were highly and significantly correlated between each compartment.

Conclusions: These results support the crucial role of prenatal changes in the developing brain related to GABA neurotransmission, energy, nucleotides and inflammatory processes in the development of ASD-like phenotypes. It also emphasizes the role of the maternal environment, including a maternal inflammation in the pathophysiological mechanisms related to animal model of prenatal exposure to VPA. It also brings new insight into the biochemical modifications in the maternal environment that could be further investigated in the quest for early biomarkers of ASD.

408.014 (Poster) Preclinical Hearing-in-Noise Testing (HINT) Using Conspecific Ultrasonic Vocalizations (USVs) in the CNTNAP2 Mouse Model of ASD
A. E. Luebke and P. White, University of Rochester Medical Center, Rochester, NY

Background: Progress on treatments for communication difficulties in ASD has been hindered by lack of animal models with reliable assays of communication processing. Currently, model mice of ASD have been frequently studied, but the focus has been specifically on the output and repertoire of social vocalizations (Burkett et al. 2015). Moreover, the ability to identify relevant speech signals in one’s environment is clearly important for early social development, but also continues to play a critical role in learning and adaptive functioning across the lifespan. For example, a study of children with ASDs found that atypical scores on the Short Sensory Profile’s Auditory Filtering domain were significantly related to poor academic performance and inattention to cognitive tasks (Ashburner et al, 2008). Children and adolescents with ASD also exhibit significant difficulties hearing in background noise, or auditory filtering.

Objectives: We investigated auditory filtering capabilities using our hearing-in-noise test for the mouse, which makes use of the acoustic startle to assess the mouse’s ability to detect prepulse signals/targets presented in quiet or embedded in masking noise. Our prepulse signals/targets were either traditionally used noise bursts or novel conspecific ultrasonic vocalizations (USVs).

Methods: We modified established methods to test acoustic startle abilities behaviorally (Ison et al., 2017) to develop a hearing-in noise test for the mouse (mouse HINT). Our mouse HINT test made use of the acoustic startle response (ASR) and the ability of prepulses to inhibit the ASR [i.e., prepulse inhibition (PPI)] to assess the mouse’s ability to detect prepulse signals presented in quiet or embedded in masking noise. We determined signal-to-noise thresholds to both a noise burst (NB) and ultrasonic vocalization (USV) stimuli in quiet and in broadband noise. We assessed these differences to ten different conspecific mouse USVs separately or acoustically combined as “mouse babble” and tested in three mouse strains: C57Bl/6; FVB, 129SvEv, and C57Bl/6 x 129 SvEv. In addition, as mouse pups lacking the CNTNAP2 gene [CNTNAP2 (-/-)] emit less retrieval calls, and exhibit reduced repertoire of syllable vocalizations (Burkett, et al. 2015), we examined USV detection capabilities in mice lacking the CNTNAP2 gene and ASD mouse model.

Results: We determined there were mouse strain differences in USV discrimination abilities, yet for all strains tested the combination of 10 USVs (“mouse babble”) was the most effective startle stimulus in both quiet and background noise, and was more effective as a prepulse stimulus than a noise burst commonly used in ASR testing. Moreover, CNTNAP2 (-/-) mice exhibited less robust startle responses to mouse “babble” in both quiet and background noise.

Conclusions: We conclude conspecific USVs are a more robust and salient auditory target to study prepulse inhibition of acoustic startle than noise burst targets, and the CNTNAP2 (-/-) ASD mouse model not only has limited USV production, but also exhibits limited USV detection and discrimination capabilities. This type of analysis may provide a basis for future therapeutic test platform aimed at reducing auditory behavioral deficits.
Background: Aberrant connectivity between the medial prefrontal cortex (mPFC) and the mediodorsal thalamus (MD) is correlated with challenges in navigating social interactions. In mice, the mPFC Layer 5 pyramidal neurons that project to MD express the dopamine receptor D2 gene (Drd2). Previously, we showed that optogenetic excitation of Drd2+ cell bodies in mPFC was sufficient to reduce social exploration behavior in mice. Conversely, optogenetic inhibition of mPFC Drd2+ neurons was sufficient to rescue decreased social exploration behavior in the valproic acid autism model (Brumback et al. 2018). mPFC Drd2+ neurons are in the extratelencephalic class of neurons, and project to other subcortical regions besides MD. It is unclear if the projections to MD were specifically required for the effects on social behavior. Layer 6 cells also project to MD and it is unclear if similar manipulations of Layer 6 neurons would have similar effects on social behavior.

Objectives: The objectives of our study are to determine whether the reciprocal connections between MD and mPFC are necessary for social exploration and assess differences between Layers 5 and 6.

Methods: Male and female mice were injected bilaterally with an AAV encoding channelrhodopsin into mPFC or MD to assess whether directionality of information flow between the two brain regions is necessary for social behavior. In wildtype mice, Synapsin or CamKII promoters were used to target all projection neurons. In other mice, we expressed Cre-dependent channelrhodopsin under the Drd2-Cre (Layer 5) and Ntsr1-Cre (Layer 6). Light fibers were placed over the axons in the postsynaptic target region (MD or mPFC). Four weeks post-surgery, mice were run through 2 rounds of open field, novel social exploration, novel object exploration, and olfaction habituation/dishabituation tests to assess the effects of light stimulation on behavior. Mice were randomly assigned light on or off during week 1 of behavior and given the opposite light condition the following week.

Results: Overall, excitation of pan-neuronal or layer-specific fibers projecting to MD had no effect on total distance moved or time spent in the center of an open field. Excitation of Layer 5 Drd2-expressing neurons decreased time spent sniffing a social but not nonsocial stimulus whereas excitation of layer 6 Ntsr1-expressing neurons increased time spent sniffing both social and nonsocial stimuli. Conversely, excitation of pan-neuronal mPFC fibers in MD resulted in no changes to any behaviors measured. Excitation of projections from MD to mPFC was sufficient to decrease social sniffing time without affecting object sniffing time.

Conclusions: These experiments begin to uncover part of the complex mechanisms involved in regulating social behavior. Our results corroborate previous findings showing that subcortically-projecting mPFC neurons are necessary for social exploration in mice. We provide novel findings that these effects involve MD and are layer specific. We further show that MD neurons projecting to mPFC are also necessary indicating a bi-directional exchange of socially relevant information. Further studies will examine how neuromodulation of these specific cell populations influence prefrontal-dependent behaviors in mouse models of neuropsychiatric conditions.

Objectives: Our aim is to examine ultrasonic vocalizations (USVs) emitted by the model pups upon maternal isolation and clarify acoustic alterations of USVs comparing with those emitted by the wild-type pups.

Methods: The numbers of animals were 12 model pups (six male and six female) and 21 wild-type pups C57BL6/J (11 male and 10 female). Each pup was repeatedly isolated from the dam and littersates on postnatal days (PNDs) 4, 7, 10, 13, 16, and 19, and USVs emitted by the pup were recorded for 5 min and analyzed by using the Sonotrack System and Call Classification Software for Mice (Metris, The Netherland). The genotyping was executed on PND 28. Therefore, the experimenters did not know which pups were model or wild-type pups.

Results: The model pups exhibited extraordinary elevations of USVs compared with the wild-type pups on PNDs 10 (p < 0.001), 13 (p < 0.001), and 16 (p < 0.05), Fig. 1. On these experimental days, the model pups increased USV percentages with longer durations (15–100ms), whereas the wild-type pups increased those with shorter durations (4–15ms). An USV with frequency-changes more than 2 kHz was defined as frequency-modulation. The model pups increased percentages of frequency-modulated USVs of up, down, and other
complex changes but the wild-type pups increased percentages of frequency-constant USVs with frequency-change less than 2 kHz. When an USV consists of several segments, each segment was counted as a syllable. The model pups increased USV percentages with 2–3 syllables, whereas the wild-type pups produced one syllable-USVs. The Call Classification Software classified USVs into 14 categories based on syllable, duration, and frequency-modulation. The model pups indicated higher percentages of USVs categorized into Down and Step-Up types, whereas the wild-type pups indicated higher percentages of USVs categorized into Short type.

Conclusions: Maternal isolation induces higher anxiety in pups because pups are unable to survive without maternal care. Accordingly, pups emitted USVs to call their dams. In this study, the model pups produced more USVs with longer durations, frequency-changes, and multi-syllables. These acoustic characteristics are more attractive and noticeable for dams than USVs with shorter durations, frequency-constant, and one syllable. Maternal isolation seems to cause much higher anxiety for the model pups. Tamada et al. (2010) determined brain serotonin in the model pups on 1–3 weeks after birth and reported the reductions of serotonin levels. This suggests latent anxiety disorder in the model pups. Altogether, we conclude that the model pups emitted altered USVs due to much hyper anxiety.

408.017 (Poster) Uncovering Genotype-Phenotype Relationships across the Tbr1 Allelic Spectrum
M. Co1, C. N. LeBlanc1, A. Nishida1, K. M. Wright and B. J. O’Roak, (1)Molecular and Medical Genetics, Oregon Health & Science University, Portland, OR, (2)Vollum Institute, Oregon Health & Science University, Portland, OR

Background: The transcription factor gene TBR1 is strongly associated with a neurodevelopmental condition involving intellectual disability and autism. Patient mutations in TBR1 differ broadly in their type (e.g., frameshift, missense) and exonic location, potentially causing loss-of-function, gain-of-function, or dominant-negative effects. We previously characterized mice carrying different Tbr1 alleles: 5’ frameshift patient mutation p.A136Pfs*80 (p.A136fs), T-box missense patient mutation p.K228E, or knock-out by replacement of exons 2–3 with a neomycin cassette (“neo-KO”). Both neo-KO and p.A136fs resulted in loss of TBR1 protein, while p.K228E caused upregulation of a highly stable but dysfunctional TBR1 mutant protein. All three alleles produced congruent axon defects but discordant cortical cellular defects, including severe apoptosis unique to neo-KO. It is not fully understood how these Tbr1 alleles impact gene expression programs to produce phenotypic similarities and dissimilarities. Furthermore, the functional effects of other TBR1 patient mutations, such as 3’ frameshifts, have yet to be defined.

Objectives: We aim to identify the core molecular effects and brain developmental phenotypes resulting from different patient-specific TBR1 mutations. We also aim to identify distinct effects of each mutation that could underlie the heterogeneity of symptoms in TBR1-related conditions.

Methods: We analyzed Tbr1 mutant mouse lines p.A136fs, p.K228E, neo-KO, and an additional KO allele with exon 2–3 deletion using germline Cre-loxP (“del-KO”). Heterozygotes (reflecting human TBR1 heterozygosity) and homozygotes were compared to wild-type (WT) littermates, and both sexes were included. Postnatal cortex was analyzed using Western blot, quantitative PCR, and immunohistochemistry (IHC). RNA-seq was conducted in embryonic cortex to identify differentially expressed genes (DEGs) in Tbr1 mutants. TBR1 3’ frameshift patient mutation p.T532Rfs*144 (p.T532fs) was analyzed using in vitro assays in transfected HEK-293T cells.

Results: In Tbr1 neo-KO, p.A136fs, and p.K228E homozygote embryonic cortex, we identified a core set of ~600 genes dysregulated in all three lines. These genes include known TBR1 targets (Reln, Wnt7b, and Rorβ) as well as extracellular matrix (ECM) and cytoskeletal genes. In heterozygotes, fewer DEGs were identified; DEGs shared by at least two of three Tbr1 lines play roles in ECM (Cxcl12, Col23a1, Hs3st3b1), metalloprotease activity (Adams3, Tll2), and cytoskeleton (Nefl). The neo-KO allele produced more overall DEGs than p.A136fs or p.K228E, and DEGs unique to neo-KO were enriched for mitotic cell cycle functions, potentially underlying their severe apoptosis. Unlike neo-KO, del-KO mutants did not show severe apoptosis by IHC, suggesting detrimental effects of the neomycin cassette on cell survival. Finally, our preliminary in vitro analysis of p.T532fs protein found enhanced stability in the cycloheximide assay, and p.T532fs also enhances stability of WT TBR1 co-expressed in the same cells.

Conclusions: Analyses of multiple Tbr1 alleles suggest a common emerging etiology of dysregulated ECM and cytoskeletal genes during cortical development, potentially underlying the congruent axon defects in Tbr1 mutant brains. Moreover, 3’ frameshift mutations may enhance TBR1 stability similar to T-box missense mutants, suggesting a common pathogenic mechanism for mutant TBR1 proteins. Ongoing studies of patient-specific TBR1 mutations will further decode mechanisms controlling brain development and enhance our understanding of autism etiology.
Panel Chair: Caitlin Clements, Labs of Cognitive Neuroscience, Boston Children's Hospital
Labs of Cognitive Neuroscience, Brookline, MA

Discussant: April Levin, Neurology, Boston Children's Hospital, Brookline, MA

Resting state EEG offers a powerful, low-cost method to assess neural activity in young children. Features of the resting state power spectrum have been associated with cognition and development, and group level differences in oscillatory measures have been noted for those with ASD or elevated likelihood of ASD. This panel further describes behavioral correlates of resting state EEG in children, particularly investigating associations with sleep problems, restricted and repetitive behaviors, sensory processing challenges, and nonverbal and verbal developmental level. The panel also presents a diversity of features that can be extracted from the EEG power spectrum, and multiple methods of doing so, including periodic (oscillations) and aperiodic (exponent) signals extracted via FOOOF (Fitting Oscillations and One Over F), and transient beta activity computed via the Spectral Events Toolbox. Panelists and discussant will provide background and context for interpreting resting state EEG, and describe strengths and limitations of different features of EEG for gaining insight into behaviors and for use as potential biomarkers in clinical trials.

204.001 (Panel Discussion) Resting State Transient Beta Activity in Young Children with ASD
G. Parra1, K. E. Takachi1, C. MacKay1, Y. Braverman1, L. Cornelissen1 and A. R. Levin1, (1)Boston Children's Hospital, Brookline, MA, (2)Neurology, Boston Children's Hospital, Brookline, MA, (3)Anesthesiology, Boston Children's Hospital, Boston, MA

Background: While resting electroencephalography (EEG) offers substantial promise in developing biomarkers for autism spectrum disorder (ASD), understanding the neurophysiological mechanisms that underlie patterns of human EEG activity remains a challenge. Measurements of transient beta events (TBE) offer an exception to this challenge. These events are brief (lasting ~150 ms), recurrent, and reproducible patterns of EEG activity in the 15-29 Hz band. TBEs are driven by precisely timed thalamocortical circuit activity that has been well characterized in animal and computational models. TBEs also modulate sensory processing, leading to suppression or facilitation of sensory stimuli depending on the exact timing at which sensory events occur; this is particularly relevant given the paradoxical mix of hyper- and hyposensitivity that can be seen in ASD.

Objectives: We examined transient beta activity over the somatosensory cortex at rest in young children with ASD compared to those with typical development (TD). In a subset of subjects, we evaluated the relationship between TBE and phenotypic measures of sensory processing.

Methods: We collected data from children aged 3-4 years with ASD (n=22) and TD controls (n=24), matched across groups for age and gender. Continuous multichannel EEG was recorded while participants watched a silent video. TBEs located over the somatosensory cortex (C3, C4) were analyzed using the Spectral Events Toolbox in MATLAB. The mean and standard deviation of TBE features were computed for each individual across multiple 5000-ms epochs (average of 35 epochs per individual), and these were compared across groups using a Mann-Whitney U test. The Sensory Profile 2 (SP2) was completed by caregivers for a subset of participants (nASD=16, nTD=15), and associations between TBE rate and SP2 measures were examined with Spearman correlations. p<0.05 was considered statistically significant.

Results: TBE rate, power, and frequency span were all significantly higher in ASD, relative to TD (p=0.04, d=0.44; p=0.03, d=0.24; p=0.001, d=0.51, respectively). Intra-individual variability in TBE rate (as measured by the standard deviation of TBE rate across trials within an individual) was higher in individuals with ASD, relative to TD (p=0.03, d=0.61). TBE rate was significantly positively correlated with multiple SP2 measures, including tactile hyperactivity (r=0.50, p=0.004; see Figure 1).

Conclusions: Our data suggest TBEs occur more frequently and with greater power at rest in individuals with ASD compared to those with typical development (TD). In preschool children, the rate of TBE occurrence is more variable across epochs in ASD. Moreover, TBE rate is positively correlated with multiple measures of sensory processing. These differences provide insight into the mechanisms of sensory processing and allow us to generate new theories. For instance, given the role of TBE timing on sensory facilitation or inhibition, the greater variability of TBE occurrence in ASD could explain how ASD can give rise to both hyper- and hypo-sensitivity in the same individuals. Further data will be collected as part of this study to increase sample sizes and continue to study these features and associations.

204.002 (Panel Discussion) Evaluating EEG Based Biomarkers of Restricted and Repetitive Behaviors for Toddlers with or without ASD
H. Chung1, C. L. Wilkinson1, A. Job Said1, C. A. Nelson1 and H. Tager-Flusberg1, (1)Department of Psychological and Brain Sciences, Boston University, Boston, MA, (2)Department of Developmental Medicine, Boston Children's Hospital / Harvard Medical, Boston, MA, (3)Boston Children's Hospital, Brookline, MA, (4)Department of Developmental Medicine, Boston Children's Hospital, Boston, MA

Background:
Restricted and repetitive behaviors (RRBs) are one of the primary characteristics of the autism spectrum disorder (ASD). In typical development, repetitive motor behaviors appear early, declining after the first year of life. Across the autism spectrum, a greater severity of all RRBs, even simple repetitive motor behaviors are seen across early childhood (Kim et al., 2010).

Limited knowledge is available concerning the neurophysiological substrates associated with RRBs. Studying E/I balance could be particularly relevant to manifestation of RRBs as the imbalance of excitation and inhibition is suggested to be associated with social/cognitive deficits in autism (Rubenstein & Merzenich, 2003; Markram & Markram, 2010). Within EEG, the aperiodic exponent has been linked to the E/I balance (Gao et al., 2017). However, it has not yet been studied whether abnormalities found in E/I balance, measured via the aperiodic exponent, may account for severity of RRBs particularly manifested in ASD in early childhood.

Objectives:

We aimed to investigate the relation between severity of RRBs and the aperiodic exponent across 4 groups of infants (1) no concerns at 12 months (Low Likelihood-LL), (2) infants with an older autistic sibling (sibling-no ASD), (3) lower 12-month screening scores (screening-no ASD) on the (CSBS), (4) infants with an ASD outcome (ASD).

Methods:

At 12 months, aperiodic exponents were calculated via FOOOF (Donoghue et al., 2020) from a 5 minute resting-state EEG data. Exponents were extracted for frontal, central, temporal, posterior, and whole regions. At 24 months, RRBs were assessed via the Repetitive Behavior Scale-Revised parent report questionnaire. Associations between exponents and RRB were assessed using pearson correlation and linear regression with age and sex as covariates.

Results:

First, ASD group showed higher RRB scores than LL, sibling-noASD, and screening-noASD at 24 months [F(1,3) = 18.3, P < 0.001]. Next, we did not find evidence of a group level difference in exponents at 12 months [F(1,3) = 1.6, P= 0.19] (See Table 1). Finally, we asked whether the aperiodic exponent predicted severity of RRBs. Interestingly, we found a main effect of posterior exponents ( = -57.26, SE = 14.87, t = -3.85, p < 0.001) and an interaction between posterior exponents and groups in predicting RRBs [F(1,3) = 4.53, P = 0.004], with the interaction resulting from the ASD group (r = -.51, p=0.025). More specifically, there was a negative relation between the exponent and RRB, such that lower exponent, indexing higher E/I imbalance was associated with more RRBs. This relation was particularly prominent in ASD (Figure 1). A similar significant relation was observed with the model with central exponent as the predictor, and weaker trends were found with frontal, temporal, and whole exponent (model not significant).

Conclusions:

The finding that lower aperiodic exponent was associated with more RRBs in ASD highlights the importance of investigating E/I imbalance and its implications in ASD. We further plan to explore the relation between periodic oscillatory dynamics and RRB to fully understand neurophysiological mechanisms underlying behavioral manifestations in ASD.

204.003 (Panel Discussion) Considering the “Rest” in Resting State: Alpha Rhythm Associations with Sleep in Individuals with Disruptive Genetic Variants

C. M. Hudac¹, N. Pini², J. M. Bain³, R. K. Earl¹, E. E. Eichler¹, R. A. Bernier¹, E. Neuhaus¹ and S. J. Webb¹, (1)Department of Psychology; Carolina Autism and Neurodevelopment (CAN) Research Center, University of South Carolina, Columbia, SC, (2)Department of Psychiatry, Columbia University Irving Medical Center, New York, NY, (3)Department of Neurology, Division of Child Neurology, Columbia University Irving Medical Center, New York, NY, (4)Psychiatry and Behavioral Sciences, University of Washington, Seattle, WA, (5)Department of Genome Sciences, University of Washington, Seattle, WA, (6)Department of Psychiatry and Behavioral Sciences, University of Washington, Seattle, WA

Background: Sleep problems are prevalent in autism, including those related to difficulties with bedtime routine and nighttime awakenings (Liu, Hubbard, Fabes, & Adam, 2006) with 65% of parents report at least one problem in children aged 4-10 years (Sounders et al., 2009). Considering the biological foundation of sleep, it is important to consider a genetics-first approach to disentangle the potential mechanisms involving multidimensional measures of sleep and autism. Recent evidence indicates potentially unique sleep problems for young individuals with disruptive genetic variants associated with autism, such as CHD8 and DYRK1A (Earl et al., 2021). From a neurobiological perspective, it is thought that alpha rhythms (oscillations within the 8-12 Hz range) help suppress external responses to stimuli (Toscani et al., 2010; Haegens et al., 2011). Thus, reduced alpha rhythm may be related to increased sleep problems (e.g., bedtime issues, nighttime awakenings, or overall low quality).
Objectives: Here, we test the relationship between alpha rhythm (8-12 Hz) and sleep in autistic individuals with and without disruptive genetic variants associated with autism.

Methods: We utilize data from several studies that have both resting state and sleep data (N=111), including two studies that ascertained participants based upon a known genetic variant (n=39, TIGER study; n=41, BIOGENE study) and one study that ascertained based upon autism diagnosis (n=31, ZEBRA study). Resting state paradigms were comparable across studies, wherein children watched screensaver-like videos that were presented for 2-5 minutes; only eyes-open conditions are used here. Group differences in EEG frequency bands were compared using repeated-measures linear mixed effects models with Bonferroni-correction. Sleep problems were reported by parents during a clinician-administered medical history questionnaire (adapted from the Simons Simplex Collection Medical History Questionnaire) and included questions related to sleep onset, breathing issues, nighttime awakenings, and daytime tiredness. An additional subset of parents completed the Pittsburgh Sleep Quality Index (Buysse et al., 1989). Separate linear mixed effects analyses tested how binary sleep factors and sleep quality predicted peak frontal alpha power (identified from 8-12 Hz).

Results: Preliminary results include the TIGER and ZEBRA subset of participants with processed EEG data: 39 with a genetic etiology and 31 with idiopathic autism. Alpha was not associated with group differences, F(1,66)=0.014, p=.91. Alpha values were increased by 0.4 when parents endorsed problems with nighttime awakenings, p=.049. Lastly, there was a interaction between group and sleep quality, F(1,66)=6.37, p=.014, such that poor sleep quality (increased PSQI score) was related to an increased alpha power by for the genetic subgroup (0.47 slope) but not the idiopathic subgroup (0.67 slope, non-significant).

Conclusions: These results suggest that lower alpha rhythm is related to better sleep quality in genetic but not the idiopathic subgroup. Further work to understand individual difference factors, such as sex, age, cognition, and autistic symptoms, and subgrouping by specific genetic variant will be helpful in clarifying this finding.

204.004 (Panel Discussion) Characterizing the Resting State in Toddlers with Tuberous Sclerosis Complex
A. M. Engelstad, C. C. Clements, C. Hyde, A. Job Said, C. L. Wilkinson, S. Jeste and C. A. Nelson, (1)Graduate School of Education / Graduate School of Arts and Sciences, Harvard University, Cambridge, MA, (2) Labs of Cognitive Neuroscience, Boston Children’s Hospital Labs of Cognitive Neuroscience, Brookline, MA, (3) Psychology, Notre Dame, South Bend, IN, (4) Semel Institute, UCLA Medical Center, Los Angeles, CA, (5) Boston Children’s Hospital, Brookline, MA, (6) Department of Developmental Medicine, Boston Children’s Hospital / Harvard Medical, Boston, MA, (7) Children’s Hospital Los Angeles, Los Angeles, CA, (8) Department of Developmental Medicine, Boston Children’s Hospital, Boston, MA

Background: Tuberous Sclerosis Complex (TSC), a condition in which TSC1 or TSC2 mutations lead to benign hamartomas impacting neuronal function and connectivity, manifests behaviorally with features of autism, epilepsy, and intellectual disability. Approximately 50% of individuals with TSC meet criteria for Autism Spectrum Disorder (ASD). The neural mechanisms underlying ASD in individuals with TSC remain unknown, despite the known underlying gene mutation and resulting disruptions in neuronal pathways (the mammalian target of rapamycin (mTOR) pathway). Electroencephalography, or EEG, offers a window into neural oscillatory activity and may serve as an intermediate biomarker between gene expression and behavioral manifestations of ASD. Features of resting state EEG in infants with TSC have been associated with developmental outcomes. Dickinson et al (2019) reported that reduced interhemispheric alpha phase coherence in infants that were later diagnosed with ASD, and De Ridder et al (2020) found that an abnormal first EEG in infancy - or specifically, an immature EEG background - was associated with later ASD features, and lower language, cognitive, and motor scores at 24 months. Characterizing resting state EEG at baseline, before intervention, may predict treatment response for children with a known genetic etiology of autism.

Objectives: To characterize resting state EEG power in toddlers with Tuberous Sclerosis Complex and explore associations with developmental level.

Methods: Individuals with TSC (n=59) between 12 and 38 months (mean: 22.7, SD: 7.9; Table) were recruited for a behavioral intervention study. Before intervention, resting state EEG was collected using a 128-channel high density geodesic EGI cap. Children also completed the Mullen Scales of Early Learning (MSEL; Mullen, 1995). EEG data were processed using BEAPP (Levin et al., 2018), and power spectral densities were calculated using a multitaper spectral analysis then decomposed using FOOOF (Fitting Oscillations and One Over the F, Donoghue et al., 2020) into periodic and aperiodic components. Associations between aperiodic components (slope, offset) and verbal (MSEL receptive and expressive language) and nonverbal (MSEL visual reception and fine motor) scores were assessed with linear regression, controlling for chronological age.

Results: EEG data from 42 participants were included after data cleaning, yielding 71% data retention. Preliminary results showed no significant association between aperiodic slope or offset and participant age, though when binned by age, visual inspection indicated a consistent pattern of small increases in offset with age (Figure). Neither aperiodic slope nor offset predicted Mullen verbal or nonverbal composite (p>0.05).
Conclusions: Toddlers with TSC did not show a significant relationship of aperiodic slope or offset with chronological age or developmental level. More descriptively the data visually mirrored a large sample of typically developing toddlers (Wilkinson et al, in prep). Resting state EEG in TSC prior to intervention may eventually predict response to treatment and ultimately serve as biomarkers to inform personalized intervention selection. Future work will examine periodic components and additional covariates.

POSTER SESSION — BRAIN FUNCTION (fMRI, fcMRI, MRS, EEG, ERP, MEG)

409 - Brain Function (fMRI, fcMRI, MRS, EEG, ERP, MEG)

409.018  (Poster) A Survey of Epileptiform Discharges in Children with Autism Spectrum Disorders and a Pilot Study of Outcomes with Exposure to Anti-Epileptic Medication

S. M. Kaku1, M. W. James2, S. Gosala3 and A. Mysore4, (1)St John's Medical College Hospital and Research Institute, Bangalore, India, (2)Center for Advanced Research and Excellence in Autism and Developmental Disorders (CARE-ADD), St. John's Medical College Hospital, St John's Medical College Hospital, Bangalore, India, (3)Center for Advanced Research and Excellence in Autism and Developmental Disorders (CAREADD), St. John's Medical College Hospital, Bangalore, India, (4)Neurology, St John's Medical College Hospital, Bangalore, India, (5)CAREADD, St. John’s Medical College Hospital, Bangalore, India

Background:

Children with Autism Spectrum Disorder (ASD) have increased prevalence of epilepsy and/or abnormalities in EEG associated with behavioral issues (Anand & Jauhari, 2019; Giannotti et al., 2008; Hartley-McAndrew & Weinstock, 2010). The role of anti-epileptic drugs (AEDs) in such cases remains uncertain. Preliminary studies from our ongoing studies using EEG to understand autism and its cognitive and behavioral comorbidities, have suggested that prolonged EEG (up to 3 hours) recordings, including awake and sleep states, increase identification of significant epileptiform abnormalities in ASD.

Objectives:

To measure the prevalence and frequency of interictal epileptiform discharges (IEDs) in children with ASD with or without history of epilepsy in both awake and sleep states.

Explore short term clinical response to AEDs in those with IEDs.

Methods:

133 children with ASD aged 2-17 years underwent prolonged video-EEG recording for up to 3 hours using a 64-channel Philips Geodesic EGI 400 system using a specially designed protocol without use of sedatives. Children predominantly had moderate to severe ASD. The clinical contexts included regression, severe hyperactivity, self-injurious behaviors and/or aggression, with minimal response to first line psychotropics. EEGs were reviewed by the neurologist focusing on channels corresponding to the standard 10-20 system, to assess for IEDs and estimate their frequency in awake and sleep states. For 12 children with abnormal EEG, AEDs were started after educating parents regarding the empirical nature of this intervention for behavioral challenges. A pre and post treatment (2 months) assessment was done using Autism Treatment Evaluation Checklist (ATEC). Wilcoxon Sign Ranks Test was done to compare pre and post treatment scores.

Results:

Of the 133 children, 20 (15%) had IEDs in their awake-records. This yield increased to 47 children (35.3%) with extended record including a sleep phase covering Stage 1 and Stage 2 sleep. Of the 47 children with abnormal EEGs, 14 had previous history of clinical seizures and 2 had family history of seizures. Frequency of IEDs increased from ‘rare’ to ‘very frequent’/ ‘continuous spikes’ in sleep. 12 children who were exposed to AEDs were followed up after 2 months. Use of AEDs showed significant behavioral improvement clinically. There was significant improvement on the Autism Treatment Evaluation Checklist Scores in the domains of speech and language communication (p<0.005), sensory cognitive awareness (p<0.005) and health/physical behaviors (p<0.006). There were significant differences in the total scores as well (p<0.003). None of these children had additional interventions compared to baseline.

Conclusions:

Prolonged EEG recording increases the yield of IEDs in children with ASD. Sleep recording demonstrated enormous spike burden in some. High spike burden in sleep could arguably contribute to the behavioral problems in children with ASD. This reasoning led to use of AEDs with observed behavioral improvement. We acknowledge concerns about use of AEDs in those children without clinical diagnosis of
epilepsy and the uncertainties around the concept of ‘silent seizures’. We provide pilot evidence to show that AEDs may be beneficial in severe forms of ASD. Well-controlled interventional studies with larger samples, to explore cognitive and behavioral outcomes are necessary.

409.019 (Poster) Aberrant Resting-State Functional Connectivity in Individuals with ASD and ADHD Comorbidity

A. Riggs and L. Chen, (1)Neuroscience Program, Santa Clara University, Santa Clara, CA, (2)500 El Camino Real, Santa Clara University, Santa Clara, CA

Background: Autism Spectrum Disorder (ASD) and Attention-Deficit/Hyperactivity Disorder (ADHD) are conventionally thought to be very distinct neurodevelopmental disorders, but researchers have found that 30%~50% of individuals diagnosed with ASD also exhibit symptoms of ADHD. Extensive research has examined the neurobiological basis of ASD and ADHD separately, and the current literature suggests that both ASD and ADHD are characterized with aberrant brain connectivity within the default-mode, central executive, and salience networks (DMN, CEN, and SN). However, little is known about the neurobiological profiles of the comorbid group in comparison to the ASD-only group.

Objectives: The current study aimed to understand the neurobiological differences of individuals with both ADHD and ASD compared to those with only ASD. Specifically, we would like to examine the resting-state functional connectivity amongst the DMN, CEN, and SN along with the hippocampal memory network between ADHD-ASD comorbid and ASD-only groups.

Methods: Using available data from open-access datasets ABIDE (The Autism Brain Imaging Data Exchange) I from two sites (NYU and KKI) with information about comorbid conditions, we identified 23 individuals with comorbidity of ASD and ADHD and found 23 individuals with only ASD. The two groups were well-matched on gender, age, full-scale IQ and the distribution across two sites. All individuals completed a resting-state fMRI scan and their movements were within normal range during the scan. Based on the literature, we chose the following coordinates for DMN (ventromedial PFC/vlPFC: -2,38,-12; posterior cingulate cortex/PCC: -6,-44,34), CEN (bilateral dorsolateral PFC/dIPFC: -/+4,6,20,44; bilateral posterior parietal cortex/PCC: -40,-56,44 and 52,-52,50), SN (bilateral fronto-insular cortex/FIC: -34,20,-8 and 39,23,-4 and anterior cingulate cortex/ACC: 6,24,32), and bilateral hippocampus (-/+24,-14,-20) ROIs, to examine the functional connectivity differences between the ASD+ADHD and ASD-only groups. Standardized preprocessing pipelines were used for temporal alignment, normalization, smoothing and motion correction. Pearson's correlation was used to create t maps for each ROI, and significant results were thresholded at p<0.01 with 128 voxel-size (p<0.01 FDR-corrected) for each examined.

Results: We found that the ASD+ADHD comorbid group showed no increased connectivity compared to the ASD-only group but did show decreased connectivity compared to the ASD-only group amongst left dIPFC with superior temporal sulcus/gyrus, right AIC with vlPFC, left hippocampus with putamen and thalamus, as well as PCC with right insula and ACC. However, there were no significant group differences on the ASD symptom measures (from ADI-R and SRS) between the ASD+ADHD and ASD-only groups.

Conclusions: Our findings suggest that the individuals with comorbid ASD+ADHD were characterized with decreased functional resting-state connectivity compared to their ASD-only peers across the DMN, CEN, SN and hippocampal memory networks. Most of the aberrant connectivity observed in the comorbid ASD+ADHD group was associated with the CEN (e.g., dIPFC and vlPFC) and SN (i.e., FIC and insula) which are in general related to attention and state-monitoring abilities, in alignment with their attention deficits in addition to their ASD symptoms. The weaker hippocampal-putamen connections also seem to suggest a special deficit in the interaction of the memory, learning, and motor control systems in the comorbid group.

409.020 (Poster) Abnormal Properties of Resting EEG in Girls with Rett Syndrome

O. V. Sysoeva, V. Maximenko, O. Martynova and A. Hramov, (1)Institute of Higher Nervous Activity and Neurophysiology, Russian Academy of Science, Moscow, Russian Federation, (2)Baltic State University, Kaliningrad, Russian Federation, (3)Immanuel Kant Baltic Federal University, Kaliningrad, Russian Federation

Background: Rett Syndrome (RTT) is a rare neurodevelopmental disorder, caused by mutation in MECP2 gene, and associated with autism spectrum disorder. Its behavioral phenotype is quite severe as most patients with RTT (usually girls) could not talk or work independently, have problems with voluntary actions and communication. At the same time no drastic changes in brain structure or function are found. Recently emerging indexes, obtained from electrical brain activity (EEG), such as long-range temporal correlation (LRTC), believed to reflect the ability of brain networks to integrate information over extended periods, might provide important insight into the pathophysiology of RTT. Previous studies showed several abnormalities in spontaneous EEG in Rett Syndrome (for review see, Smirnov et al., 2022), while none examined the long-range temporal correlation.

Objectives: Here we aim to identify EEG parameters that are linked to pathophysiology of RTT.
Objectives: To investigate how age influences functional connectivity during visuospatial reasoning in autistic versus typical children.

Methods: 23 autistic (AUT) and 23 typical (TYP) children matched on age (6-15y), Raven’s Progressive Matrices and laterality completed a computerized fluid reasoning task in a 3T MRI scanner. The task contained 84 visuospatial problems with three levels of complexity. After preprocessing, generalized psychophysiological interaction (gPPI) and age regression analyses were performed (cluster threshold p<.05, FDR corrected, voxel threshold p<.001 uncorrected). The most activated clusters during the reasoning task were selected as seeds (precentral gyri, inferior frontal) and other frontal areas, the insula and the cingulate gyrus. In adolescents, no significant between-group differences were observed for either occipital or frontal seeds (precentral gyri, inferior frontal) and other frontal areas, the insula and the cingulate gyrus. In adolescents, no significant between-group differences were observed for either occipital or frontal seeds.

Results: In AUT participants, there was no significant relationship between age and functional connectivity involving the selected seeds and the rest of the brain. On the other hand, results from TYP participants showed positive associations between age and functional connectivity involving occipital seeds and many regions in frontal and parietal lobes, as well as between frontal seeds and many regions in frontal, parietal, temporal, and occipital lobes. This suggests rather different developmental effects in reasoning-related functional connectivity in AUT versus TYP individuals. Then, group comparisons (AUT vs. TYP) were performed within the younger (6-11y) and older (12-15y) age subgroups. Analyses in younger subgroups revealed higher functional connectivity related to complex visuospatial reasoning in AUT relative to TYP group between occipital seeds (secondary visual areas) and frontal regions, as well as between frontal seeds (precenral gyri, inferior frontal) and other frontal areas, the insula and the cingulate gyrus. In adolescents, no significant between-group differences were observed for either occipital or frontal seeds.

Conclusions: There was no significant developmental increases in functional connectivity within fluid reasoning network in autistic participants, whereas significant age-related increases in functional connectivity were observed in typical participants from 6 to 15 years old. These results nuance existing connectivity models in autism by highlighting the importance of considering developmental trajectories in brain connectivity. Consistent with the developmental shift model (Uddin et al., 2013), distinct patterns were observed in childhood and adolescence, namely the presence of over-connectivity in young AUT compared to young TYP, and no difference between AUT and TYP adolescents. In short, these results support 1) the importance of considering the age variable in autism neuroimaging studies, and 2) the presence of a developmental shift in connectivity within the fluid reasoning network in autism, going from widespread over-connectivity in childhood to fronto-parietal under-connectivity in adulthood.
409.022 (Poster) Age-Related Activity Increase in Visual Brain Regions Is Specific to Complex Visuospatial Fluid Reasoning in Autistic Children

**E. Danis**1,2, J. Degré-Pelletier1, E. B. Barbeau1 and I. Soulieres1,3, (1)Department of Psychology, Université du Québec à Montréal, Montreal, QC, Canada, (2)CIUSS-S-NIM, Montreal, QC, Canada, (3)Montreal Autism and Cognitive Neuroscience Research Group, Montreal, QC, Canada, (4)Cognitive Neuroscience Unit, Montreal Neurological Institute, McGill University, Montreal, QC, Canada

Background: In autistic adults, fluid reasoning is supported by occipital hyperactivity and prefrontal hypoactivity, suggesting a greater influence of visuoperceptual resources in reasoning (Soulieres et al., 2009; Sahyoun et al., 2010). While behavioral studies point towards better visuospatial fluid reasoning skills in autistic compared to typically developing (TD) children (Sahyoun et al., 2009; Danis et al., 2022), whether the cerebral activity pattern observed in adults is already present in school-aged autistic children remains unknown.

Objectives: To compare cerebral activity underlying fluid reasoning in autistic versus TD children, focussing on problem content, complexity and age.

Methods: 22 (1 female) autistic and 24 (5 females) TD children (6-15 years old; M=11.47, SD=2.39), matched on age, gender, handedness and Raven’s Progressive Matrices, completed 168 pictorial 2x2 matrix problems randomly presented in an event-related fMRI design. Problems varied in content (Visuospatial or Semantic) and relational complexity (0, 1 or 2 relations to manipulate mentally). Data were collected with a Siemens 3T MRI scanner and preprocessed and analyzed with SPM12 (k=20 voxels, FDR corrected cluster-level p<.05).

Results: Autistic and TD participants reached similar levels of accuracy (p=.14) and RT (p=.44), with better performance at Semantic>Visuospatial problems and at 0>1>2 relations problems. Overall, fluid reasoning was supported by a large occipito-parieto-temporal network, with increased activity in bilateral parietal lobules for the most complex problems (2 relations). In the autistic group only, better performance at the task also predicted increased activity in the left middle and superior frontal gyri. Interestingly, activity in several posterior regions (lingual and calcarine gyri, cuneus) was stronger in TD than autistic children during both semantic and visuospatial problems. Older (12-15 years old) participants showed stronger frontoparietal activity compared to younger (6-11 years old) participants at 1 and 2 relations problems. In the TD group, older participants exhibited stronger temporal, parietal and occipital activity than younger participants for complex problems. In the autistic group, weaker frontal and occipital activity was found in older versus younger participants for complex semantic problems. However, increased activity in middle frontal and precentral gyri, but also fusiform, inferior temporal, precuneus, parietal lobules and middle occipital gyri was found in older autistic participants for complex visuospatial problems.

Conclusions: Fluid reasoning elicited a comparable widespread cerebral network in autistic and TD school-aged children and adolescents. Within this network, activity in several posterior regions was stronger in TD compared to autistic children, contrary to previous findings of increased occipital activity in autistic adults relative to TD adults. Fluid reasoning development was characterized by an increase in frontoparietal activity in all participants. There was also an age-related increase in occipital activity for complex problems in TD participants, whereas the age-related increase in occipital activity was specific to complex visuospatial reasoning in autistic participants. This suggests a developmental effect in the specialization of visuoperceptual regions in autism, leading to a greater reliance on visuoperceptual processes during fluid reasoning in adulthood.

409.023 (Poster) Altered Fusiform Connectivity Underlying Face Processing Deficits in Youth with Autism Spectrum Disorder Compared to Early-Onset Psychosis

**R. Jalal1, H. Gutierrez1, K. Laulotte1, M. Rshtouni1, C. E. Bearden1, K. Karlsgodt1, A. Nair1 and M. Mahale1, (1)Psychology, Loma Linda University, Loma Linda, CA, (2)Loma Linda University, Loma Linda, CA, (3)University of California, Los Angeles, Los Angeles, CA, (4)Department of Psychiatry and Biobehavioral Sciences, University of California, Los Angeles, Los Angeles, CA

Background: Autism spectrum disorder (ASD) and early onset psychosis (EOP) are neuropsychiatric disorders characterized by social deficits, including impaired processing of facial expressions (Brennan et al., 2014; Dalton et al., 2005; Marwick and Hall, 2008; Narita et al., 2021). The fusiform gyrus has been implicated in face/emotion processing impairments cross-sectionally in both groups (Apicella et al., 2013; Kleinians et al., 2009; Schultz, 2005). Few studies have investigated the association between fusiform gyrus connectivity and emotion processing in ASD youth relative to EOP youth to identify any shared or distinct patterns unique to each diagnostic group.

Objectives:

To examine whole-brain functional connectivity of the fusiform gyrus and its relationship to emotion processing measures in a group of youth with ASD or EOP, compared to typically developing (TD) controls.

Methods:
Resting-state MRI data were acquired on a 3T Siemens scanner for 24 adolescents with ASD (Mean age = 15.89), 25 EOP adolescents (Mean age = 16.42), and 21 TD controls (Mean age = 17.26). Data were preprocessed in FSL (Smith, 2004) and AFNI (Cox, 1996), and included motion correction, nuisance regression (white matter, cerebrospinal fluid), and bandpass filtering (0.008 < f < 0.08 Hz). A 6mm right fusiform gyrus (rFG) seed (Koshino et al., 2008) was used to extract timeseries and correlate with whole-brain signal. Final connectivity maps were normalized using Fisher’s r-to-z transformation. Parameter estimates were extracted from significant clusters of rFG connectivity within each group. Pearson’s correlations were run to examine the relationship between rFG connectivity and the WebCNP Emotion Recognition Test accuracy and speed of processing scores (KER-40; Gur et al., 2010).

Results:

Between-group comparisons revealed both ASD and EOP youth demonstrated mixed over-and-under-connectivity of the rFG compared to TD controls. Specifically, ASD demonstrated rFG overconnectivity with right superior parietal lobule; but underconnectivity with left inferior occipital gyrus and right superior temporal gyrus compared to TD controls (p = .01). In contrast, EOP demonstrated rFG overconnectivity with right inferior parietal lobule, right supramarginal gyrus, and right middle temporal gyrus; but rFG underconnectivity with right inferior occipital gyrus compared to controls (p = .01). Only rFG overconnectivity was associated with poorer performance on KER-40 task in both ASD (p = .04) and EOP (p = .04) groups, and additionally with faster speed of processing (p = .05) in the EOP group.

Conclusions:

Our results suggest distinct patterns of mixed rFG connectivity in both ASD and EOP, of which the overconnectivity patterns were most associated with difficulty in recognizing facial emotions. Specifically, ASD group demonstrated rFG overconnectivity with regions implicated in social cognition (Bigler et al., 2007) and visuospatial processing (DeRamus et al., 2014). EOP youth demonstrated rFG connectivity patterns in regions associated with processing of emotional responses (Numssen et al., 2021; Wada et al., 2021). These findings suggest that atypical connectivity of the rFG may be exhibited by both ASD and EOP, contributing to emotional processing deficits in each via different pathways, such as broader social and visual difficulties in ASD and more specifically disrupted emotional response processing in EOP.

409.024 (Poster) Altered Global Modular Organization of Intrinsic Functional Connectivity in Autism Arises from Atypical Node-Level Processing

P. J. Sigar, L. Q. Uddin and D. Roy*, (1)Psychiatry and Biobehavioral Sciences, University of California Los Angeles, Los Angeles, CA, (2)Department of Psychiatry and Biobehavioral Sciences, University of California Los Angeles, Los Angeles, CA, (3)School of Artificial Intelligence & Data Science, Indian Institute of Technology Jodhpur, Rajasthan, India

Background: Autism spectrum disorder (ASD) is a neurodevelopmental condition characterised by restricted interests and repetitive behaviours as well as social-communication deficits (Picci et al. 2015). These traits are associated with the atypicality of modular organisation of the functional brain networks (Hull et al. 2017). Previous neuroimaging research demonstrates discrepancies in studies of functional brain modular organisation in ASD resulting from the examination of mixed age groups. Furthermore, alteration in the modular organisation originating from systematic nodal changes are yet to be explored in younger children with ASD. Here we used graph-theoretical measures to examine global and regional modular properties in young children with ASD.

Objectives: To address outstanding questions (a) whether alteration of global modular structure arises from the atypical modular cohesiveness of specific brain regions in children with ASD, and (b) whether alteration in the topological roles of specific brain regions is responsible for atypical modular configuration in children with ASD.

Methods: Six minutes of resting-state BOLD fMRI data (age: 5-12 years, males, IQ>75, right-handed) was obtained from the Autism Brain Image Data Exchange (ABIDE) I and II. A total sample of 34 ASD and 40 typically developing (TD) children matched for age, gender, full-scale IQ, and head motion were selected from only those sites which used a TR=2 for data acquisition. The fMRI data were preprocessed using Data Processing Assistant for Resting-State fMRI (DPARSF) toolbox (Chao-Gan et al., 2010). We used Louvain community detection method (Blondel et al. 2008) and normalised mutual information method (Kuncheva et al., 2004) to study the group differences in global modular organisation networks and modular composition, respectively. To investigate the group differences in modular connectivity and topological roles of nodes we used measures namely participation coefficient and within-module degree (Guimerà & Amaral, 2005).

Results: The ASD group showed significant differences in the global modular organization measures - global modularity, average modular size, and number of modules (p<0.05, FDR corrected) compared with the TD group (Table 1). At the global level, we observed significant similarity in modular composition across groups, however at subject-level and node-level analyses significant group differences of network structures (FDR corrected, p<0.05) were shown to be contributed to by nodes of default-mode (DMN), salience (Sal), and sensorimotor (SM) networks. Furthermore, in ASD, a significant increase in between-modular connectivity and a decrease in within-modular connectivity was observed at the nodal level contributed to by nodes from DMN, SM network, and Visual, and Limbic networks respectively (p<0.01; FDR corrected). Functional cartography revealed alteration in topological roles of nodes in ASD group (FDR
corrected, p>0.001) (Fig & table 1). The follow-up analysis showed that nodes that switched their roles were from DMN, Sal, and SM networks.

Conclusions: We demonstrate that alterations in topological roles and modular cohesiveness of brain regions anchored in DMN, SM and Sal networks possibly result in atypical global network organisation in children with ASD. Taken together our findings contribute to the growing body of literature suggest that alterations in nodal topology may start occurring at very early ages in children with ASD.

409.025 (Poster) Altered Signal Complexity in Children and Adolescents with ASD
M. Proteau-Lemieux, I. S. Knoth, J. Lim, E. Anagnostou, J. Frei, L. Capano and S. Lippe, (1)CHU Sainte-Justine Research Center, Neuroscience of Early Development lab, Montreal, QC, Canada, (2)Holland Bloorview, Toronto, ON, Canada, (3)Autism Research Centre, Bloorview Research Institute, University of Toronto, Toronto, ON, Canada, (4)McMaster University, Hamilton, ON, Canada, (5)Queen’s University, Kingston, ON, Canada, (6)Neurosciences of Early Development Lab, CHU Sainte-Justine University of Montreal, Montreal, QC, Canada

Background: Autism spectrum disorder (ASD) is a neurodevelopmental condition present in 1% of the global population, impairing the daily functioning of affected people. ASD is associated with cognitive and behavioral symptoms. In addition, severe electrophysiological alterations have been found in ASD, characterized by cortical hyperexcitability. This hyperexcitability is thought to be caused by an imbalance between excitatory and inhibitory cortical mechanisms. Previous literature has shown that electrophysiological activity measured by electroencephalogram (EEG) during resting-state is perturbated. Indeed, patients with ASD show lower power in the alpha frequency band, the prominent oscillations in humans during resting state, as well as higher gamma power. Furthermore, signal complexity, which is considered a biomarker for brain maturation in many neurodevelopmental disorders, is lower in patients with ASD compared to controls, suggesting developmental deviations in this population. However, to our knowledge, no study has explored signal alterations in higher complexity scales.

Objectives: The aim of this study was to analyze power spectral density (PSD) in frequency bands of interest (alpha and gamma), as well as signal complexity in individuals with ASD.

Methods: In this study, the EEG power and signal complexity of 43 participants with ASD aged between 5-17 (12.6±3.57) were compared to 54 neurotypical (NT) controls aged between 5-18 (9.56±3.37). All participants with ASD were verbal and their intellectual quotient (IQ) ranged from 44 to 124 (93.88±16.65).

Results: PSD results showed that patients with ASD had lower alpha power in frontal, parietal and occipital regions, and higher gamma power in fronto-central and frontal regions. Furthermore, signal complexity was reduced in patients with ASD compared to NT controls, especially in higher scales (21-40). Finally, correlation analyses showed a positive association between age and signal complexity, as well as between IQ and signal complexity in ASD patients and NT controls.

Conclusions: Our results confirm that patients with ASD have altered brain activity in the alpha and gamma frequency bands. This study was also the first to show lower signal complexity in higher scales in this population, suggesting deficits in long-range connectivity. Those results have been previously reported in fragile X syndrome, a genetic disorder known as the most common monogenetic cause of ASD. Lastly, the positive relationships between signal complexity and age, and signal complexity and IQ suggest that signal complexity is sensitive to brain maturation and functioning not only in NT controls, but also in a population of individuals with ASD.

409.026 (Poster) Amygdala fMRI Activation and Autism Symptomology in Sleeping Infants

Background: Autism Spectrum Disorder (ASD) is rarely diagnosed before two years of age and the search to discover the emergence of its early symptoms and causes has been challenging. To accurately predict which infants will develop behavioral characteristics that impact quality of social interactions, sensitive and specific biomarkers need to be discovered.

Objectives: To develop an fMRI task that 1) activates the amygdala, orbital frontal cortex and hippocampus in sleeping infants and 2) is sensitive to behavioral symptoms considered to be putative signs of ASD in infants.

Methods:
All study participants had a low likelihood of developing ASD (i.e., no first-degree relatives with ASD). Parents were administered the Autism Parent Screen for Infants (APSI) and the Vineland Adaptive Behavioral Scales – 3. MRI was performed under natural sleep with COVID safety protocols. Twenty-five infants, 14 male, 11 female, mean age = 7.4 months, SD=.64, provided valid fMRI data. **fMRI task.** Olfactometer tubes were positioned toward the infant’s nose to present phenylethyl alcohol, a rose-like pure odorant that selectively stimulates the olfactory nerve. Olfactometer equipment setup was as previously described [1]. Two block design runs were collected with four nine-second olfactory trials separated by an inter-trial interval (ITI) of 18 second (task duration, one minute, 48 seconds) [1]. The rose-like odorant, phenylethyl alcohol (concentration ≥99% v/v; Sigma-Aldrich) mixed with plain air was administered. Quiet BOLD fMRI scans were obtained on a 3T Philips Elition X with a 32-channel head coil (TR/TE=1500/30ms, 2.5 mm3 isotropic, MB=3, SENSE factor=2, 72 dynamics). Preprocessing and analyses were performed using FSL. Preprocessing included motion correction, brain extraction, detrending, distortion correction, and registration to the 7.5 month infant template [2]. A basis function with an optimized hemodynamic response for infants [3] was generated using “Make_flobs” and entered into the GLM. Odor scans were combined at the individual level using fixed effects. FLAME was used for the higher-level group mean contrast and thresholded at z > 2.3 (voxel height), uncorrected. We analyzed the relationship between olfactory activation and parent-reported autism characteristics (APSI). APSI total score was entered as a regressor variable into a whole-brain, mixed-effects FLAME model thresholded at z > 2.3 (voxel height), uncorrected.

Results: The APSI mean total score was 7.72, SD = 4.07, range = 2-20. Group analyses conducted using a whole-brain field-of-view yielded significant activation across primary and secondary olfactory cortices (Fig. 1A) including the amygdala, orbital frontal cortex, hippocampus, piriform, thalamus, and cerebellum. Higher APSI total scores were associated with higher bilateral amygdala (Fig. 1B) and occipital cortex activation.

Conclusions: Preliminary results indicate amygdala activation to our odor fMRI paradigm is related to behavioral characteristics that confer a greater likelihood for developing ASD. Further longitudinal research with a larger group of infants with both high likelihood and low likelihood of ASD is required to confirm this correlation and determine whether this imaging approach can help anticipate the future onset of atypical socioemotional behaviors.

**409.027 (Poster) Attribution of Salience to Social Versus Nonsocial Stimuli Differs in ASD and TD Youth**

*A. Thun1, G. Patterson1, K. K. Cummings1, J. Jung2, L. Abbasi3, S. Y. Bookheimer4, M. Dapretto4 and S. A. Green5, 1Interdepartmental Neuroscience PhD Program, UCLA, Los Angeles, CA, 2University of Denver, Denver, CO, 3The University of North Carolina at Chapel Hill, Chapel Hill, NC, 4Dept of Psychiatry and Biobehavioral Sciences, University of California, Los Angeles, Los Angeles, CA, 5University of California, Los Angeles, Los Angeles, CA,*

**Background:** Challenges with social and sensory information are core features of autism spectrum disorder (ASD) and atypical sensory processing may contribute to social challenges (Hamilton et al., 2018). Previous studies have indicated that sensory over-responsivity (SOR) in ASD is related to hyperactivation in the amygdala and reduced downregulation of the amygdala by the orbitofrontal cortex (OFC) during mildly aversive stimuli (Green et al., 2015). Further, SOR is thought to be associated with over-attrition of salience to extraneous sensory information (Green et al., 2016). For typically developing (TD) youth, both the amygdala and OFC are critical components in the brain circuit responsible for salience attribution of social and sensory information (Zalla et al., 2013; Gothard et al., 2022). This study examined amygdala and OFC neural activation during mildly aversive social compared to nonsocial stimuli to better understand how increased attribution of salience to socially irrelevant sensory information in ASD could contribute to difficulties in social interaction.

**Objectives:** To determine differences in brain responses during exposure to mildly aversive social versus non-social auditory stimuli in youth with and without ASD.

**Methods:** Twenty-one ASD and 25 TD controls, age 10-17 years, were presented with four stimulus conditions in a counterbalanced block design fMRI paradigm: social auditory, nonsocial auditory, social auditory+tactile (joint), and nonsocial auditory+tactile (joint). Social and nonsocial stimuli were matched for aversiveness level based on pilot testing and consisted of sounds of children screaming in play and white noise, respectively. The tactile stimulus was a scratchy sponge rubbed on participants’ inner arms. A region-of-interest approach was used to extract right and left amygdala and OFC parameter estimates (PEs) from each of the four conditions. Repeated-measures analyses of variance were conducted using PEs with social relevance of stimulus (nonsocial vs. social), stimulus type (joint vs. auditory), and laterality (right vs. left) as within-subject factors as well as diagnostic group (ASDs vs TD) as a between-subject factor. Full-scale IQ, age, and sex were tested as covariates and included if significant at p<0.1.

**Results:** There was a significant interaction between diagnostic group and social relevance, indicating that the TD group increased both amygdala and OFC neural response in the social compared to the nonsocial condition whereas the ASD group did so in the nonsocial compared to the social condition. Furthermore, there was a significant three-way interaction between diagnostic group, social relevance of stimulus, and laterality of OFC neural activity, with most of the significance driven by the left OFC. There were no other significant main effects or interactions.

**Conclusions:** The TD group showed selective activation of attention and emotion-regulation regions to social compared to nonsocial stimuli, indicating greater salience attribution to socially relevant information. Conversely, the ASD group showed increased selective
activation of attention and emotion-regulation regions to nonsocial compared to social stimuli, which suggests an over-allocation of attention to the general aversiveness rather than the social significance of sensory information. This challenge with filtering out extraneous information could contribute to difficulty prioritizing socially significant information in youth with ASD.

409.028 (Poster) Atypical Neural Adaptation to Vocal and Non-Vocal Sounds in Autism

A. Merchie, E. Houy-Durand\textsuperscript{1,2}, F. Bonnet-Brilhault\textsuperscript{1,2}, C. Escera\textsuperscript{3,4,5}, J. J. Aucouturier\textsuperscript{6,7} and M. Gomot\textsuperscript{8}, (1)UMR 1253, iBrain, Université de Tours, Inserm, Tours, France, (2)Exac-T, Centre universitaire de pédopsychiatrie, CHRU de Tours, Tours, France, (3)Brainlab-Cognitive Neuroscience Research Group, Department of Clinical Psychology and Psychobiology, University of Barcelona, Barcelona, Spain, (4)Institute of Neurosciences, University of Barcelona, Barcelona, Spain, (5)Institut de Recerca Sant Joan de Déu (IRSDJ), Esplugues de Llobregat, Barcelona, Spain, (6)FEMTO-ST Institute, Université de Bourgogne Franche Comté, CNRS, Besançon, France, (7)STMS Lab IRCAM, Sorbonne Université, CNRS, Paris, France, (8)INSERM Grand Ouest, Tours, France

Background:

Atypicalities in auditory change detection have been demonstrated several times in autism through the Mismatch Negativity (MMN) (Chen et al., 2020). Recently, it was proposed that differences in the MMN response to deviant stimuli may actually result from difficulties to adapt to the standard stimuli that precede them. At the brain level, neural adaptation is characterized by a decrease in activity when the number of repetitions of a same sound increases, and can be measured with Auditory Evoked Potentials (AEPs) through the modulation of P1 and N100 amplitude. Studies on autistic individuals showed a lack of modulation of brain responses to pure tones (Kolesnik et al., 2019) and to human sounds (Ruiz-Martinez et al., 2020), but these studies used oddball paradigms that are not designed to specifically study adaptation. Here, we propose to use the roving paradigm (Baldeweg et al., 2004), which allows to measure the Repetition Positivity (RP), the preferred cue for studying neural adaptation.

Objectives:

The objective of the current study was to characterize the RP and the dynamic of adaptation to vocal and complex non-vocal sounds in autistic adults (ASD), and to compare them to typically-developing (TD) adults.

Methods:

Adaptation to different types of 300ms sounds (voice and complex non-vocal controls composed of the fundamental and first fourth formant frequencies) was measured through the modulation of P1, N100 and RP in a roving paradigm. Sounds were repeated in trains of 4, 8 or 14 repetitions while measuring brain response with 64 active electrodes. Eight autistic and fifteen typically-developing adults were included.

Results:

The comparison of the RP amplitude between TD and ASD groups revealed a significant difference ($\chi^2(1)=18.13$, $p<.001$, $\eta^2=.26$). RP was barely observed in ASD, indicating no adaptation to either sound category. However, the RP is a difference wave calculated by subtracting the response to the minimum of repetitions from the maximum, without considering the dynamic characterized through the N100 and P1 amplitude modulation.

When looking at intermediate repetitions, for non-vocal sounds, in TD, the N100 amplitude was modulated after 9 to 11 ($p<.05$) until 12-14 repetitions ($p<.01$). In ASD, no modulation of the amplitude was observed regardless the number of repetitions ($p>.05$), confirming findings from previous subcortical study (Font-Alaminos et al., 2020).

For vocal sounds, in TD, 12-14 repetitions were necessary to observe a P1 amplitude modulation ($p<.05$). In contrast, it varied in ASD from 5-8 ($p<.05$) to 9-11 repetitions ($p<.05$), but returned to its original level in response to 12-14 repetitions ($p>.05$) indicating an instability of adaptation.

Conclusions:

The number of repetitions and the social nature of sounds appeared to influence the adaptation process and its dynamic in our sample. The lack of stabilization of habituation in ASD participants might contribute to the atypical detection of changes and the need for sameness in ASD.

Even in a small sample, this lack of stabilization in ASD participants seems quite robust as it was found for both sound categories and should be confirmed on a larger sample, to be collected as part of final study.
Background: Autism (AT) and schizophrenia (SZ) are both characterized by differences in social cognition and behavior compared to neurotypical (NT) development (Fernandes et al., 2018). These conditions are hypothesized to have common neurobiological features, however, event-related potential (ERP) studies of social-emotional processing in these populations have yielded mixed results (Levy et al., 2021). The Late Positive Potential (LPP) ERP is an index of sustained and motivated attention to salient stimuli (Liu et al., 2012; Schupp et al., 2000). Individuals with SZ demonstrate attenuated LPP amplitudes to emotionally valenced stimuli, although effect sizes are small (Castro et al., 2019). Few studies have examined the LPP in autistic individuals (Keifer et al., 2019) and no study to date has compared the LPP across AT, SZ, and NT.

Objectives: This study examined LPP amplitude in response to happy and fearful facial expressions in autistic adults, neurotypical adults, and adults diagnosed with schizophrenia using a gaze-contingent paradigm.

Methods: Participants included 68 adults (31 NT, 25 AT, 12 SZ) aged 18-39 years (M=25.41, SD=5.82) with FSIQ≥70 (M=107.40, SD=16.78) as measured by the WASI-2 (Wechsler, 2011). Diagnoses were confirmed using the ADOS-2 (Lord et al., 2012) and the PANSS (Kay et al., 1987). Electroencephalogram data were recorded using 128-channel HydroCel Geodesic Sensor Nets at 1000Hz and simultaneous eye-tracking data were recorded using SR-Eyelink at 500Hz while participants passively viewed a gaze-contingent paradigm. Neutral adult faces were presented and after participants fixated on the eyes for 500ms, it displayed an emotional expression (happy or fearful) for 1000ms. As such, participants were fixating on the eye-region when the emotional face appeared. Data were processed usingERPLAB (Lopez-Calderon & Luck, 2014), and the LPP was scored as mean activity between 300-1000ms after emotional face onset.

Results: Results of a two-way ANOVA examining the effect of group (NT, AT, SZ) and facial expression (happy, fearful) on LPP amplitude revealed a significant difference in LPP amplitude by group (F(2,130)=4.427, p<.05) such that the AT group evinced larger LPP amplitudes than the NT and SZ groups (p's<.05, Figure 1). No significant differences were found in LPP amplitude by facial expression or the interaction of group and expression (p's>.4).

Conclusions: In contrast to previous literature (Benning et al., 2016), autistic adults demonstrated increased elaborative processing of emotional facial expressions compared to neurotypical adults and adults with schizophrenia. Adults with schizophrenia did not differ in LPP amplitude from the NT group, although the sample size was small. Importantly, the current paradigm was gaze-contingent, meaning that it required participants to look to the eye-region before it advanced. While social neuroscience studies have long focused on attenuated processing of social stimuli in autism, autistic individuals have qualitatively reported hypersensitivity to eye contact (Trevisan et al., 2017). The current results align with the theory that autistic individuals may experience amygdala-related hyperarousal when making eye-contact (Stuart et al., 2022). Future studies should continue to evaluate the role of hyperarousal in social-emotional processing in autistic individuals.
**Objectives:** We evaluate and compare the overall background slope of the resting state EEG power spectrum in children with the above disorders, as well in typically developing (TD)controls.

**Methods:** Resting state EEG data acquisition is currently ongoing from children with PMS (n=21), TSC (n=18), PHTS (n=6), as well as age-matched typically developing controls (TD, n=7) across six sites as part of the Developmental Synaptopathies Consortium. Data collection is standardized across sites and pre-processed using the Harvard Automated Preprocessing Pipeline for EEG (HAPPE) which is embedded in the Batch EEG Automated Processing Platform (BEAPP). To evaluate the aperiodic slope of the power spectrum, we used the Fitting Oscillations and One Over F (FOOOF) algorithm. To compare slope across groups, we used an independent Kruskal Wallis test with post-hoc analysis using Bonferroni correction.

**Results:** Children with PMS had significantly lower values of slope when compared with TSC (adj. p = 0.02) and PHTS (adj. p= 0.024). There was a trending difference when PMS was compared against the TD group, however this did not survive correction.

**Conclusions:** Flattened slope in PMS may reflect a shift to local rather than global processing, as well as a disruption in the balance of excitation/inhibition activity. Future analysis will assess relationships between slope and phenotypic measures between the different mTOR pathway related disorders. These analyses could also be considered for back translation applications to understand basic differences in neural circuit function between the disorders.

---

**Background:**
Cognitive flexibility helps us to navigate through our ever-changing environment. Difficulties in cognitive flexibility may be associated with rigid behavior as often described in individuals with ASD. Reversal learning paradigms can be used to examine this type of behavior and assess individual performance. Computational modeling of behavioral performance and analysis of model parameters allows for a closer linking of biologically plausible models, psychological mechanisms, and measurable behavior. Although such modelling approaches are increasingly used in cognitive neuroscience, their application to typically developing (TD) samples and to individuals with neurodevelopmental conditions such as ASD is still scarce.

**Objectives:**
We combined behavioral modelling of a reversal learning task with fMRI neuroimaging in TD and ASD individuals to investigate the neural substrates of cognitive flexibility and their modulation by the context of the learning feedback.

**Methods:**
We used hierarchical Gaussian filter modeling to analyze reversal learning data in 28 TD children and 25 TD adolescents and the effect of various feedback types during fMRI scanning, and additional behavioral runs outside the scanner. Data collection and analysis of children and adolescents with ASD is ongoing.

**Results:**
The behavioral results demonstrate that children make more overall errors and regressive errors (when a previously learned response rule is chosen instead of the new correct response after the initial shift to the new correct target), but less perseverative errors (when a previously learned response set continues to be used despite a reversal) adolescents. Analyses of the extracted model parameters of the winning model revealed that children seem to use new and conflicting information less readily than adolescents to update their stimulus-reward associations. Furthermore, a subclinical index of rigidity in everyday life (parent-ratings) is related to less explorative choice behavior during the probabilistic reversal learning task. Preliminary fMRI analyses show that TD adolescents compared to TD children show a greater reward prediction error (RPE) response in the amygdala across feedback conditions, and a greater RPE response in the dMPFC in a social feedback condition.

**Conclusions:**
Combining behavioral modelling and neuroimaging reveals deeper insights into the behavioral and neural mechanisms of cognitive flexibility and developmental shifts in TD individuals. Therefore, it is a valuable tool for the investigation of neurodevelopmental samples with known difficulties in cognitive flexibility and the relation to every-day clinical behavioral measures.

409.032 (Poster) Brain Oscillations of Face and Gaze Processing in Children with Autism Spectrum Disorder
S. Yrttiaho, T. M. Helminen, J. Lauttia, J. K. Hietanen, K. Eriksson and A. Kylähen, (1)Faculty of Social Sciences/ Psychology, Tampere University, Tampere, Finland, (2)Faculty of Social Sciences/ Psychology, Tampere University, Tampere, FINLAND, (3)Department of Pediatric Neurology/ Faculty of Medicine and Health Technology, Tampere University and Tampere University Hospital, Tampere, Finland

Background: In autism spectrum disorder (ASD), processing of human faces and eye gaze differ from that of typically developing individuals. The manifestation of these differences appears to consist of complex trajectories that are affected by brain development as well as overall intellectual capacities. Thus, there is need to assess the brain basis of face and gaze processing across different ages of children with ASD.

Objectives: The current study sought to reveal distinct patterns of cortical activity in children with ASD in response to faces and direct eye gaze. We aimed to explore different frequencies of event-related brain oscillations which, to our knowledge, have not been previously investigated in the context of socially meaningful stimuli in the selected population.

Methods: We investigated brain activity during the processing of faces and non-face objects (faces vs. cars) as well as eye gaze (direct vs. downcast gaze) in children with ASD (age: 4.7–8.3 years, M(SD) = 6.5(1.0); N = 17) using electroencephalography (EEG). Cortical activity was investigated through event-related theta-, alpha-, beta- and gamma-frequency power from segments of EEG following a four-second period after stimulus onset. Control participant groups included typically developed (TD; age: 4.5–8.4 years; M(SD) = 6.3(1.0); N = 16) and developmentally delayed (DD; age: 5.7–8.1 years; M(SD) = 6.9(0.9); N = 11) children. Estimated intelligence quotient was matched across ASD and DD groups [M(SD)=59.4(11.7)].

Results: For the ASD group, maximum difference between face and car condition centered at parieto-occipital electrodes in the theta frequency band (5–7 Hz, permutation test p-value = 0.049, t(16) = 2.69, p = 0.016, d = 0.67, Figure 1). For the TD and DD groups, no difference between face and car condition were found in the theta band (cluster probabilities > .30). A trend for increased theta-band activity in response to direct vs. downcast gaze was also found for the ASD participants [t(14) = 2.00, p = 0.065, d = 0.53]. Frontal alpha-band activity was additionally found in ASD and DD participants in response to face vs. car stimuli (permutation test p-values < 0.05).

Conclusions: The results point to the role of theta-band oscillations, previously implicated with attention allocation, in processing of faces in children with ASD. An interpretation of heightened theta-power in children with autism is proposed in the light of increased processing demands related directly to intrinsic deficits in specialized brain networks, or to limited expertise gained in facial processing. At this point, this interpretation of overcompensated processing warrants further investigation to be confirmed. Alternatively, the role of oscillatory activity in ASD children corresponding to the normative theta-band (4–8 Hz), might relate to some functionally different process such as down-tuned alpha-band activity (8-13 Hz).

409.033 (Poster) Cardiac Autonomic Imbalance Is Manifested across the Brain-Heart Axis in Children with ASD: Insights from Effective Connectivity Modelling

Background: Because of its negative link to stress and anxiety, as well as its positive link to a wide range of positive psychological outcomes, cardiac autonomic balance (denoted by heart rate variability, HRV) is increasingly considered as a marker of mental health and homeostasis. In healthy adult subjects, HRV has also been shown to covary with changes in connectivity between brain regions of the central autonomic network (CAN), demonstrating a functional integration between cardiac and neural systems for maintaining and regulating homeostasis. The high-frequency component of HRV (HF-HRV) in particular, exclusively denoting parasympathetic (“vagal”) outflow, is associated with increased functional coupling between the medial prefrontal cortex (mPFC) and amygdala, thought to reflect a prefrontal top-down inhibition of amygdala-centered circuits. In children with ASD, extremely high prevalence rates of anxiety and stress are noted. Autonomic imbalance at the level of the heart is often reported, yet its extent, functional relevance and the role of the CAN network herein remain undetermined.

Objectives: We aim to investigate the occurrence of cardiac autonomic (im)balance as well as associated differences in intrinsic CAN connectivity in 59 school-aged children with ASD (8-12 y/o) compared to 39 age- and IQ-matched typically developing (TD) children.
Methods: Cardiac monitoring was performed during concurrent neuroimaging while at rest (resting-state MRI). We focused on the HF-HRV component (0.24-1.04 Hz) as an index of cardiac vagal tone. Besides addressing functional connectivity between CAN brain regions, spectral dynamic causal modelling (spDCM) was adopted to specifically delineate effective connectivity within the CAN. As such, we can explicitly model the influence that one node (mPFC) exerts over another (amygdala) within a network model of causal neural dynamics. Parametric empirical Bayes (PEB) procedures were used to test how individual (within-subject) neural connections within the CAN relate to different between-subjects effects (group, HF-HRV%, parent-reported SRS scores).

Results: At the group level, we show similar vagal cardiac-regulation in children with and without ASD during rest. Yet lower parasympathetic outflow at the level of the heart was found in ASD children with more severe ASD symptomatology, indicative of higher autonomic arousal. No group differences in CAN functional connectivity could be detected, but the effective connectivity analyses demonstrated increased excitatory bottom-up connections from the amygdala to the mPFC in ASD children, combined with increased excitatory top-down mPFC-amygdala coupling. Neuro-cardiac integration between functional amygdala-vPFC connectivity and HF-HRV was only shown in TD (r=-.36, p=.03), but not in ASD children (all p>.38). The spDCM analysis in combination with PEB estimation did show however that with increasing HF-HRV, the overly excitatory amygdala connections also decreased in children with ASD.

Conclusions: Despite no overall differences in cardiac vagal tone between TD vs. ASD children, the effective connectivity analyses demonstrated increased excitatory bottom-up amygdala connections within the CAN network in children with ASD. Most importantly, higher cardiac vagal tone was related to lower ASD symptomatology and less excessive excitatory amygdala connections, providing further evidence for a functionally integrative brain-heart system that can be addressed as a marker of disrupted homeostasis in children ASD.

409.034 (Poster) Clinically Relevant Association between Visual EEG Abnormalities and Excitation/Inhibition Ratio in the Longitudinal European Autism Project

**ABSTRACT**

**Background:** Imbalances between synaptic excitation and inhibition during the resting state may destabilize sensory and cognitive information processing in autism spectrum disorder (ASD). The various genetic and cellular mechanisms implicated in ASD predict that such imbalances will differ in directionality and may be an element in understanding clinical heterogeneity. To test these claims at the clinical level, we recently applied a new functional measurement of network-level E/I ratio (fE/I) and revealed that fE/I variability was enhanced in ASD and related to visually-graded EEG abnormalities ranging from slowing to epileptiform activity (1) (2), which in literature also have been associated with E/I imbalances (3, 4). Here, we replicate and expand on these findings in the large EU-AIMS compilation of EEG recordings in ASD.

**Objectives:** To determine whether variability in brain E/I set-points may explain elements of the clinical heterogeneity in ASD and corroborate the impact of EEG abnormalities towards E/I imbalances in ASD.

**Methods:** We divided the sample (n = 476) into two age groups, children (age 6–18 years) and adults (age 19–31 years), taking into account the differences in EEG development throughout the lifespan (3). From this, EEGs of 146 children with ASD and 104 neurotypical children were analyzed. We quantified the proportion of EEG abnormalities according to the atlas of Luders and Noachtar (1), evaluated their influence on spectral (relative power), long-range temporal correlations (DFA exponent) and functional excitation-inhibition ratio (fE/I), and their association with core symptomatology in these groups.
**Results:** We found that visual EEG abnormalities were associated with lower fE/I and lower power of alpha oscillations, indicating inhibition dominated networks, not only in children with ASD (n = 23) but also in the small subset of neurotypical children with abnormal EEGs (n = 14). Clinical relevance of this association was indicated by a positive correlation between fE/I and the Vineland Adaptive behavior scores in ASD without EEG abnormalities. In contrast, in those with abnormal EEG, fE/I showed a positive correlation with repetitive behavior.

**Conclusions:** In sum, we corroborate an association between qualitative and quantitative EEG proxies of E/I balance. We confirm that the presence of inhibition-dominated networks is associated with the presence of EEG abnormalities. Our findings further indicate that this EEG phenotype has value to predict the impact of E/I imbalances on behavioral outcomes, which holds promise for stratification purposes in clinical trials.

**409.035 (Poster) Comparing Mismatch Negativity between Autism and Schizophrenia: Using Machine Learning Model to Differentiate the Two Conditions**

Y. L. Chien, M. H. Hsieh, C. Y. Cheng and S. F. F. Gau, (1)National Taiwan University Hospital, Taipei, Taiwan, (2)National Taiwan University Hospital, Taipei, Taiwan, (3)Department of Psychiatry, National Taiwan University Hospital & College of Medicine, Taipei, Taiwan

Background: Autism spectrum disorder (ASD) Schizophrenia (SCZ) are frequently co-occur, that challenges differential diagnosis. Mismatch negativity (MMN) and P3a abnormality were reported both in SCZ and ASD. It is uncertain whether EEG biomarkers can differentiate ASD from SCZ.

Objectives: This study aims to Investigate whether MMN and P3a parameters can differentiate ASD from SCZ, and exams the features that can better differentiate ASD, SCZ, and typically developing controls (TDC).

Methods: We used the CatBoost to classify the three groups, i.e., ASD vs. TDC (N=86:98), SCZ vs. TDC (48:44), and SCZ vs. ASD (50:86). After the ground channels were removed, 151 features remained. We split the data into training and testing sets in a ratio of 7:3. Hyper-parameter tuning was processed in training set to yield the best hyper-parameter set. We calculated the feature importance by permutation for each classification.

Results: All MMN/P3a features well differentiated SCZ/TDC (AUC=0.84) and ASD/SCZ (AUC=0.76), but not ASD/TDC (AUC=0.5). Floating mean amplitude overall had the best performance in differentiating SCZ/TDC (AUC=0.87). Amplitudes, rather than latency, could differentiate SCZ/ASD (AUC=0.72 vs. 0.58). As for feature importance, fMMN latency is the best feature to differentiate ASD from SCZ. Peak amplitude/latency are more important features for differentiating SCZ and TDC.

Conclusions: Findings suggest that the MMN and P3a parameters might help to differentiate ASD from SCZ, and differentiate SCZ from TDC with acceptable accuracy, implying that MMN and P3a might assist in differential diagnosis of ASD and SCZ.

**409.036 (Poster) The Relationship between Resting-State EEG Graph Metrics of Network Efficiency and Social Cognition in Autism**

E. de Jonge, P. Garces, A. de Bildt, Y. Groen, E. Jones, P. J. Hoekstra and A. Dietrich, (1)Department of Child and Adolescent Psychiatry & Accare Child Study Center, University of Groningen, University Medical Center Groningen, Groningen, Netherlands, (2)Neuroscience and Rare Diseases, Roche Pharma Research and Early Development, Roche Innovation Center Basel, Basel, Switzerland, (3)Department of Child and Adolescent Psychiatry & Accare Child Study Center, University Medical Center Groningen, Groningen, NETHERLANDS, (4)Clinical and Developmental Neuropsychology, University of Groningen, Groningen, Netherlands, (5)Centre for Brain and Cognitive Development, Birkbeck University of London, London, United Kingdom

Background:
Autism is associated with specific social cognition characteristics and is thought to be underpinned by differences in functional network organization in the brain. However, whether long-range and/or local connectivity is different in autistic adolescents compared to non-autistic adolescents remains unclear. Moreover, the relevance of functional network organization to social cognition is yet unknown.

Objectives:

We first aimed to identify autism-related characteristics of resting-state networks in adolescence, a life-phase critical for social development. Second, we took a first step in exploring relationships with empathy and theory of mind (ToM), aspects of social cognition commonly implicated in autism.

Methods:

Data was recorded as part of EU-AIMS LEAP. We constructed functional connectivity networks based on weighted Phase Lag Indexes (wPLI) using resting-state EEG data of 68 (16 females) autistic and 56 (19 females) nonautistic adolescents. Social cognition measures and graph metrics describing whole-brain network organization were compared between groups. Subsequently, we investigated relationships between characteristics of aforementioned graph metrics and measures of social cognition.

Results:

Autistic adolescents showed lower empathy and ToM ability as measured by the Empathy Quotient (EQ) and the Reading the Mind in the Eyes task (RMET) compared to nonautistic adolescents. Moreover, they had reduced global efficiency in the alpha band, indicating less efficient long-range information integration in the brain. Clustering coefficient (overall network efficiency) and small-worldness (segregation) did not differ between groups. In adolescents with high autistic trait severity, lower alpha global efficiency was associated with higher empathy, while this association was significantly less strong for those with low autistic trait severity. Additionally, we observed a borderline significant ($p=.053$) relationship between higher global efficiency and better ToM ability as measured by the RMET.

Conclusions:

Our results suggest less efficient integration of information across distant regions of the brain in autistic compared to nonautistic adolescents, possibly indicating differences in network maturation. Exploratory network-behavior analyses suggest that long-range integration may be relevant to some of the social cognition characteristics associated with autism. These tentative findings offer a promising avenue for further research into the biological underpinnings of the social characteristics associated with autism.

**409.037 (Poster) Development of Self-Referential Encoding in Autism Spectrum Disorder**

**H. Sweatman, Z. Gracia Tabuenca and X. Cha**

1 Integrated Program in Neuroscience, McGill University, Montréal, QC, Canada, 2 Montreal Neurological Institute, Montreal, QC, Canada, 3 Neurology and Neurosurgery, McGill University, Montreal Neurological Institute, Montreal, QC, Canada

**Background:** Social cognition is commonly impaired in autism spectrum disorder (ASD), significantly affecting an individual’s relationships and well-being. We must understand the roots of this deficit in the brain and behaviour to develop effective targeted interventions. One such root factor may be episodic memory, memory for past events and experiences, known to be selectively impaired in ASD (Gaigg et al., 2014). During social interactions, one must recall previous interactions to infer mental states of social partners. A reduced ability to process self-related information may underlie this memory deficit. We can investigate the interaction between the self and episodic memory through the idea that information encoded in relation to the self is better remembered, termed the self-referential effect (SRE). Previous studies demonstrated a diminished SRE in individuals with ASD (Grisdale et al., 2014). To date, it remains unclear how self-referential memory encoding is supported in the brain in children with ASD.

**Objectives:** We aimed to compare the SRE of recollection between neurotypical (NT) children and children with ASD. Furthermore, we compared how the brain engages in episodic encoding and the SRE in each group. We expected that ASD children would show less self-referential facilitation associated with diminished activation in the midline cortical and lateral parietal regions compared to NT children (Leshikar and Duarte, 2013).

**Methods:** Forty children with ASD with IQ above 25th percentile between the ages of 8 and 12 years were recruited, along with 40 age- and sex- matched neurotypical children. In the MRI scanner, participants viewed trait adjectives paired with either a picture of a smiley face representing themselves or a picture of a Despicable Me minion (other). Children were asked to think about whether the trait adjective described the referent and select yes or no. After the scan, participants were tested on their recognition of the words using the Remember/Know paradigm (Yonelinas and Jacoby, 1995).

**Results:** Comparing recognition accuracy for remember trials in the self versus other conditions in a preliminary sample of 11 children with ASD (mean age 12.01 ± 2.74) and 29 NT children (mean age 12.55 ± 2.71) revealed a greater SRE for NT children compared to the
ASD group (Figure 1A; t(38) = 2.21, p = .033). Our preliminary imaging results include data from 10 children in each group (NT: mean age 10.70 ± 1.61; ASD: mean age 11.92 ± 2.87). The NT group showed expected activations in mPFC and precuneus for self-referential processing, while the ASD group showed only the anterior activations (Figure 1B). Subsequent memory activations appeared in the mPFC and posterior cingulate in the NT group and in the posterior hippocampus in the ASD group (Figure 2).

Conclusions: These preliminary data provide evidence for a reduced SRE in children with ASD associated with diminished midline cortical activation. This research informs our understanding of the neural roots of social cognitive impairments in ASD which may inform interventions to improve self-relational processing, episodic memory, and in turn, social cognition to lessen the impact of ASD on the personal life of the individual.

409.038 (Poster) Diagnostic and Familial fcMRI Differences in 24-Month-Olds with and without Autism

Background: We presently know very little about brain functional connectivity differences across autism spectrum disorder (ASD) and typical development in very young children. Characterization of neural correlates for the development of ASD may improve early identification, enable future intervention trials, and lead to the validation of biomarkers for demonstrating treatment engagement.

Objectives: To test for potential ASD diagnostic and familial likelihood group-related differences in functional connectivity at the whole-brain and network level in 24-month-old children at high (HL) and low familial likelihood (LL) for developing ASD.

Methods: We conducted cross-group comparisons for high likelihood ASD-positive (HLP: has clinical best estimate diagnosis of ASD, N=23) and -negative (HLN, N=91) and low likelihood ASD-negative (LLN, N=27) children with Infant Brain Imaging Study (IBIS) Network fcMRI data. Advances in fcMRI processing increased yield for usable data, allowing for these tests. Analyses followed a pre-specified analytic plan: 1) GLM-based tests on jackknifed individual-to-group (within/between) fcMRI matrix correlations, 2) tests of brain-wide network structure differences using normalized mutual information (NMI), 3) cross-group tests of brain-wide differences using object oriented data analysis (OODA), 4) network-level tests for group differences using our updated fcMRI enrichment approach, 5) whole-brain cross-group classification using support vector machine (SVM), 6) testing for differences in network structure with jackknifed comparisons for NMI for individual-to-group network derivations, 7) tests for cross-group differences in brain region of interest (ROI) composition in specific functional networks using Jaccard metrics, and 8) cross-group clustering based on individual differences in network ROI composition.

Results: OODA (alpha = 0.0167, 3 comparisons) revealed a significant difference between HLP and LLN fcMRI matrices (p = 0.012). HLP trended for difference from HLN (p = 0.047). HLN and LLN matrices did not differ (p = 0.225). Post hoc testing did not identify contributions from specific networks. fcMRI enrichment using an ANOVA link function found strong signal for the posterior cingulate default mode network 1 (pcDMN1) – temporal default mode network (tDMN) pair (p = 0.0070) that survived a machine learning secondary vetting procedure (p = 0.038). fcMRI enrichment for post hoc Tukey-corrected t-tests on nominally significant omnibus ANOVA connections in the pcDMN1 – tDMN pair, showed: HLP differed from HLN (p = 0.0461). HLP did not differ from HLN (p = 0.2254). HLN differed from LLN (p = 0.0004). A secondary t-test on pcDMN1 – tDMN connectivity showed HL (HLP and HLN combined) differed from LL (p = 0.0013). SVM separated HLP from HLN: accuracy = 98.2% (96.3-100), PPV = 91.7% (91.7-100), NPV = 100% (96.6-100). Observed PPV and NPV exceeded any values produced with 1000 data reshuffles. Consensus features scattered across brain networks. A crystalized version of the classifier built with leave-out methods accurately classified LLN matrices (it never trained on) “ASD-negative:” accuracy = 88.5%, PPV = N/A, NPV = 100%. Analyses 1, 2, 6, 7, 8 produced no significant results.

Conclusions: We found evidence for a familial difference between HL and LL subjects involving reduced DMN connectivity, and ASD diagnostic differences involving functional connections distributed across brain networks in 24-month-old infants.

409.039 (Poster) Differences in Oxytocin Receptor Genes in Children with ASD : Impacts on Symptom Severity through Brain Functional Connectivity
N. Yoon1, S. Kim1, S. Ha1, M. Kim2, M. R. Oh1, J. J. Kim1, J. M. Lee1 and B. N. Kim1, (1)Child and Adolescent Psychiatry, Seoul National University Hospital, Seoul, Korea, Republic of (South), (2)Department of Electronic Engineering, Hanyang University, Seoul, Korea, Republic of (South), (3)King's College London, London, United Kingdom, (4)Psychiatry, Hanyang University Medical Center, Seoul, Korea, Republic of (South), (5)Department of Biomedical Engineering, Hanyang University, Seoul, Korea, Republic of (South)

Background:

Oxytocin receptor gene (OXTR) is one of the potent genes suggested to be involved in the pathogenesis of Autism Spectrum Disorder (ASD). However, it is unclear through which mechanisms genetic and epi-genetic diversity affects clinical symptoms of ASD. Imaging genetics of OXTR is expected to serve as a bridge between genetic differences and phenotypes in ASD.

Objectives:

In this study, we aimed to identify the relationship between genetic/epi-genetic differences, resting-state functional connectivity (rs-FC), and clinical severity in ASD children.

Methods:

For 41 ASD children and 50 typically developing (TD) children (mean age 4 and 7 years respectively, 32 (78%) and 23 (46%) boys respectively), SNP genotyping at rs2254298 and rs53576, and estimations of methylation level in 2 CpG sites (-923, -934) of OXTR were performed. Using the independent component analysis on fMRI, we classified brain regions into six intrinsic networks and analyzed rs-FC of each network. Autistic symptoms were measured by the Childhood Autism Rating Scale (CARS), the Autism Diagnostic Observation Schedule (ADOS) and the Social Responsiveness Scale (SRS). In addition, social and developmental age were measured. The associations between genetic/epi-genetic information, rs-FC, and clinical scores were explored.

Results:

In ASD children, rs-FC were significantly decreased in default mode network (DMN), cognitive control network (CC), somato-motor network (SM) and visual network (VIS) with risk allele (A) of rs2254298 while the opposite results were found in the TD children. The decreases in rs-FC between CC and CC and rs-FC between CC and SM were negatively correlated with SRS and ADOS respectively. The decrease in rs-FC between SM and VIS was negatively correlated with SRS and positively correlated with developmental age.

Homozygous AA carriers of rs53576 showed lower rs-FC in DMN, CC, SM, VIS and auditory network (AUD) than other genotyped groups in ASD. Similar to rs2254298, the TD group showed opposite results in each network. Decreased rs-FC between DMN and CC showed a negative correlation with ADOS score and a positive correlation with social age, and decreased rs-FC between CC and SM showed negative correlations with both SRS and ADOS.

In the two rs-FCs (Subcortical network (SUB)-DMN and SUB-CC), the higher the methylation level of the CpG site (-924), the lower the linkage strength in children with ASD. On the contrary, hyper-methylation of the CpG site strengthened the rs-FC in TD children. In the ASD group, hyper-methylation related SUB-CC connectivity was negatively correlated with the ADOS score.

Conclusions:

We found that the genetic/epi-genetic alterations of OXTR in ASD were significantly associated with decreased functional connectivity of brain networks related to cognition, sociality, sensory, and movement. In addition, significant associations between rs-FCs and the clinical symptom severity were observed. The results could be interpreted as the differences in OXTR in ASD affect phenotypes such as impaired social cognition and abnormal behavior through changes in brain functional connectivity. In future studies, more in-depth exploration of specific brain regions is required in larger samples.

Differences in Temporal Brain Response in Children Born Preterm and Term and Its Relationship with Social Communication Abilities

M. Magan Maganto1, E. Diez Villoria2, Á. Bejarano3, B. Palomero Sierra4, M. V. Martin Cilleros1, I. Ruiz-Ayúcar5, J. Lugo Marín and R. Canal-Bedia6, (1)UNIVERSITY OF SALAMANCA, Salamanca, SPAIN, (2)University of Salamanca, Salamanca, Spain, (3)UNIVERSITY OF SALAMANCA, Salamanca, Spain, (4)Universidad de Salamanca, Salamanca, Spain, (5)Psychiatry, Hospital Universitari Vall d'Hebron, Barcelona, Spain, (6)Instituto Universitario de Integración a la Comunidad INICO-InFoAutismo., Universidad de Salamanca, Salamanca, Spain

Background:
Due to improvements in neonatal care, a larger number of preterm children survive. However, this leads to increased risk of physical/neurodevelopmental disorders, with higher rates of autism in premature populations (Laverty et al., 2021). For this reason, it is critical to identify potential early neural biomarkers and thus facilitate monitoring, support and early intervention (Green et al., 2017).

Objectives:

To analyze social-selective cerebral response in bilateral temporal areas of children born preterm and term. Our hypothesis was that preterm children would show a different response in regions of interest (ROIs) related with social processing while looking at social dynamic stimuli. Also, we wanted to explore the relationship between brain response and psychological measures to predict future developmental trajectories.

Methods:

This research forms part of an ongoing prospective longitudinal design, where children born preterm and term will be assessed at 12, 18, 24 and 36 months. Only preliminary results at 12 months are presented here. Functional Near Infrared Spectroscopy (fNIRS) was used following the procedure of Lloyd-Fox, et al. (2018) except stimuli were presented without audio. The ROIs were: inferior-frontal gyrus (IFG); anterior-middle-temporal gyrus/superior-temporal gyrus (aMTG-STG); and posterior-superior-temporal sulcus/temporoparietal junction (pSTS-TPJ). Psychological measures were Vineland-III (adaptive behavior); Bayley-III (cognitive and language function); SACS-R (autism screening); and ADOS-2 (autism diagnostic).

Response to stimuli was explored using between-groups t-tests comparing HbO$_2$ concentration changes across ROIs and channels for time windows based on other fNIRS studies (Braukmann et al., 2018). Correlations between ROI HbO$_2$ averages and psychological measures were calculated to evaluate relationships between brain responses and difficulties in development. Furthermore, average HbO$_2$ for social-dynamic and non-social-dynamic stimuli was compared to explore differences in brain response based on ASD screening results and ROIs.

Results:

A total of 67 children (41 preterm; 26 term) were assessed at 12 months. After data processing and cleaning, 36 datasets (25 preterm; 11 term) were valid. Visual inspection of hemodynamic responses showed differentiated patterns between groups in almost all the ROIs, especially in time windows later than 10 seconds after the onset of stimuli. The only significant difference in HbO$_2$ concentration changes was found in the right IFG. Significant HbO$_2$ response differences were found for children failing 3 critical items on the SACS-R (N= 2) compared to 0 failed items (N=17) in the right pSTS-TPJ. Social vs non-social response was also significantly different in these groups for the left MTG-STG.

Conclusions:

These preliminary results suggest a relationship between prematurity and increased IFG involvement in social attention tasks for 12 month children, which other studies connect to ASD (e.g., Chan & Han, 2020). Additionally, results are consistent with recent data from meta-analyses (e.g., Hodgson, Lambon-Ralph & Jackson, 2022) that relate pSTS-TPJ and MTG-STG areas with the processing of social-dynamic stimuli (i.e. theory of mind and face processing, respectively), and suggested that the cerebral response is different based on the social-communication abilities of the child. More data is needed to discuss whether this is particularly associated with premature birth and with the possible future diagnosis of autism.

409.041 (Poster) Differential Neurobiology of Sensory over-Responsivity in ASD and OCD: A Preliminary Analysis

L. Tu$^1$, K. A. Collins$^1$, M. M. Breland$^1$, M. Ludlow$^1$, A. Lieval$^1$, R. H. Tohe$^1$ and E. R. Stern$^{1,4}$, (1)Nathan Kline Institute, Orangeburg, NY, (2)Ferkauf Graduate School of Psychology, Yeshiva University, Bronx, NY, (3)Center for the Developing Brain, Child Mind Institute, New York, NY, (4)Department of Psychiatry, New York University Grossman School of Medicine, New York, NY

Background:

Autistic individuals and those with Obsessive-Compulsive Disorder (OCD) often report subjective sensory over-responsivity (SOR)—a predisposition to experience rapid, intense, and/or durable responses to sensory stimuli. To our knowledge, the shared and differential neurobiology of SOR in Autism Spectrum Disorder (ASD) and OCD has not been thoroughly investigated.

Objectives:

To characterize sensory profile differences across ASD and OCD. To investigate neural correlates of SOR via resting-state functional magnetic resonance imaging (rsfMRI).
Methods:

Data were analyzed from 10 autistic participants without OCD and a full scale IQ≥70 (age 26.4 [5.4], range 19-36), 27 participants with OCD but not ASD (age 26.2 [5.1], range 19-36), and 22 neurotypical control (NC) participants without psychiatric diagnosis (age 24.6 [3.1], range 20-31), confirmed via semi-structured psychiatric research diagnostic interview. Autistic participants met Autism Diagnostic Observation Schedule (ADOS-2) instrument classification of ASD. Participants with major medical, neurologic, or comorbid psychiatric diagnosis (e.g., bipolar or schizophrenia spectrum disorder) were excluded. All 3 groups were sex- (all male) and age-matched. Use of psychiatric medication was permitted in autistic and OCD cohorts.

Participants were scanned on a 3.0T Siemens TIM Trio with a 32-channel head coil. Resting-state functional scans were acquired using a high-resolution multiband-accelerated echo-planar sequence for full brain coverage. Preprocessing of functional data was performed using Statistical Parametric Mapping (SPM) v.12 and python and included: gradient distortion correction, realignment of functional images, normalization to MNI template, and 6-mm FWHM spatial smoothing.

The Adolescent and Adult Sensory Profile (AASP) (Brown & Dunn, 2002; Dunn, 2001) is a self-report questionnaire assessing responses to everyday sensory experiences. Following prior work, SOR was calculated using the Sensation Avoiding and Sensory Sensitivity subscales (Podoly et al., 2022).

Between-group comparisons on SOR scores were performed using one-way ANOVAs. Resting-state functional connectivity analysis was performed using the Conn toolbox (Whitfield-Gabrieli & Nieto-Castanon, 2012). Functional connectivity analyses focused on global connectivity which measures, for each participant, the connectivity between a given voxel and every other voxel in gray matter, with higher connectivity reflecting greater neural centrality or “hubness” (Martuzzi et al., 2011; Whitfield-Gabrieli & Nieto-Castanon, 2012) in an area. Group-level analyses interrogated the relationship between SOR scores and global connectivity within the ASD and OCD groups separately using regression. Preliminary connectivity results were thresholded at voxelwise \(p<0.005\) (uncorrected).

Results:

SOR scores were significantly different between the participant groups, \(F(2, 56)=11.9, p<0.0005, \eta^2=0.3\). Tukey post-hoc analysis revealed that both autistic (\(M=2.5, SD=0.5\)) and OCD participants (\(M=2.6, SD=0.6\)) had significantly higher SOR scores than NC participants (\(M=1.9, SD=0.4\)) \((p<0.005 \text{ for both})\). Autistic and OCD participants did not differ in SOR scores \((p>0.5)\).

Analysis of global connectivity indicated that SOR scores were associated with medial orbitofrontal connectivity in OCD but sensorimotor connectivity in autistic participants.

Conclusions:

Autistic individuals and those with OCD reported increased SOR compared to neurotypical control participants. While OCD and autistic participants were similar behaviorally, SOR was associated with distinct group-specific resting-state functional architecture. Overall, findings support SOR as a shared behavioral phenotype in ASD and OCD that may be driven by differential neural circuitry.

409.042 (Poster) Disruptions in Amygdala Activation Are Linked to Eye Gaze Processing in Autism: An fMRI Meta-Analysis

I. Iturmendi-Sabater1, M. Vasishth1, M. R. Guardavaccaro1, S. B. Eickhoff1, D. G. Sukhodolsky2 and K. Ibrahim1, (1)The University of Toronto, New Haven, CT, Canada, (2)Institute of Medical Science, University of Toronto, Toronto, ON, Canada, (3)Yale Child Study Center, Yale University School of Medicine, New Haven, CT, (4)Institute of Systems Neuroscience, Medical Faculty, Heinrich Heine University Düsseldorf, Düsseldorf, Germany, (5)Institute of Neuroscience and Medicine, Brain and Behaviour (INM-7), Research Centre Jülich, Jülich, Germany, (6)Child Study Center, Yale University, New Haven, CT

Background: Social impairments of autism, including reduced eye contact and eye gaze abnormalities, are associated with disruptions in networks involved in social cognition. Previous studies have shown perturbations in social cognitive regions—including the amygdala—during eye gaze processing in autistic versus unaffected controls. However, while prior meta-analytic work has suggested hypoactivation in ‘social brain’ networks during broader social cognition tasks, no meta-analytic study has quantitatively examined the neural correlates across domains of eye gaze processing in autism.

Objectives: The current study examined fMRI studies across domains of gaze processing in autism including eye gaze direction, attention directed towards the eye region, shifts in eye gaze, and viewing of emotionally expressive faces while cued to focus on the eyes. The primary aim was to quantitatively summarize the existing imaging literature to identify convergent patterns of neural disruptions associated with gaze processing in autism.
Methods: The literature review and selection of manuscripts was conducted following the Preferred Reporting Items for Systematic Reviews and Meta-Analyses guidelines (PROSPERO: CRD42021239132). Studies investigating gaze processing in autism were identified through a literature search for imaging experiments examining eye gaze, eye movement, and gaze cueing conducted in ASD samples. Searches were conducted using Cochrane, PubMed, Ovid MEDLINE, Embase, CINAHL, PsycINFO, Web of Science, and ERIC. Inclusion criteria included: full text in English and published between January 1990 and December 2021 in a peer-reviewed journal; used task-based fMRI across domains of gaze processing; examined ASD vs healthy control contrasts; and foci of significant activations were reported in standardized stereotaxic space (e.g., Montreal Neurological Institute [MNI] atlas). Region-of-interest studies were excluded. A total of 4,322 articles were selected for screening and 204 for full text review by two independent reviewers. A quantitative synthesis was conducted using Activation Likelihood Estimation, implicated in MATLAB, to identify regions of spatial convergence. Group-x-Condition interactions were conducted and sub-analyses to clarify patterns of hyper- versus hypoactivation and task domains. Non-parametric p values were thresholded using a cluster-level family-wise-error-corrected p<0.05 and a cluster-forming threshold of p<0.001, which were transformed into Z scores.

Results: Twenty-seven experiments from twenty articles met inclusion criteria, comprising 354 autistic individuals (M_age = 19.6 years; 86.4% males; M_Q=111.88) and 348 controls (M_age= 19.5 years; 82.2% males). Experiments involved gaze direction (n = 8) and cueing (n = 12) tasks. Significant activation differences were found in autism versus controls in the left amygdala (MNI coordinates: -24, -6, -20; z-value = 4.2). Sub-analyses showed that aberrant amygdala activation was characterized by patterns of hypo- and hyperactivation in ASD during gaze processing. Additionally, gaze cueing and direction paradigms as well as child and adult samples contributed to this finding.

Conclusions: Consistent with previous findings, eye gaze processing in autism was related to aberrant amygdala activation, which may reflect disruptions in the recruitment of neural resources involved in social cognition including mentalizing, emotion regulation, and/or attentional control.

409.043 (Poster) Unsupervised Data-Driven Stratification of Global Excitation-Inhibition Imbalance Autism Subtypes from EEG Data

N. Bertelsen1,2, V. Mandelli1, A. Vitale1, E. M. Buscoli1, and M. V. Lombardo1,2. (1)Center for Neuroscience and Cognitive Systems, Istituto Italiano di Tecnologia, Rovereto, Italy, (2)University of Trento, Centre for Mind/Brain Sciences (CIMeC), Rovereto, Italy.

Background: Heterogeneity in autism manifests at multiple scales - from genome to phenotype. While clinical subtyping efforts have shown promise, neural subtyping has been relatively much less explored. However, because neural subtyping is more proximal to the biology, it may yield better insight into autism-relevant neurobiology. In this work we apply a neural subtyping approach to test the excitation-inhibition (E:I) imbalance theory of autism.

Objectives: Here we examine whether autism can be split into robust, generalizable, and stable neural subtypes using an unsupervised data-driven stratification approach applied to E:I-relevant time-series statistical metrics, such as the Hurst exponent (Trakoshis et al., 2020, eLife).

Methods: EEG data recorded during eyes open and closed resting state conditions was analyzed in a sample of male children from data releases 1-10 of the Child Mind Institute Healthy Brain Network (CMI-HBN; age range: 5-21 years; autism n=310 ; typically-developing (TD) n=129). The Hurst exponent (H) was computed across 93 channels and input into stability-based relative clustering validation analysis (reval with k-means clustering; Landi et al., 2021, Patterns) to identify subtypes and estimate generalization accuracy. The SigClust library in R was used to test the null hypothesis that similar clusters could be obtained from a single multivariate Gaussian distribution. For each channel, linear mixed effect models were used to test the effects of subtype, age, and the subtype*age interaction. Principal component analysis (PCA) was also used to reduce the dimensionality of the dataset down to orthogonal latent variables and allow for inference about global versus more localized effects.

Results: Stability-based relative clustering validation revealed the presence of two autism subtypes with high generalization accuracy > 92% and which highly differ from a single multivariate Gaussian null distribution (p < 9.99e-5). Autism subtype 1 had higher H than the TD group (Cohen’s d > 0.24) and can be interpreted as having normatively lower E:I ratio. Conversely, autism subtype 2 had lower H (i.e., higher E:I ratio) compared to the TD group (Cohen’s d < -0.34). These effects were ubiquitous across all 93 channels (FDR q < 0.05). PC1 of a PCA analysis parsimoniously captures this global effect differentiating subtype and accounts for >71% of the variance in the data.

Conclusions: Two highly generalizable E:I-relevant autism subtypes can be identified in resting state EEG data, with opposing patterns of difference from the TD group. The subtypes reveal global differences in E:I imbalance, which could inform future studies examining global spatial effects with higher spatial resolution (e.g., resting state fMRI). These insights may be important when theorizing about how heterogeneous neurobiological mechanisms affect different types of individuals and also for testing the effects of pharmaceutical agents targeting E:I imbalance.
Background: The temporoparietal junction (TPJ) in the ventral attention system supports social cognition, particularly in the theory of mind (ToM). Nevertheless, how the social network interrelates with the salience network and functionally connects with the executive network in daily-life tasks is still poorly understood. Cognitively demanding goal-directed tasks are thought to involve the dynamic interplay of these large-scale neural networks. In previous work, we found that when performing a virtual shopping task matching the performance of controls, adolescents with autism spectrum disorder (ASD) hyperactivate three core networks: executive, saliency, and social cognition. This raises the question of how individuals with ASD recruit these networks when attempting to successfully perform real-life tasks, particularly, how connectivity between networks changes during information processing in complex navigation tasks.

Objectives: We aimed to study the functional connectivity between ToM, ventral attention, and executive function (EF) networks in ASD in realistic quotidian scenarios, while different types of social/non-social contexts are available.

Methods: Fifteen adolescents with ASD (14 male, 1 female; median age=16 years 4 months) and 14 chronologically age and Performance IQ-matched typically developing (TD) participants (12 male, 2 female, median age=15 years 2 months) performed the EcoSupermarketX (a shopping simulation task including three conditions: ‘no cue’, ‘non-social’ [arrows] or ‘social’ [avatars] cues), during neuroimaging. A psychophysiological interaction (PPI) analysis was performed with the left-TPJ as seed region to examine functional connectivity with other brain areas/networks. Comparative analyses were performed between groups for each of the three conditions.

Results: Using PPI analyses, we found group differences (random effects analysis, p<0.001) in the connectivity between left-TPJ and several other regions, particularly from the ventral attention network. The connectivity patterns varied depending on the condition. In the ‘no cue’ condition the PPI analysis revealed greater functional connectivity between left-TPJ and right-TPJ, right-insula, precenural gyrus, middle frontal gyrus, and visual association regions (middle occipital gyrus) in ASD than in TD. In the ‘non-social cue’ condition the PPI analysis revealed that in the ASD group the functional connectivity between left-TPJ and visual association regions (precuneus and lingual gyrus) was increased compared to TD. In the ‘social cue’ condition the PPI analysis revealed greater functional connectivity between left-TPJ and right fusiform and parahippocampal gyri, right posterior cingulate, middle and medial frontal gyri, and precuneus in ASD than in TD.

Conclusions: ASD adolescents in the absence of cues to perform goal-oriented ecological task, need to recruit more the ventral attention network, such as the insula, compared to TD. When there is a simple visual cue orienting the performance (non-social - arrows), the dominating part in the circuit is the connection TPJ-visual areas. In the social condition (social cue - avatars), there is a more complex pattern of hyperconnectivity of the TPJ to low- and high-level areas related to EF and action selection, in ASD comparing to TD individuals. Such distinct hyperconnectivity patterns of the TPJ in daily-life tasks and dependence on the type of cues (absent, simple visual or social cues) may provide a circuit level signature of neural diversity in ASD and provide a possible intervention target.

Background: Autism Spectrum Disorder (ASD) and Attention-Deficit/Hyperactivity Disorder (ADHD) are two commonly co-existing neurodevelopmental disorders with a lifetime prevalence rate of 40.2% (Rong et al., 2021) and often overlap in areas of functional impairments, such as academic performance, social relationships, and occupational outcomes (Antshel & Russo, 2019). At the trait level, approximately half of children with ASD show signs of ADHD symptoms. At the neurological level, ASD groups have been shown to demonstrate increases in the in error-processing measured by error-related negativity (ERN) in electroencephalography (EEG)/event-related potential (ERP) studies (Henderson et al., 2015) while ADHD groups have shown results of decreased ERNs compared to neurotypically developing children (Liao et al., 2018). However, despite their high comorbidity rates, no study to date has examined the co-occurring trait effects of each disorder on the ERN.

Objectives: The current study investigates whether co-occurring specific symptom clusters of ADHD (i.e., inattention and hyperactivity/impulsivity) mediates the relationship between autistic traits and mean ERN amplitudes in children with and without ASD.

Methods: Data collection for this study is completed and includes a total of 42 children (female=16) between the ages of 10-16 years old (M=15.2 years, SD=20 months) diagnosed with ASD (n=17) and without ASD (n=26) using gold-standard diagnostic methods, such as the
Background: Current diagnostic criteria for autism spectrum disorder (ASD) encompass impairments in two symptom domains: social-communication (SC) and repetitive and restrictive behaviours (RRB). Although often clinically presented together, there is evidence from molecular genetic, heritability and behavioural studies (1-3) that these two symptom domains are dissociable and may diverge onto different biological pathways.

Objectives: To investigate if social and non-social symptoms share the same neurobiological underpinning in autistic and neurotypical individuals. In a prior study, we found correlations between performance in SC tasks and availability of serotonin transporter (5-HTT), dimensionally in both the ASD group and control group (4). Here, we investigate if non-social traits also correlate with 5-HTT availability in the same sample.

Methods: Fifteen adult subjects (11 males/4 females) with ASD and normal IQ, and fifteen age, sex and IQ matched neurotypical subjects were examined with positron emission tomography (PET) and the radioligand [123I]CMA/43 binding to 5-HTT. To obtain a measure of RRB with sensitivity also for non-autistic control subjects, we used factor analysis to construct an index of RRB derived from subscales from three personality instruments: Temperament and Character Inventory (TCI), Revised NEO Personality Inventory (NEO-PI-R) and Swedish university Scales of Personality (SSP). Subscales were selected by a group of experienced clinicians based on content validity. The RRB index was validated against the RRB subscales in Social Responsiveness Scale (SRS) and Autism Spectrum Quotient (AQ). To tap further into the RRB domain, we measured cognitive flexibility with tests from the Delis-Kaplan Executive Function System (D-KEFS). In a subsample of six ASD and seven control subjects, sensory reactivity was assessed with the Sensory Reactivity in Autism Spectrum questionnaire.

Results: None of the RRB measures correlated with 5-HTT availability. In the smaller subsample, we found negative correlations between sensory reactivity and 5-HTT availability in several brain regions.

Conclusions: In contrast to SC, RRB measurements did not correlate with 5-HTT availability except for sensory symptoms in a smaller subsample. This indicates that 5-HTT is less important for RRB than for SC, and suggests that RRB and SC may diverge onto different neurobiological mechanisms. Sensory symptoms may differ biologically from the other non-social ASD criteria. Further studies of how different symptoms map onto the same or different neurobiological mechanisms are warranted to guide development of precision pharmacological treatments.

Background: Gain control refers to the modulation of neural responses based on context. Current approaches used to assess gain control in autism spectrum disorder (ASD) rely on participants to provide verbal responses of perception, or assessment of behavioral cues, and are necessarily subjective in nature. Given that gain control of sensory responses is altered in ASD, there is a need to identify objective and quantifiable measures of gain control that allow testing across ages, cognitive abilities, and in non-verbal populations.

Objectives: We developed an EEG-based measure of gain control in tactile processing, and evaluated the measure in relation to diagnosis of ASD or typical development (TD). We then studied the associations between the EEG measures and phenotypic measures of sensory processing.

Methods: In an ongoing pilot study, we have collected data from children aged 3-4 years with ASD (n=6) and TD controls (n=17), matched across groups for age and gender. Multichannel EEG was recorded while mechanical stimuli were presented. Stimuli consisted of vibrotactile stimulation delivered to one of three locations, chosen at random for each trial: index finger, middle finger, or both simultaneously. Gain control was evaluated through a spatial suppression index (SSI) determined by somatosensory evoked potential (SEP) amplitudes across paradigm conditions:

$$SSI = \frac{[SEP(\text{Index}) + SEP(\text{Middle}) - SEP(\text{Both})]}{[SEP(\text{Index}) + SEP(\text{Middle})]}$$

SSI of zero thus indicates no suppression (i.e., the response to stimulating both fingers equals the sum of the responses to stimulating either finger alone). Positive SSI indicates some suppression (which is expected due to lateral inhibitory mechanisms in neural circuits), whereas negative SSI indicates an unexpected facilitation of the response when both fingers are stimulated together.

Focusing on P50 and P100 SEPs over the left somatosensory cortex, we compared SSIs across groups using independent sample t-tests, and studied associations between SSIs and a parent report measure of sensory processing (Sensory Profile 2; SP2) using Pearson correlations.

Results: The SSI of the P50 is significantly lower in children with ASD, relative to TD ($p=0.02, d=1.02$), while the P100 SSI did not significantly differ between groups. The P50 SSI did not correlate significantly with SP2 seeking scores ($r=-0.36, p=0.15$), while the P100 SSI had a significant negative correlation with SP2 seeking scores ($r=-0.59, p=0.01$; see Figure 1).

Conclusions: EEG-based measures of gain control offer a promising avenue for biomarker development in ASD, because these objective and quantifiable measures can index underlying neural network function and have translational utility. Initial results suggest our EEG measures could capture distinct patterns of spatial suppression in ASD. As a group, participants with ASD show reduced spatial suppression, relative to TD, but our SSI measures capture a wide distribution of individual responses in ASD. This shows promise for capturing the heterogeneity of sensory phenotypes in ASD, which includes both hypo- and hyper-sensitivity. Further data will be collected to increase sample sizes in this study.

**409.047 (Poster) EEG Measures of Reduced Tactile Gain Control in ASD**

**G. Parra**, Y. Braverman, K. E. Takach, C. MacKay, L. Cornelissen, and A. R. Levin, (1)Boston Children’s Hospital, Brookline, MA, (2)Neurology, Boston Children’s Hospital, Brookline, MA, (3)Anesthesiology, Boston Children’s Hospital, Boston, MA

Background: Attention-deficit hyperactivity disorder (ADHD) and autism spectrum disorder (ASD) are neurodevelopmental disorders that commonly co-occur and each lead to significant impairment in functioning which is amplified when both occur together. While traditionally the inattentive and hyperactive symptoms of ADHD are considered separately from the social communication and interaction impairments in ASD, social impairment has long been recognized as a common presentation in individuals with ADHD. Social impairments in ADHD often present the challenge of distinguishing between ADHD, ASD, or both disorders co-occurring (ASD+ADHD).

Developing a technique to assist with appropriate diagnosis will prevent delays in access to critical services and treatments that may alter the course of the disorders and minimize the level of impairment experienced by individuals due to delayed or missed diagnosis.

Objectives: Identifying potential biomarkers that are uniquely associated with ASD alone, ADHD alone, and ASD+ADHD, based on distinct EEG profiles of spectral power and coherence among cortical brain regions.

Methods: We analyzed EEG recordings (from the Child Mind Institute’s Healthy Brain Network) during resting eyes open (EO) and eyes closed (EC) conditions. Data were from 4 groups of boys (age range: 5-16 Yrs): (1) Typically Developing (TD, n=86), ADHD without clinical diagnosis of ADHD (n=33), ADHD without clinical diagnosis of ASD (n=112), and (4) co-occurring ASD +ADHD (n=103). Analysis consisted of computing (1) absolute and relative spectral power from 31 EEG channels covering frontal, central, temporal, parietal, and occipital sites of both hemispheres, and (2) pair-wise coherence (magnitude) among the EEG sites. Both spectral and
coherence analysis was performed over Delta (0.5-4 Hz), Theta (4-8 Hz), Alpha (8-12 Hz), Beta (12-30 Hz), and Gamma (30-50 Hz) frequency bands. The mean spectral power and coherences at each frequency band of the 4 groups were compared using ANOVA, and for the specific cases where p (adjusted for multiple comparisons) was < 0.05, pair-wise comparisons were performed among the 4 groups.

**Results:** There was no difference in spectral power of ASD compared to the other 3 groups during EO or EC conditions. The ADHD group had a higher power in the right frontal area at mid Beta range (16-20 Hz) compared to TD and ADHD+ASD groups. Magnitude of coherences showed significant differences among the four groups in the left hemisphere between frontal, central, temporal, and parietal/occipital areas. Specifically, during EC, the coherence between the left-temporal and left-parietal/occipital sites showed significant increase in ASD compared to TD, ADHD, and ASD+ADHD groups. EC coherences within the left temporal area at gamma band frequencies showed a significant decrease in ADHD+ASD compared with ADHD, ASD, and TD groups.

**Conclusions:** The results of this study suggest several potential biomarkers, based on the spectral power and coherence magnitude at specific frequency bands, for distinguishing TD, ASD, ADHD, and combined ADHD+ASD groups. Future work will include combining these candidate biomarkers, via classification and machine learning methods, to produce more sensitive-specific biomarkers for separating the groups.

409.049 **(Poster) Early Bilingualism and Autism: Charting the Relationship between Early Bilingualism and the Neural Basis of Social Cognition in Autism.**

B. G. Digard, S. Fletcher-Watson, A. Sorace and A. C. Stanfield; (1)Division of Psychiatry, University of Edinburgh, Edinburgh, United Kingdom, (2)Salvesen Mindroom Research Centre, University of Edinburgh, Edinburgh, UNITED KINGDOM, (3)Department of Linguistics, University of Edinburgh, Edinburgh, United Kingdom

Background: Research reports a positive relationship between early bilingualism (acquisition of a 2nd language – L2 – before age 5) and the development of cognitive perspective taking in typical development, with associated neural differences, though research with adult populations is more inconsistent due to methodological discrepancies. While the social domain is particularly relevant in autism, with the development of autistic children’s sociocognitive skills following a different trajectory to that of their neurotypical peers, little research has investigated how the sociocognitive development of autistic people was shaped by bilingualism. Early findings suggest that this positive relationship between early bilingualism and the development of cognitive perspective taking also exists in autism, even when measured in an adult population, though not for affective perspective taking. What, then, are the neural basis of this relationship?

Objectives: This study describes the relationship between early bilingualism and the neuroactivity underlying cognitive perspective taking of autistic people compared to their neurotypical peers.

Methods: A sample of 17 autistic (with a clinical diagnosis, 53% female, mean age = 32.4 years, 9 early and 8 late bilinguals) and 15 neurotypical (67% female, mean age = 29.1 years, 8 early, 7 late) bilingual adults living in the U.K. took part in the study. Autistic and neurotypical participants only differed in their autism quotient score, and early and late bilinguals only differed in the age of acquisition of L2, with all other variables matching across groups (age, gender, non-verbal IQ as measured by the WASI-II, number of languages proficiently known and L2 overall proficiency as self-reported in a Language History Questionnaire). Participants completed a cartoon-based neuroimaging cognitive and affective perspective taking task to record their neuroactivity patterns during perspective taking. First-level whole-brain analysis identified the neural activity associated with each experimental condition of the task (cognitive, affective, control). Second-level analysis (repeated measures ANOVAs) explored the relationship between bilingualism groups and experimental conditions across the whole group. The influence of autism was assessed only on the regions showing a significant interaction between bilingualism groups and conditions with 2x2 ANOVAs across bilingualism groups and autism diagnosis.

Results: The neuroactivity linked with cognitive perspective taking differed between early and late bilinguals in the right anterior cingulate cortex (rACG). No relationship between bilingualism and affective perspective taking neuroactivity was found. In the rACG, for equal task performance (mean response time, accuracy), early bilinguals showed less activation than late bilinguals. There was no interaction between bilingualism group and autism diagnosis (Figure 1).

Conclusions: This study is the first to address the neurological profile of autistic bilinguals. The neurological findings support those at the cognitive level. Indeed, these findings suggest early bilingualism could influence the development of cognitive perspective taking in a long-lasting way in both autistic and neurotypical development, but not that of affective perspective taking. This deepens our understanding of the ability of the developing autistic mind to approach and respond to language learning, in terms of non-linguistic social processes. This contributes to an evidence base to support autistic people in their language learning journey.

409.050 **(Poster) Evaluating Peak Alpha Frequency As a Biomarker for Angelman Syndrome**

M. S. Bowen-Kauth, A. E. Youngkin, C. A. McNair, A. H. Dickinson and M. S. Sidorov; (1)Center for Neuroscience Research, Children’s National Hospital, Washington, DC, (2)Duke University, Durham, NC, (3)University of North Carolina at Chapel Hill, Chapel Hill, NC, (4)University of California, Los Angeles, Los Angeles, CA, (5)Pharmacology and Physiology, George Washington University, Washington, DC
Background: Angelman syndrome (AS) is a neurodevelopmental disorder caused by loss of expression of the maternal copy of the UBE3A gene. Phase 1 trials are currently underway in children using antisense oligonucleotides to unsilence the dormant paternal copy of UBE3A and re-express UBE3A protein in the brain. For these and other trials to succeed, there is a need to develop biomarkers that can objectively assess target engagement and/or treatment efficacy. Electroencephalography (EEG) is a safe and well-tolerated method to assess and quantify resting state brain rhythms in children with AS. Peak alpha frequency (PAF), defined as the frequency at which EEG oscillations are strongest within the alpha band, is a particularly valuable marker of neurodevelopmental trajectories. Our previous work demonstrated that in children with autism, PAF trajectories are abnormal and PAF is linked to non-verbal cognitive abilities.

Objectives: We seek to test the hypothesis that peak alpha frequency does not develop normally in individuals with AS and thus represents an EEG biomarker that may be well-suited for use in clinical trials.

Methods: We quantified PAF in EEGs from individuals with AS and age-matched neurotypical controls. Current preliminary analysis includes 30 AS EEGs gathered via the AS Natural History Study, which is a subset of the ~150 total EEGs available. We assessed and compared the developmental trajectory of PAF using linear regression.

Results: In this subset of EEGs, PAF did not follow the typical developmental trajectory in AS. In addition, PAF was more difficult to detect in AS EEGs compared to neurotypical EEGs. There were no clear differences in age or in other EEG properties between individuals where PAF was detected and individuals where PAF was not detected.

Conclusions: PAF has potential as an EEG biomarker for AS. Ongoing work seeks to expand the sample size and enable broader conclusions.

409.051 (Poster) Examining Frontal Alpha and Gamma Power in Young Children at Elevated Likelihood for Autism

M. Erdogan¹, L. Deurinck², T. Van Lierde³, F. Moeremans³, L. van Esch³, P. Warreyn³, I. Noens³ and H. Roeyers³, (1)Department of Experimental-Clinical and Health Psychology, Ghent University, Department of Experimental-Clinical and Health Psychology, Ghent, Belgium, (2)Ghent University, Ghent, Belgium, (3)Department of Experimental-Clinical and Health Psychology, Ghent University, Ghent, Belgium, (4)Parenting and Special Education Research Unit, KU Leuven, Leuven, Belgium, (5)Department of Experimental-Clinical and Health Psychology, Ghent University, Ghent, BELGIUM, (6)Parenting and Special Education Research Unit, Faculty of Educational Sciences, KU Leuven, Leuven, Belgium

Background: Differences in brain development preceding autism arise before toddlerhood (Varcin & Jeste, 2017). Language development within the autistic population is highly variable, however it is unclear which brain factors underlie this heterogeneity. Prospective studies of children at elevated likelihood (EL) for autism can provide insight into underlying markers. Electroencephalography (EEG) studies in EL-children have shown that frontal power can be linked to language development (Wilkinson et al., 2019) and overall autism characteristics (Gabard-Durnam et al., 2019), though no clear markers have been postulated.

Objectives: This study investigated whether frontal EEG power at 10 and 14 months (M) is associated with language and autism characteristics in EL-children at 14 and 24M.

Methods: As part of a prospective longitudinal study, resting-state EEG was collected at 10M and 14M (N=55). Frontal power (electrodes F3, F7, F4 and F8 located according to the 10-20 system) in the alpha (6-13Hz) and gamma (30-50Hz) frequency bands was examined. Language outcome was assessed using the index scores of the Bayley Scales of Infant and Toddler Development at 10M, 14M and 24M. The Autism Diagnostic Observation Schedule (ADOS-2) was used to classify children in two groups (‘high’ and ‘low’ amount of characteristics) at 14M and 24M. Total raw scores were used to assess autism characteristics.

Results: Significant group differences in frontal power were found at 10M between groups when classified at 14M (U(N=39) = 78.00, z = -1.78, p = .039) but not at 24M (U(N=24) = 38.00, z = 0.4, p = .68). No group differences were observed in frontal alpha or gamma at 14M, nor in gamma at 10M. When looking at total ADOS-2 scores, correlations revealed a marginally significant negative association between frontal alpha at 10M and autism features at 14M (r = -.30, p = .05). All other correlations were non-significant. Secondly, associations between language scores at 10M, 14M and 24M and frontal power at 10M and 14M were assessed. Significant positive associations were found between language scores at 10M and frontal alpha at 10M (r = .45, p = .002). Language scores at 24M were associated with frontal alpha at 14M (r = .33, p = .049) and frontal gamma at 14M (r = .34, p = .040). No significant associations were found between language scores at 14M and frontal power at 10M or 14M. As this is an ongoing study, results based on a larger sample and additional analyses will be presented during the meeting.

Conclusions:

This study exploratively investigated the relationship between autism characteristics, language development and frontal power in EL-siblings. Reduced frontal alpha, but not gamma, at 10M was associated with increased autism characteristics at 14M. Furthermore, increased frontal gamma and alpha power at 14M were associated with better language at 24M. Additionally, increased frontal alpha at
Explorable Autism Spectrum Disorder Models from EEG, Clinical and Cognitive Data for Mechanism Discovery and Targeting

**Background:** The various underlying genetic, cellular and environmental factors that make up the individual with Autism Spectrum Disorder (ASD) ensure the futility of one-size-fits-all approaches. One of several targetable mechanisms in ASD is presumably the imbalance in synaptic excitation-inhibition (E/I), specific to ASD and related disorders. Bumetanide, a mechanism-based treatment, successfully reinstated E/I balance, as depicted by electroencephalographic (EEG) signals in an R.C.T. (n=88)\(^2\), but only with partial translation into behavioral improvement\(^1\). A step towards a better mechanism targeting is the consideration of E/I balance within the broader picture of individual characteristics i.e. clinical severity, cognition or presence of EEG abnormalities. For example, we showed that individual severity, together with brain signal characteristics such as E/I balance and power in central(-parietal) regions, effectively predicted behavioral improvement in hold-out patient samples\(^1\). Also, we showed that EEG abnormalities and cognitive deficiencies are more specific to “inhibition-dominated” brain modes, than to ASD itself as defined behaviorally.

**Objectives:** These findings call for stratified-to-individualized approaches to treatment recommendations which are anchored in neurophysiological findings, alongside evaluation and refinement of treatment targets beyond behavioural domains. By incorporating clinical and cognitive measures, we refine mechanistic ASD models based on E/I balance to achieve a comprehensive picture of the disorder.

**Methods:** Behavioral and cognitive assessments were performed in a subset of n=57 ASD R.C.T. participants aged 7-15 years: 23 controls and 34 treated with bumetanide. In addition, brain signal characteristics such as E/I balance and power were computed from resting-state EEGs measurements\(^3\). Three dimensions: brain signals, cognition, behaviour and their dependencies were combined into a systemic approach called a structural equation model. This systemic approach allowed, in line with DSM-V behavioral dependencies, modelling multi-dimensional outcomes and incorporating proxy outcomes such as caregiver assessments. Goodness-of-fit measures were assessed to choose the best-fitting structural models.

**Results:** We found significant associations within dimensions, i.e., between behavioral improvement and caregiver assessments, and across dimensions, i.e., between brain signals and cognition, which served to define model dependencies. The final models revealed a comparable bearing of individual brain signals and cognitive variation on (social) behavioral improvement. Incorporating caregiver assessments led to comparable goodness-of-fit measures, supporting the consideration of such assessments as proxy measures. In line with previous behavioral improvement prediction results\(^4\), clinical severity was confirmed as the strongest predictor, brain signal characteristics coming second. Treatment group analyses suggest moderation, by virtue of cognition and brain signal characteristics, of the mechanism-based treatment effect on core behaviour.

**Conclusions:** These structural models bridge various dimensions from network brain dynamics to behaviour towards an explainable ASD. First, the explainability and biological anchoring of these models may prove helpful where, in the absence of a measure, a clinical decision requires proxies. Second, they may be used to predict, in addition to explain. Their effectiveness over predictive “black box” models prioritizing accuracy over explainability, is to be subsequently validated. Third, these models aim to better inform mechanisms and refine pharmacological targets. We are currently further investigating how individual characteristics influence the action of treatments hypothesized to reinstate E/I balance.

Exploring the Geometry Aware Resting State Neural Signature of Cognitive Empathy in Autism

**Background:** Autism differences in behavioral indices of cognitive empathy like emotion recognition (ER) accuracy and theory of mind are consistently reproduced across studies. Much of what we know about a possible core empathy network comes from functional MRI studies that interrogate empathy using performance-based tasks. Task-based functional connectivity captures state rather than trait capacities and makes it difficult to ascertain what findings are generalizable to everyday life and what is confined to the controlled nature of the lab.
Family and Age-Related Brain Functional Connectivity Patterns in Children with Autism Spectrum Condition and Their Siblings

R. Calvo Escalona, D. Ilzarbe, M. Rosa, J. C. Pariente, E. Muñoz, O. Puig Navarro, and M. L. Lazaro; (1)Hospital Clinic Barcelona, Barcelona, Spain, (2)Child and adolescent psychiatry and psychology, August Pi i Sunyer Biomedical Research Institute (IDIBAPS), Barcelona, Spain, (3)Hospital Clinic, Barcelona, Spain, (4)Multimodal neuroimaging in high risk and early psychosis, August Pi i Sunyer Biomedical Research Institute (IDIBAPS), Barcelona, Spain, (5)Hospital Clinic of Barcelona, Barcelona, Spain, (6)Magnetic Resonance Image Core Facility, August Pi i Sunyer Biomedical Research Institute IDIBAPS, Barcelona, Spain, (7)CIBERSAM, Barcelona, Spain

Background: Increased brain functional connectivity has been reported in children with Autism Spectrum Condition (ASC) compared with their healthy peers (1). In contrast, adults with ASC usually exhibit reduced brain functional connectivity (2). An altered neurodevelopment has been hypothesized to explain this switch in brain functioning during adolescence (3). Furthermore, family history of ASC has been related with this dysmaturation in newborn infants (4), showing an intermediate functional connectivity in adolescents relative to controls and their siblings with ASD5 in the Default Mode Network.

Objectives: We aim to evaluate group and age-related resting-state functional connectivity within several brain networks in children and adolescents with ASC compared to their siblings without ASC and neurotypic controls.

Methods: This is a case-control cross-sectional study including 45 autistic children and adolescents without intellectual disability, 20 of their siblings without ASC and 73 neurotypical controls (including 23 sibling-pairs). An eight-minutes eyes-closed resting-state functional MRI scan was acquired in a 3T scanner. Nineteen participants were excluded from further neuroimaging analyses due to excessive motion (8 ASD, 3 siblings, 8 controls). Independent component analysis was performed to identify the spatial maps of twenty brain functional networks. The spatial maps of each component for each subject were compared in a whole brain analysis using a multilevel mixed-effects linear regression model introducing group, age, group by age interaction and sex as fixed effects, and including family factor as random effect.

Results: There were significant group differences in the functional connectivity among groups: autistic children and adolescents exhibited diminished functional connectivity in parietal sensorimotor areas within the cerebellar network relative to the neurotypic controls (p < .04); and also diminished functional connectivity in areas associated to the sensory-motor network relative to their siblings (p < .02). There were no significant group by age differences in the functional connectivity among groups.

Conclusions: Our findings point to shared and differential brain functional connectivity patterns in children and adolescents with family-risk of ASC compared to their siblings with ASC; with potential as brain-based marker for identifying and monitoring ASC traits and setting. Resting state functional connectivity (rs-FC) methods offer a task-independent alternative for capturing intrinsic networks of functional brain organization that are more stable and allow for a more generalized characterization of brain function.

Objectives: The first objective was to replicate previous task-based findings of group differences across the network of regions involved in cognitive empathy using resting state data. The second, exploratory objective was to gauge the behavioral relevance of rs-FC between component pairs of regions within this network.

Methods: Our sample included 37 ASD (27 males, ages 8-35) and 39 neurotypical controls (26 males, ages 8-34), matched in age, sex, and full-scale IQ. We used the non-parametric multivariate distance matrix regression (MDMR) method to test the relationship between group and the similarity in patterns of rs-FC among regions that are relevant for cognitive empathy. Our MDMR distance metric was the geodesic distance that accounts for the intrinsic positive semi-definite cone geometry of neural functional connectivity. We used multiple linear regressions in our exploratory aim to identify potentially important interactions between specific pairwise relationships and diagnostic group for predicting ER accuracy. ER was assessed as the percentage of correctly labeled emotions when looking at emotionally charged images.

Results: Using a combination of rs-FC and a geometry-aware metric of similarity, the geodesic distance, we found that the connectivity among regions important for cognitive empathy are more similar for individuals within the same diagnostic group than between diagnostic groups (Fp = 0.017, p = 0.024). Our exploratory analysis for identifying neural correlates of ER in autism point to two potentially important pairwise relationships: connectivity between 1) the basolateral amygdala with the posterior temporoparietal junction and 2) the basolateral amygdala with the right inferior frontal gyrus.

Conclusions: Our MDMR finding is in line with previous studies that report autism specific connectivity patterns among empathy relevant brain regions. The presence of a task-independent connectivity profile in empathy regions that is more similar among autistics suggests a promising avenue for further elucidating autism specific connectivity using resting state methods with low cognitive demands. Our exploratory findings suggest that our autistic participants engaged a different neural strategy for ER that relies more on emotional-cognitive coupling than our neurotypical controls. A positive relationship between ER accuracy and the BLA connectivity with self-referential social cognitive regions like the pTPJ and rIFG in autism would suggest that autistic individuals access their own emotional states to better understand emotions in others.
diagnosis. Longitudinal studies are required to properly evaluate age-trajectories in children and adolescents with family-risk of ASC; and their correlates with functioning.

**409.055 (Poster) Finding a Perfect Match: An ERP Study Comparing Age and IQ Matching**

_E. Matsuba_, E. L. Cary, E. F. Soto, E. Watts, C. MacKenzie, J. Osborne, X. Chen, M. Shuter and N. Russo. (1)Department of Psychology, Syracuse, NY, Canada, (2)Department of Psychology, Syracuse University, Syracuse, NY, (3)Psychology, Syracuse University, Syracuse, NY, (4)Syracuse University, Syracuse, NY

**Background:** The Developmental Approach emphasizes parsing apart cognitive and developmental factors towards better understanding autism and other neurodevelopmental disabilities. Methodologically, this means matching groups on age and IQ so that results are not confounded by developmental factors. This approach has yet to be consistently implemented in neuroscience studies, as most assume that early neural measures are not influenced by cognitive processes. Here, we take a step towards demonstrating the role of IQ in early neurophysiological responses by examining the influence of age and performance IQ on Event-Related Potentials (ERPs).

**Objectives:** Given the importance of understanding how latent group characteristics impact neurophysiology, the primary aims of this project are to assess differences in the P1 and mismatch negativity (MMN) within groups of autistic and typically developing (TD) children when matched on age alone and performance IQ alone.

**Methods:** The P1 and MMN were compared across 2 sets of autistic and TD children. The first group was matched on chronological age (\(t(1, 20) = -0.310, p = .760\)) and the second was matched on the Perceptual Reasoning Index (PRI) of the Wechsler Abbreviated Scale of Intelligence, Second Edition (WASI-II; \((t(1, 20) = 0.187, p = .853)\). The ERPs were elicited using an auditory oddball paradigm, consisting of alternating standard 1200Hz (80%) and deviant 1000Hz (20%) tones. The 50% fractional peak latency and mean amplitude were extracted from a frontocentral electrode cluster (E5, E6, E7, E12, and E106). Preliminary data below are based on 11 participants per group, with recruitment ongoing.

**Results:** When matched on age only, autistic and TD children (mean age = 12; mean PRI = 109) did not differ on the P1 fractional peak latency (\((t(1, 20) = -0.934, p = .361)\). However, when matched on PRI only (mean age = 13, mean PRI = 107) there were no differences in P1 fractional peak latency (\((t(1, 20) = -0.879, p = .390)\), but autistic children had significantly larger mean P1 amplitudes compared to their TD peers (\((t(1, 20) = -2.029, p = .056)\). For the MMN, there were similarly no differences between group on the MMN fractional peak latency (\((t(1, 20) = 0.309, p = .761)\) nor mean amplitude (\((t(1, 20) = 1.118, p = .277)\) when groups were matched on age. When matched on PRI, groups did not differ on fractional peak latency (\((t(1, 20) = 0.035, p = .972)\) but the autistic group had marginally larger mean MMN amplitudes (\((t(1, 203.153) = 1.904, p = .079)\).

**Conclusions:** Autistic children had larger P1 and MMN mean amplitudes when matched on PRI and no observed differences when matched on age. This demonstrates how methodological decisions regarding group composition influence subsequent results and conclusions, even in neurophysiological research. Thus, researchers should carefully consider developmental approaches (i.e., matching strategies) in neuroscience research with autistic individuals.

**409.056 (Poster) Unlocking Social Brain Function in Autism: Variation By Sex and Neurotype of Microdynamics of Face Processing**

**Background:** Accumulating evidence has started to define the autistic female phenotype, including higher social attention than males, that may contribute to late- and mis-diagnosis. Moreover, in our recent study, autistic and non-autistic females differed in the distributions of
Objectives: To investigate whether sex/neurotype influence the onset, duration, and order of configural processing, we tested the significance of interactions between these factors and the event-related response to upright/inverted faces across time, grouped adjacent time-bins into time-clusters, and examined differences of potential within.

Methods: Analyses involved 764 participants of the Longitudinal European Autism Project (204 non-autistic - average age 17.99 (SD = 5.62) years, average FSIQ 101.29 (19.23) - and 330 autistic males - 17.04 (SD = 5.32) years, FSIQ 96.25 (19.60); 107 non-autistic - 16.53 (5.68) years, FSIQ 103.21 (19.29) - and 123 autistic females - 16.95 (6.19) years, FSIQ 93.50 (19.11)), who watched 500-ms-long upright and inverted static photographs of faces (292 * 375 px), 168 times in 4 blocks (4.5 minutes), while EEG (10-20 64 channels with 120/300 Hz) was recorded. The data passed time delay correction (average 32.27 ms, SD = 20.22), bandpass and DFT-based filtering (0.1-40 and 50 Hz), resampling (500 Hz), EOG-cleaning and iterative interpolation, resulting in a final sample of 492 participants (65%). To obtain the time-clusters, we entered the pre-processed amplitude at P8 (aggregated to 10 ms time-bins) in 2 bootstrapped permutations as a function of a mixed model assuming stimulus (upright/inverted) as fixed and random intercept and slope, in interaction with fixed effects of (1) sex (male/female) and (2) group (autistic/non-autistic).

Results: We found 2 partially overlapping time-clusters (Figure 1). A significant stimulus by group interaction defined the earlier time-cluster (170-440 ms). Within this cluster, difference between upright/inverted was bigger in autistic (d = -0.54, SE = 0.24, p-value = 0.02), than non-autistic (d = 0.47, SE = 0.20, p-value = 0.02), and females than males (d = 0.76, SE = 0.26, p-value = 0.004) - however the stimulus-by-group and stimulus-by-sex interactions did not interact with each other.

A significant sex by condition interaction defined the later time-cluster (250-550 ms). Within it, difference between upright/inverted was bigger in males (d = -1.66, SE = 0.33, p-value <0.001) than females (d = 0.87, SE = 0.21, p-value <0.001); with age, stimuli difference became bigger (d = 0.11, SE = 0.01, p-value <0.001), irrespective of sex.

Conclusions: Configural processing varied by sex and group, with earlier main effect of group, and later main effects of sex. Sex differences in the earlier cluster might be due to partial overlap or feedback effect. These observations suggest that mean sex differences may be prominent later in the waveform as a potential constraint or moderator across groups. The amplitude difference in females may represent stronger perceptual amplification linked to different expressions of behaviour, such as visual social attention.

409.057 (Poster) Frequency-Tagging EEG Reveals Similar Neural Sensitivity in Men with and without Autism to Subtle Differences in Facial Identities and Expressions

Background: The fluent processing of facial cues (e.g. identities and expressions), which is vital for successful social interactions, might be challenging for individuals with autism spectrum disorder (ASD).

Objectives: Considering the mixed behavioral results on facial identity and expression processing in ASD, we wanted to overcome influences of compensatory strategies. Therefore, in the present study, we applied frequency-tagging EEG to assess the automatic and implicit neural sensitivity of adults with and without ASD to subtle facial cues.

Methods: We examined the neural sensitivity of 23 adult men with ASD and 23 neurotypical controls (matched on age, sex and IQ) to rapidly and implicitly detect subtle changes in facial identities and expressions, using frequency-tagging EEG. In oddball paradigms, base rate images were presented at 6 Hz, periodically interleaved every fifth image with an oddball image (i.e. 1.2 Hz oddball frequency). To examine the neural sensitivity to facial identities, base rate images were the neutral face of one individual; oddball images were neutral faces of different individuals. These stimuli were presented either upright or inverted, to also gain more insight in the automatic perceptual strategy used to process faces. To investigate the neural sensitivity to facial expressions, base rate images of neutral faces with different identities were periodically interleaved with an expressive face (angry, fearful, happy, and sad, in separate sequences). These distinctive frequency tags for base rate and oddball stimuli allowed direct and objective quantification of the neural identity-discrimination or expression-categorization responses.

Results: We found no differences in the neural sensitivity of participants with and without ASD, neither when discriminating between facial identities, nor when detecting different facial expressions. Both groups also showed a similar face-inversion effect, with reduced neural responses for inverted versus upright faces. When processing facial expressions, sad faces elicited significantly lower brain responses than angry, fearful and happy faces in both groups. Looking at the topographical distribution of the neural activity revealed that identity-discrimination responses were mostly recorded over the right occipito-temporal region for both adults with and without ASD. The
control group also displayed these higher-level right occipito-temporal response peaks when detecting differences in facial expressions, yet, for men with ASD, responses were higher in the medial-occipital region.

Conclusions: We applied frequency-tagging EEG to investigate the neural sensitivity of adult men with and without ASD to facial identities and expressions. Our results indicate that participants in both groups are equally capable to rapidly and implicitly detect differences in identity and emotional expression. Additionally, for both participants with and without ASD (i) the holistic processing of facial identities gets disrupted when faces are presented upside-down, as evidenced by the face-inversion effect, and (ii) distinguishing sadness from neutrality in the blink of an eye seems to be harder than any of the other emotions. The right hemisphere advantage reflects the larger involvement of higher-level visual areas. However, for the rapid changes in facial expressions, men with ASD might rely more on a feature-based approach, as the activity in the medial-occipital region suggests the dominance of low-level visual processing.

409.058 (Poster) Functional Brain Network Alterations during Early Childhood in ASD

Background:

Autism Spectrum Disorder (ASD) is a neurodevelopmental condition defined by difficulties in social communication and restricted/repetitive interests and behaviour that can vary along a continuum of severity. Growing consensus suggests that individuals with ASD exhibit abnormal functional connectivity, resulting in alterations of large-scale brain networks. From a clinical perspective, the demand is thus high for non-invasive and easy to-use tools to identify early pathological alterations in brain networks.

Objectives:

The goal of the study was to characterise early alterations of functional brain connectivity in young children with ASD, as well as their developmental trajectory.

Methods:

We explored differences in functional brain network topology using resting-state EEG in 40 young children with ASD compared with 73 typically developing children, aged 2-8 years. We used a framework for advanced EEG analysis called 'EEG source connectivity method' combined with graph theory-based analyses. The functional networks were reconstructed at the cortical level from scalp EEG electrodes. The identified networks were then analysed by graph measures that allow their characterisation at different scales from node- and edge-wise topology to global-wise analysis (Figure 1).

Results:

Our results revealed alterations in functional brain connectivity between the two groups in the alpha band. Children with ASD exhibited a higher edge-wise global connectivity index than typically developing children already at 2 years of age. Node-wise analysis showed a local overconnectivity in ASD children with mainly frontotemporal and latero-occipital alterations.

Conclusions:

These results shed light on the abnormal network topology in ASD children, which may indicate some loss of neighbourhood architecture to a random network. Future work is needed to determine how these alterations contribute to the emergence of cognitive and behavioural symptoms observed in young children diagnosed with autism or other neurodegenerative disorders.

409.059 (Poster) Functional Connectivity between the Visual and Salience Networks Reflects Individual Variation in Social Behavior in a School-Age Sample Enriched for Autism Spectrum Disorder

Methods: Data were analyzed from 12- and 24-month-old infants in the multisite Infant Brain Imaging Study (IBIS), a prospective study of ROIs contributing to network enrichment based on published literature.

Objectives: (a) To test whether correlations between social motivation and ROI-ROI functional connectivity (fc) are enriched within specific brain networks. (b) To characterize the directionality of implicated fc-behavioral associations, as well as behavioral associations of brain-behavior relationships for social motivation during the first two years of life, when core autistic symptoms arise, may therefore elucidate neural systems contributing to the development of ASD.

Results: ROI pairs within the visual and salience networks (Vis-Sal fc) were significantly associated with social affect symptoms (SA) at school-age (p = 0.00002; Figure 1B). Though none of the individual ROI-pair associations reached experiment-wide significance, 97% of the 333 ROI pairs in Vis-Sal were positively associated with SA (expected 50% under the null). No other behaviors were significantly associated with Vis-Sal connectivity (all enrichment p > 0.20), or with connectivity in other network pairs. Average connectivity for the Vis-Sal pair was significantly correlated with SA scores (partial r: 0.36, 95% CI: 0.17-0.52, p < 0.001). The association remained highly significant after accounting for all other behaviors, sex, and age (96 = 3.72, p = 0.0003).

Conclusions: Functional connectivity between the visual and salience networks is associated with individual variation in social affect symptomology in a sample enriched for ASD. Visual-salience connectivity may represent both a neuroimaging marker of risk (stronger connectivity, greater clinical impairment) and resilience (weaker connectivity, less impairment) that deserves further study. Given recent evidence from our group linking genetic liability for ASD to the development of the visual system during infancy, these results also suggest that visual and sensory network development may play a role in the emergence of autistic social traits. Future work in our sample will seek to chart the development of visual network structural and functional connectivity during the period leading up to a diagnosis of ASD.

Background: Autism spectrum disorder (ASD) is a highly heritable and clinically heterogeneous developmental disorder affecting 1-2% of the population. Phenotypic variability among individuals with ASD is a key challenge in developing effective interventions to improve quality of life. Neuroimaging markers that reflect individual variation in behavior will be critical to parsing heterogeneity, understanding the neurobiology of ASD, and designing personalized intervention targets.

Objectives: To identify functional brain networks associated with ASD-relevant behaviors including variations in symptomology, comorbidities, and developmental functioning.

Methods: Resting state functional connectivity (fc) MRIs were collected from 121 school-age children (7.5-11.6y, 55 male) from the longitudinal Infant Brain Imaging Study. Children were recruited as infants with a family history of ASD (n = 78) or controls (n = 43); 20 children (13 male) received an ASD diagnosis during the study. We used multiple regression to screen for associations between fc of ~40k region of interest (ROI) pairs (285 ROIs assigned to 12 networks) and six behavioral variables:ADOS (1) social affect and (2) restricted and repetitive behavior calibrated scores; and standardized measures of (3) generalized anxiety, (4) inattention, (5) motor coordination, and (6) matrix reasoning. Analyses controlled for study site, sex, and age. We identified clusters of brain-behavior associations within and between functional networks (empirical p-values via rotation tests). Partial correlations and regression were used to characterize the association between average connectivity in a network pair and individual behaviors.

Results: ROI pairs within the visual and salience networks (Vis-Sal fc) were significantly associated with social affect symptoms (SA) at school-age (p = 0.00002; Figure 1B). Though none of the individual ROI-pair associations reached experiment-wide significance, 97% of the 333 ROI pairs in Vis-Sal were positively associated with SA (expected 50% under the null). No other behaviors were significantly associated with Vis-Sal connectivity (all enrichment p > 0.20), or with connectivity in other network pairs. Average connectivity for the Vis-Sal pair was significantly correlated with SA scores (partial r: 0.36, 95% CI: 0.17-0.52, p < 0.001). The association remained highly significant after accounting for all other behaviors, sex, and age (96 = 3.72, p = 0.0003).

Conclusions: Functional connectivity between the visual and salience networks is associated with individual variation in social affect symptomology in a sample enriched for ASD. Visual-salience connectivity may represent both a neuroimaging marker of risk (stronger connectivity, greater clinical impairment) and resilience (weaker connectivity, less impairment) that deserves further study. Given recent evidence from our group linking genetic liability for ASD to the development of the visual system during infancy, these results also suggest that visual and sensory network development may play a role in the emergence of autistic social traits. Future work in our sample will seek to chart the development of visual network structural and functional connectivity during the period leading up to a diagnosis of ASD.

Background: Early deficits in social motivation have been hypothesized to constrain social learning, thereby leading to atypical development of social communication and autism spectrum disorder (ASD). Recent work found that social motivation differs by level of familial ASD liability in infancy (Marrus et al., 2022), suggesting it may serve as an early marker of heritable ASD factors. Characterizing brain-behavior relationships for social motivation during the first two years of life, when core autistic symptoms arise, may therefore elucidate neural systems contributing to the development of ASD.

Objectives: (a) To test whether correlations between social motivation and ROI-ROI functional connectivity (fc) are enriched within specific brain networks. (b) To characterize the directionality of implicated fc-behavioral associations, as well as behavioral associations of ROIs contributing to network enrichment based on published literature.

Methods: Data were analyzed from 12- and 24-month-old infants in the multisite Infant Brain Imaging Study (IBIS), a prospective study of infants at high (HL) and low familial likelihood (LL) of an ASD diagnosis. Participants had concurrent functional neuroimaging and...
behavioral data at 12 (n=92; HL/ASD/HL/noASD/LL/noASD=8/58/26) and/or 24 months (n=97; HL/ASD/HL/noASD/LL/noASD=15/63/19). A clinical best estimate ASD diagnosis was assigned at 24 months. A social motivation composite with strong face validity for social motivation (Marrus et al., 2022) was generated using items from multiple parent-report measures in the IBIS battery. Resting state functional MRI data were collected during natural sleep using gradient-echo echo-planar image acquisition on cross-site calibrated 3T Siemens TIM Trio scanners. Analyzed subjects had at least two 6.25-minute runs and 150 frames of motion-scrubbed data. Two hundred thirty functionally-defined ROIs were sorted into networks using the Infomap community detection algorithm (Rosvall and Bergstrom, 2008) on 12- and 24-month data (Figure 1A). Enrichment analysis identified networks and pairs of networks whose fc strongly correlated with behavior, (p<.001 considered significant), followed by a machine learning procedure for secondary validation (Hawks et al., 2021). ROIs whose connections frequently contributed to enrichment were examined in the Neurosynth database (Yarkoni et al., 2011) for behavioral associations in older subjects based on posterior probabilities aggregated from scientific literature.

Results: At 12 months, the anterior frontoparietal control-1–somatomotor-2 (aFPC-SMN2) network pair showed significant enrichment (p=.0002), whereby contributory ROI pairs exhibited a negative association with social motivation across a range of positive and negative fc values. (Figure 1B). This finding did not pass secondary validation. At 24 months, the posterior FPC–anterior default mode network-2 (pFPC-aDMN2) network pair showed significant enrichment (p=.0006) and passed secondary validation. This network pair displayed an overall positive association with social motivation across a range of positive and negative fc values. Neurosynth terms strongly associated with ROIs in both the pFPC and aDMN2 encompassed aspects of social and general cognition.

Conclusions: The most strongly implicated networks associated with early social motivation included task control networks (i.e., FPC) and the DMN, for which differences have been observed at later stages in ASD. Future directions include investigating whether these early brain-behavioral relationships correlate with long-term outcomes of IBIS infants through school age and adolescence.

409.061 (Poster) Global Motion Processing in Infants' Visual Cortex and the Emergence of Autism
J. Hardiansyah, P. Nyström, S. Bolte, A. Ronald and T. Falck-Ytter, (1)Center of Neurodevelopmental Disorders (KIND), Centre for Psychiatry Research; Department of Women’s and Children’s Health, Karolinska Institutet, Stockholm, Sweden, (2)Uppsala University, Uppsala, Sweden, (3)Center for Neurodevelopmental Disorders at Karolinska Institutet (KIND), Department of Women’s and Children’s Health, Karolinska Institutet, Stockholm, Sweden, (4)Birkbeck College, London, UNITED KINGDOM

Background: Differences in basic perceptual processes have been documented in autistic children and adults. Specifically, studies have suggested a link between autism and altered processing of global visual motion. Yet, it is unknown whether distinctive patterns of global motion processing in infancy precede the onset of autism symptoms.

Objectives: We aimed to understand the patterns of visual cortex (VC) activation during the basic visual processing of local form, local motion, global form, and global motion, and to test any difference in these patterns between samples of infants at elevated likelihood & low likelihood of autism, and a large general sample of infants. We also sought to see if differences in these basic visual processes during infancy are predictive of later autistic symptoms during toddlerhood.

Methods:

Using electroencephalography, we assessed basic visual processing in 525 (265 male, 260 female) 5-month-old infants from two different study cohorts: EASE (Early Autism in Sweden) and BATSS (BabyTwins Study in Sweden). Fifty-two infants were at elevated likelihood (EL) and 21 infants were at low likelihood for autism (LL) in EASE, and 452 infants (not screened for autism) were twins (242 monozygotic and 210 same sex dizygotic) in BATSS.

Visual stimuli. We employed 4 types of stimuli to evoke global form, global motion, local form, and local motion processing on EEG. EEG measurement was taken at 5 months for all infants

Behavioral assessment. To measure later autistic traits in EASE sample, we used ADOS-2 (Autism Diagnostic Observation Schedule v2) CSS scores taken at 36 months. As comparable measures for BATSS sample, we used ITC (Infant Toddler Checklist) and Q-CHAT (Quantitative Checklist for Autism in Toddlers) taken at 18 and 24 months, respectively.

Twin modelling. To assess genetic and environmental influences on individual variability in these basic visual processes, we employed the ACE/ADE models on BATSS sample only.

Results: (See attached figure) Visual cortex activation profiles during global form, global motion, local form, and local motion processing were first established for 473 infants not at elevated likelihood for autism (EASE LL + BATSS). Compared to this sample, global motion topographic profiles were different (enhanced lateral and reduced midline VC activation; p < .001) in infants who later exhibited autistic symptoms at clinically significant levels (c; bottom panel). Among EASE infants, a higher lateral-relative-to-midline activation only during global visual motion processing was associated with higher levels of autistic symptoms in toddlerhood (r = .465, p < .001) (a & b;
upper panels). Finally, we found that individual differences in these global motion profiles heritable (95%-CI: .047 – .392) in BATSS infants.

Conclusions: Using EEG, we demonstrated in the sample of EL infants that a different topographical VC organization of global motion processing is positively associated with autistic symptoms in toddlerhood. In particular, EL infants with later severe autistic symptoms were shown to have enhanced lateral but reduced midline VC activation. Based on the infant twin sample, we showed that individual differences in this topographical activation during global motion processing partly reflect genetic variation in the broader infant population.

409.062 (Poster) Glutathione Metabolism Imbalance Related to Autism Quotient Pattern in Adults: Advances in Diagnosis
C. D. Jimenez-Espinosa, F. J. Marc ano Serrano and J. L. González-Mora, (1)Physiology, Neurochemistry and Neuroimage Lab., Santa Cruz de Tenerife, Spain, (2)Neurochemistry and Neuroimage Lab., University of La Laguna, Santa Cruz de Tenerife, Spain, (3)University Hospital of Canary Islands HUC, La Laguna, Spain

Background: Autism spectrum disorder (ASD) is a neurodevelopmental disorder whose precise etiology seems to be as heterogeneous as its severity levels. Nevertheless, accumulating evidence suggests that oxidative stress could be a common feature in autism, which may be further exacerbated by inflammatory phenomena, immune deregulation, and certain autoimmune risk factors, that may also contribute to the development and pathogenesis of autism. Following our research line linked to the tripeptide glutathione (GSH) as a key mechanism underlying symptoms of ASD, the hypothesis of GSH metabolism imbalance correlates with impairments on the domains of autism quotient (AQ).

Objectives: To study the correlation of glutathione (one of the major antioxidants) to the Autism Quotient (AQ) domains for adults using 1H-MRS in vivo.

Methods: We quantified glutathione reduced (GSH), creatine (Cr), and N-acetyl aspartate (NAA) signal in anterior (ACC) och posterior (PCC) cingulated cortices separately by magnetic resonance spectroscopy (MRS) on a 3.0 Tesla MR scanner, to assessed 22 adult patients with ASD and compared with 44 healthy subjects, matched for age, gender. AQ test were applied where the subgroup algorithm, which combines the scores on the five AQ domains (social skills, attention switching/tolerance to change, attention to detail, communication, and imagination) derived the cutoff threshold to yield reliable autism subgroups as following: AQ1 (0–10 points) = below average; AQ2 (11–21 points) = average values of the normal population; AQ3 (22–31 points) = above average; AQ4 (32–50points) = very high index of autistic characteristics. The Autism Quotient had an average score of 35. Statistic one-way ANOVA was applied. Pearson’s correlation hallmarks our goal.

Results: The Pearson correlation coefficient represented graphically, showed a positive significant correlation between AQ domain ‘Communication’ to GSH (r = 0.51, p = 0.01); to GSH/Cr ratio (r = 0.51, p = 0.01); and GSH/NAA ratio (r = 0.56, p = 0.004) in AQ2 group (see Fig.1; Fig.2); in AQ3 to GSH negative significant correlation (r = -0.69, p = 0.05) in the PCC. Contrary in AQ4 to GSH/NAA positive significant correlation (r = 0.54, p = 0.05) in ACC.

Notably, in AQ1 group is a significant negative correlation between GSH/Cr ratio to ‘Attention switching/tolerance to change’ domain (r = -0.57, p = 0.03); and significative positive correlation between GSH/NAA ratio to ‘Attention to details’ domain (r = 0.52, p = 0.05) in PCC; indicating the intervention of creatine, responsible of cell damage caused by lack of oxygen and protector by preventing the depletion of energy ATP, and N-Acetyl aspartate (marker of density neuronal). AQ2, AQ3, and AQ4 groups maintain a pattern correlation to AQ domains different than the AQ1 group (considered group of healthy subjects) and highlight the differences in the autistic characteristics within ASD, and as hallmark of the ‘Communication’ deficit (Bjorklund, G., 2021).

Conclusions: The opportunity to measure the concentration of GSH in cingulated cortices creates a new and promising approach for intensified diagnosis and the effects of a new venue clinical trial in ASD.

409.063 (Poster) Hemispheric Specialization for Lateralized Networks in Autistic and Neurotypical Individuals
M. Peterson and J. A. Nielsen, Brigham Young University, Provo, UT

Background: One well-replicated finding is that of reduced cerebral lateralization in autistic individuals during speech and language (Eyler et al., 2012; Herbert et al., 2022; Harringshaw et al., 2016; Kleinhans et al., 2008; Knaus et al., 2008, 2010). However, it is unknown if these disruptions in hemispheric lateralization in autism are localized to language-relevant regions (McCann, 1982), or if they are more pervasive. Current evidence is mixed, with findings for generally increased activity in the right hemisphere in autism (Anderson et al., 2010; Knaus et al., 2008; Takeuchi et al., 2004; Tesink et al., 2009; A. T. Wang et al., 2006), generally decreased activity in the left hemisphere (Eyler et al., 2012; Harris et al., 2006; Müller et al., 2003), and both increased activity in the right hemisphere and decreased activity in the left hemisphere (Boddaert et al., 2003; Kleinhans et al., 2008; Redcay & Courchesne, 2008).
Methods: The hypothesis was tested with a cross-sectional dataset composed of 109 autistic and 78 typically developing individuals ages 5-21 years. Functional MRI neuroimaging analyses were performed using the CBIG2016 preprocessing pipeline (Kong et al., 2019; Li et al., 2019) and the Kong2019 multi-session hierarchical Bayesian modeling parcellation pipeline (Kong et al., 2019). Hemispheric specialization was estimated using the autonomy index on a vertex-by-vertex basis (Wang et al., 2014), which was then averaged within each of six previously identified lateralized networks: Temporal Parietal, Control A, Default A, Dorsal Attention A, Salience A, and Control B. A series of ANCOVAs were used to examine the relationship between network-averaged hemispheric specialization and diagnostic group, mean-centered age, mean-centered age squared, site, number of available volumes per task, and average framewise displacement in R version 4.2.0 using the package car.

Results: The slopes of network-averaged specialization were similar for the autistic and neurotypical groups for each of the six lateralized networks examined (Temporal Parietal: \( F(1, 177) = 1.69, p = 0.19 \); Control A: \( F(1, 177) = 0.74, p = 0.39 \); Default A: \( F(1, 177) = 1.71, p = 0.19 \); Dorsal Attention A: \( F(1, 177) = 0.41, p = 0.52 \); Salience A: \( F(1, 177) = 2.67, p = 0.1 \); and Control B: \( F(1, 177) = 0.24, p = 0.62 \). Additionally, no significant differences between the autistic and neurotypical groups were observed for each of the six networks after recentering age at 5, 10, 15, and 20 years.

Conclusions: In contrast to our hypothesis and previous reports of decreased lateralization in autistic individuals, we found no group differences in network-averaged specialization between 5-21 years. When considered in combination with previous reports, our results suggest that the selected networks are lateralized prior to age five and maintain this level of lateralization throughout later childhood and adolescence.

409.064 (Poster) Hypo Brain Activity in Response to Affective Touch in Autistic Children

W. Ni, G. Liu, T. Li, and L. Yi, (1)School of Psychological and Cognitive Sciences and Beijing Key Laboratory of Behavior and Mental Health, School of Psychological and Cognitive Sciences, Peking University, Beijing, China, (2) School of Psychological and Cognitive Sciences and Beijing Key Laboratory of Behavior and Mental Health, Peking University, Beijing, China

Background:

Affective touch, triggered by gently touch, plays a fundamental role in social-emotional development. Studies have found that autistic people perceived affective touch differently using self-report and brain activity recording (e.g., Cascio et al., 2012; Kaiser et al., 2016). Yet it remains unclear how affective touch affects “social brain” activity and functional connectivity in autistic children.

Objectives:

This study aimed to investigate the brain activity and functional connectivity responding to affective touch in children with ASD.

Methods:

Twenty-three autistic boys (\( M_{\text{age}} = 5.72, SD = 0.42 \)) and twenty-three age-matched typically developed boys (\( M_{\text{age}} = 6.01, SD = 0.62 \)) participated in our study. Their sensory processing function was parent-reported by the Sensory Processing and Self-Regulation Checklist (SPSRC, Lai et al., 2019). A lower score represented a less typical performance. Before the formal experiment, an experimenter gently brushed participants on their right forearm and palm for one second and asked participants how pleasant they felt about the touch. Children needed to rate their pleasantness on a 1-5 Likert scale (1 = “not at all” and 5 = “extremely”). During the formal experiment, children’s fNIRS signals were measured by NIRSport (NIRx Medical Technologies, LLC; sampling rate: 3.47 Hz). The experiment contained two conditions (brushing forearm or palm) and ten blocks for each condition.

Results:

First, we analyzed the pleasantness rating data and its correlation with sensory processing. Autistic group (\( M = 4.89, SD = 0.32 \)) rated both types of touch more pleasant than TD group (\( M = 4.29, SD = 0.81 \)), \( F(1,41) = 18.16, p < .001 \). We found no main effect of condition nor interactive effect between group and condition (Figure 1A). The pleasantness of the forearm brush was negatively correlated with the sensory under-response score, \( r = -.36, p = .02 \). Pleasantness of the palm brush was positively correlated with the sensory over-response score, \( r = .38, p = .012 \), see Figure 1B. Second, we explored touch-evoked brain activity in ASD and TD groups. In the ASD group, the left somatosensory cortex (SMS) and left middle superior temporal sulcus (mSTS) showed significant activations to palm brush > forearm brush (\( ps < .01 \)). In the TD group, the left posterior STS, the bilateral middle frontal gyrus (MFG), and right inferior frontal gyrus (IFG) revealed significant activation to forearm brush > palm brush (\( ps < .05 \), Figure 2A). Finally, we conducted a psychophysiological
interaction (PPI) to measure functional connectivity between brain regions. We set the left somatosensory cortex as a seed region. The functional connectivity between left middle STS, right MFG, right somatosensory cortex, and the seed of left somatosensory cortex in TD children was stronger when children were brushed on the forearm than the palm (ps < .05, Figure 2B). However, no difference was found in ASD children between two conditions.

Conclusions:

Autistic children exhibited hypo brain response in the “social brain” and somatosensory cortex during affective touch than non-affective touch. They did not have robust connectivity between SMS and the “social brain” as TD children did.

409.065 (Poster) Identification of Brain Functional Network Substrates of ASD Subtypes According toIQ Imbalance: A Transformer-Based Graph Neural Network Model

J. I. Kim, S. Kim, N. Yoon, A. B. Cho, B. N. Kim and J. M. Lee, (1)Psychiatry, Hanyang University Medical Center, Seoul, Korea, Republic of (South), (2)Department of Electronic Engineering, Hanyang University, Seoul, Korea, Republic of (South), (3)Seoul National University, Seoul, Korea, Republic of (South), (4)Child and Adolescent Psychiatry, Seoul National University Hospital, Seoul, Korea, Republic of (South), (5)Department of Biomedical Engineering, Hanyang University, Seoul, Korea, Republic of (South)

Background: Adaptive functioning and intelligence are important features when assessing the phenotypic heterogeneity of autism spectrum disorder (ASD). Discrepancy between verbal and non-verbal intelligence is prevalent in ASD children and has been suggested as a distinct subtype of ASD, but the neural correlates underlying IQ imbalance has not been well investigated.

Objectives: The purpose of this study was to classify ASD subtypes according to verbal and non-verbal IQ imbalance profiles by applying a transformer-based graph neural network model (GNN) model to learn graph representation related to cognitive imbalance.

Methods: We utilized the resting-state fMRI data of the Autism Brain Imaging Data Exchange I, II (ABIDE) database. After preprocessing quality control, 411 ASD individuals with available scores IQ were selected. IQ discrepancy scores were calculated by subtracting the performance IQ (PIQ) from the verbal IQ (VIQ) score. Individuals with VIQ-PIQ greater than or equal to 15 standard score points were assigned to the VIQ > PIQ group; those with VIQ-PIQ less than or equal to -15 points were assigned to the PIQ > VIQ group; those with a discrepancy between -14 and 14 points were assigned to the “no-discrepancy” (ND) group. As a result, 76 were included in the VIQ > PIQ group, 243 were included in the no-discrepancy group, and 90 were included in the PIQ > VIQ group.

Preprocessing of the fMRI data was performed according to the following steps: removing the first 5 volumes, slice-timing correction, realignment, spatial normalization into MNI, and smoothing with a 6-mm FWHM Gaussian kernel and quality control.

To construct a functional connectivity matrix for an individual, we used the AAL(Automated Anatomical Labeling) atlas. We averaged rs-fMRI time series at each ROI and computed a functional connectivity matrix based on Pearson’s correlation of functional time series between every pair of ROIs (94 x 94). The resulting Pearson correlations(r) were normalized to z via Fisher’s z-transformation. Prior to training, the inter-site variability and the covariate effect of sex and age at MRI scan were removed using element-wise Combat harmonization and linear regression methods. The matrix was then proportionally thresholded with a sparsity of 5% to remove noisy elements, resulting in an undirected and binarized matrix. In our model for graph classification, each layer consists of a transformer self-attention network followed by a GNN layer such as GCNs for considering the structure of graph.

Results: After graph learning, the graph classification accuracy (%) on the test sets was 59.04 ± 0.86.

Conclusions: We introduced a deep learning algorithm for classification using the brain functional network. We adopted a transformer-based GNN model leveraging the transformer on all input nodes. We propose an algorithm that can consider the unsupervised transductive setting to address the limited availability of class labels.

409.066 (Poster) Identifying Barriers to Successful EEG Collection in Autistic People with High Support Needs: An Example of Phelan McDermid Syndrome and Autism

J. Cooke, A. San Jose Caceres1, C. Terzo1, C. Molloy1, L. Bianchi1, L. Gallagher1, D. Murphy1 and E. Loth1, (1)Forensic and Neurodevelopmental Sciences, Kings College London, Institute of Psychiatry, Psychology & Neuroscience, London, United Kingdom, (2)Forensic and Neurodevelopmental Sciences, Hospital General Universitario Gregorio Marañón, London, Spain, (3)Hospital General Universitario Gregorio Marañón, Madrid, Spain, (4)Trinity College Dublin, Dublin, Ireland, (5)Forensic and Neurodevelopmental Sciences, Kings College London, Institute of Psychiatry, Psychology & Neuroscience, London, UNITED KINGDOM, (6)Forensic and Neurodevelopmental Sciences, Institute of Psychiatry, Psychology & Neuroscience, King's College London, UK, London, United Kingdom

Background:
Autistic people with high support needs are often excluded from or unable to access neurophysiological research, such as Electroencephalography (EEG), due to the complexity of their needs and/or limitations in existing research practices. Phelan McDermid Syndrome (PMD) is a rare synaptopathy associated with moderate to severe Intellectual Disability (ID) and autism. Promoting EEG research within synaptopathies could further our understanding of synaptic biology in autism. Existing research data can be used to identify barriers to successful EEG collection.

Objectives:

- To assess phenotypic differences between PMD and idiopathic Autistic (iASC) participants.
- To assess the frequency of EEG collection across our sample.
- To identify any phenotypic differences between successful and unsuccessful EEG collection.

Methods:

Autistic traits were assessed using the Autism Diagnostic Observation Schedule (ADOS-2), and Verbal Mental Age (VMA) and Non-Verbal Mental Age (NVMA) were assessed using the Mullens Scales of Early Learning (MSEL). EEG was typically collected at the same visit, though researchers were flexible around family schedules. Parents completed the Autism Diagnostic Interview Revised (ADI-R) and Vineland Adaptive Behaviour Scales 2nd edition (VABS-II) with a researcher, plus online questionnaires about their child, including The Aberrant Behaviour Checklist (ABC), Child Behaviour Questionnaire (CBQ-short), Reiss Scales, Brief Sensory Experience Questionnaire (Brief SEQ) and the Short Sensory Profile (SSP). Participants were grouped according to successful or unsuccessful EEG collection and descriptive and phenotypic variables were compared.

Results:

23 PMD & 31 iASC participants (N=54) were assessed at time of reporting. Age ranged between 2-24 years with 1 PMD outlier aged 47. Males were overrepresented in iASC (n=28, \( p < .001 \)). 74% of PMD participants met criteria for autism spectrum based on research assessment. On average, PMD participants had lower NVMAs (Mdn = 1.25 years, \( p < .001 \)) and adaptive functioning (Mdn = 44, \( p < .001 \)) than iASC participants (Mdn = 2.75 years, Mdn = 59). Parents also reported less Restricted & Repetitive Behaviours (RRBs) on the ADI-R (Mdn = 7, \( p < .001 \)) than iASC (Mdn = 7, \( p < .001 \)). EEG data was collected from 36 out of 54 (67%) participants (19 PMD, 17 iASC). Data was not collected from 17 participants (3 PMD, 14 iASC) due to refusal (n=15), excessive movement (n=1), or lack of time (n=1). We found that EEG collection was more likely with PMD than iASC participants (\( \chi^2(1, N=52) = 5.255, p = .022 \)) but age, NVMA, and level of adaptive functioning did not differ between successful and unsuccessful EEG collection. Unsuccessful EEG collection was characterised by increased levels of fear (U = 10.500, \( p = .015 \)) and discomfort (U = 14.500, \( p = .042 \)), as well as heightened hyper-responsiveness (U = 7.000, \( p = .020 \)) and visual/auditory sensitivity (U = 167.500, \( p = .014 \)).

Conclusions:

Autistic people with high support needs may benefit from strategies that aim to reduce fear and discomfort around EEG data collection. Researchers may also want to pay attention to the responsiveness of participants and the visual and auditory components of an EEG session to maximise potential for successful EEG collection.

**409.067 (Poster)** Increased Absolute and Relative Gamma Power and Reduced Relative Alpha Power in Autism: A Meta-Analysis of Resting-State EEG Power across Canonical Frequency Bands

*W. S. Neo, D. Foti, B. Keehn and B. Kelleher,* (1)Psychological Sciences, Purdue University, West Lafayette, IN, (2)Speech, Language, and Hearing Sciences, Purdue University, West Lafayette, IN

Background: Autism is associated with structural and functional neural anomalies. Narrative reviews of resting-state EEG power findings have broadly suggested a U-shaped profile in autism, with increased delta, theta, beta, and gamma power and decreased alpha power compared to neurotypical individuals. Yet, these EEG power differences have not been systematically synthesized, limiting the potential use of resting-state EEG power as a biomarker to enhance the efficiency of early autism diagnosis. In addition, there remains a need to characterize how various study characteristics (e.g., eyes-closed vs. eyes-open paradigms) may account for heterogeneous EEG power findings and inform the design of clinical diagnostic processes.

Objectives: Using a meta-analytic approach, we quantified resting-state EEG power differences between autistic and neurotypical individuals across absolute/relative delta, theta, alpha, beta, and gamma frequency bands. We also examined resting-state paradigm as a potential moderator of effect sizes.

Methods: We used PRISMA standards to conduct systematic literature searches in multiple electronic databases and conference proceedings to identify published and gray literature that compared resting-state EEG power between autistic individuals with a DSM/ICD clinical diagnosis and neurotypical individuals for at least one canonical EEG frequency band. After abstract and full-text screening to
determine eligibility, we extracted sample and study characteristics, including descriptive and inferential statistics for EEG power. For each study and absolute/relative frequency band, we computed Hedges’ \( g \). We performed separate meta-analyses for each absolute/relative frequency band using random-effects models with inverse-variance weights to obtain pooled effect sizes. For significant meta-analytic models, we tested whether pooled effect sizes were different for eyes-closed versus eyes-open paradigms.

Results: Our meta-analyses included 41 studies (149 effect sizes) with a total of 1,246 autistic (82.3% male; \( M_{age} = 9.8 \) years) and 1,455 neurotypical individuals (70.7% male; \( M_{age} = 9.8 \) years). Notably, autistic individuals exhibited greater absolute and relative gamma power (absolute: \( g = 0.44, 95\% \text{ CI} [0.08, 0.79], p = .021 \); relative: \( g = 0.89 [0.46, 1.31], p = .012 \)) and lesser relative alpha power (\( g = −0.36 [−0.63, −0.10], p = .011 \)). In contrast, pooled effect sizes for the remaining absolute/relative frequency bands were not significant (−0.14 \( < g < 0.37, .287 < p < .626 \)). Moderator analyses revealed that pooled effect sizes were of greater magnitude in eyes-closed than eyes-open paradigms for absolute gamma power (eyes-closed: \( g = 0.92, \) eyes-open: \( g = 0.21, p = .046 \)) and vice versa for relative alpha power (eyes-open: \( g = −0.60, \) eyes-closed: \( g = 0.08, p = .004 \)).

Conclusions: Consistent with prior narrative reviews, our meta-analyses demonstrated moderate to large effect sizes of increased absolute and relative gamma power and reduced relative alpha power in autism, suggesting that resting-state gamma and alpha power may be candidate electrophysiological markers for identifying autism. The differential moderating effects of resting-state paradigm for absolute gamma and relative alpha power highlight how diagnostic-focused studies and protocols may need to consider the joint impact of various EEG data collection and analysis parameters. Additional studies that examine participant-level moderators may further contribute to more personalized, psychophysiological approaches for diagnosing autism.

409.068 (Poster) Increased Spatial Variability of Brain Activation in Autistic Adults

A. M. O’Brien^1, A. M. D’Mello^1 and J. D. E. Gabrieli, (1)Speech and Hearing, Bioscience and Technology, Harvard University, Cambridge, MA, (2)McGovern Institute, Massachusetts Institute of Technology, Cambridge, MA, (3)Psychiatry, UT Southwestern, Dallas, TX, (4)Psychology, University of Texas at Dallas, Dallas, TX

Background: Functional magnetic resonance imaging (fMRI) has been widely used to explore brain differences in autistic individuals, but the resultant literature is full of inconsistent findings. Studies that compare brain activation during the same cognitive processes report hyper-, hypo-, and equal brain activation in autistic individuals compared to neurotypical controls. Behaviorally, autism is characterized by a high degree of variability. Brain-based variability may underlie observed discrepancies in the neuroimaging literature and behavioral variability. While structural MRI analyses have shown greater brain-based variability in autism, no one has systematically examined whether similar variability is found in fMRI data.

Objectives: We compared the spatial variability of activation loci in the brains of autistic and neurotypical adults in response to four categories of stimuli to determine whether autistic individuals showed greater variability in functional brain activation.

Methods: We used an fMRI adaptation task in autistic (n=31) and neurotypical (n=26) adults to maximally activate brain regions most important for representing stimuli across four categories (spoken words, written words, faces, objects), including two modalities (visual, auditory). To examine group differences in spatial variability for each category, we created binarized maps of suprathreshold activation (\( p<0.001 \)) for each participant, and, within groups, identified regions where at least 80% of participants showed overlap (“overlapping parcels”). Between groups, we compared the number and volume of overlapping parcels to determine whether and where groups showed differences in the degree of activation overlap. We then probed whether lack of overlap was related to differences in (1) within-group noise, (2) between-group activation magnitude, or (3) variability in spatial location of participants’ peak activation as compared to other participants in the same group.

Results: Across all stimulus categories, both groups showed the lowest degrees of spatial variability in primary and specialized posterior processing regions including the right fusiform (for faces), the left primary visual cortex (for printed words), bilateral superior temporal gyri (for spoken words), and lateral occipital cortices (for objects). However, autistic adults showed high degrees of spatial variability in the medial prefrontal cortex (for faces) and the left visual word form area (for printed words), including reduced number and size of overlapping parcels. Importantly, increased spatial variability was not a product of increased within-participant noise in the autism group or between-group differences in activation magnitude. Instead, we found increased spatial variability in autistic participants as measured by greater distance between participants’ peak activation in these regions.

Conclusions: The autistic adults show increased variability in the spatial distribution of functional brain activation, primarily in higher-order processing regions associated with face and printed word recognition. Increased variability in the brain was found for perceptual categories that specialize later in development (faces, printed words), suggesting that later-developing processes may be more susceptible to variable representation. These findings may account for contradictions in previous neuroimaging research: the methodologies used for selecting and extracting activation from regions of interest may impact the directionality of group differences. Future findings of activation differences in autistic individuals should be interpreted within the context of spatial variability of brain activation.

409.069 (Poster) A Preliminary Investigation of E-I Balance As a Potential Marker of Adaptive Functioning in ASD
Background: There are currently no known biological markers for autism spectrum disorder (ASD). However, emerging data from post-mortem studies, neuroimaging, and electroencephalography studies suggest that an imbalance between neuronal excitation and inhibition (E-I) may be a promising avenue for investigation of potential treatment targets. E-I balance is reflected in various neuroimaging measures, including the spectral slope of the aperiodic activity in magnetoencephalography (MEG) signals. Despite this promise, the potential of 1/f slope remains relatively unexplored in ASD, especially in the context of treatment response in clinical trials.

Objectives: Our objective was to investigate the feasibility of using 1/f as a potential marker of adaptive functioning and treatment response in ASD.

Methods: We used data from a 16-week, randomized, double-blind, placebo-controlled trial of arbaclofen vs. placebo in children and adolescents with ASD. A subset of participants with resting-state magnetoencephalography (MEG) data and measures of adaptive functioning were included in this study (N = 45; 11 female; age = 12.62 ± 3.25). The sample includes both drug and placebo groups, but the labels remain blinded. MEG data were obtained using a 151-channel CTF system (600 Hz sampling rate) while participants watched a naturalistic movie (Inscapes). Data were epochoched into one-second segments, bandpass filtered (1–150 Hz, 4th-order two-pass Butterworth filter), and eye movement and cardiac artifacts were removed. The resulting data was beamformed to estimate the time series of 90 cortical and subcortical brain regions, and Welch's method was used to estimate power spectral density for each region. The 1/f slope of the power spectrum, suggested to be a marker of E/I, was estimated using the FOOOF method between 5–45Hz for each region and averaged across the brain. We measured the socialization domain of adaptive functioning using the Vineland-3. Linear regression was used to examine the association between the averaged global spectral slope and baseline and change in the Vineland score (social subscale). A square root transformation was used to linearize the association between 1/f and Vineland scores. Age, sex, and collection site were included as covariates in the model.

Results: Regression analysis revealed a significant positive association between the Vineland social score at baseline and the square root of 1/f (regression coefficient=68.5±30.65, F(4,33)=3.83, p=0.03). The association between change in the Vineland scores and 1/f was not significant. Visual inspection of the data revealed high variability in the data and the potential existence of subgroups (Figure 1).

Conclusions: An important limitation of the study is group assignments (drug vs placebo) were unknown at the time of analysis. Despite this, our results provide very preliminarily, but promising support for the feasibility of using 1/f as a potential marker of adaptive, although future studies are needed to replicate these findings in larger cohorts. We also found large heterogeneity in the data, motivating future investigations of subgroups and drivers of variability as well as additional analyses to understand the effect of group on response.
To investigate rsfMRI connectivity within and between the FPN and DMN in children with autism with and without intellectual disability (above and below IQ of 70).

Methods:

Resting-state fMRI was acquired during natural nocturnal sleep in 123 (45 female) children aged 2 to 4 years with autism spectrum disorder. Seventy-two children (22 female) had developmental quotients in the range of ID (< 70) (ID+ASD group) (M=50.6 SD=0.7, Range=2769) and 51 children (23 female) had developmental quotients within the normative range (≥ 70) (ASD group) (M=84.8, SD=10.6, Range=70-111). Intellectual ability and autism diagnosis were assessed by clinical psychologists using the Mullen Scales of Early Learning and the Autism Diagnostic Observation Schedule (ADOS). Resting-state images were preprocessed using the Configurable Pipeline for Analysis of Connectomes (v.1.84; Craddock et al., 2013). Images were time-shifted, motion-corrected, filtered (01-<0.08Hz), and registered to structural then MNI space. Volumes with frame-wise displacement greater than 0.25mm were removed, which did not significantly differ between groups (p=71; with mean scrubbed being 23.5 from 300-frame scan). Time-series from white matter and cerebral spinal fluid, 24-degree motion, and global signal were entered as nuisance regressors. Correlations were computed between time-series extracted from regions within the FPN and DMN defined by the CC200 atlas (Craddock et al., 2012). Multivariate distance matrix regression assessed multivariate differences in rsfMRI connectivity within the FPN and DMN, and between these networks. Follow-up univariate analysis identified regions with the greatest differences in connectivity.

Results:

Significant multivariate differences were revealed within the FPN (p=0008), led by hyper-connectivity between the angular gyri and superior medial frontal regions and between the middle temporal gyrus and the precuneus, and hypo-connectivity between the supramarginal gyri and bilateral inferior parietal cortex (FDR q<.05) in the ID+ASD group. Significant multivariate differences were evident in the DMN (p = .006), led by hyper-connectivity between the posterior cingulate cortex and bilateral angular and middle temporal gyri (q<.05) in the ID+ASD group. Significant multivariate differences were also observed in correlations between the FPN and DMN (p=0.0044), led by hyper-connectivity between left middle temporal and right inferior parietal cortex/supramarginal gyrus and between right superior parietal cortex and left lingual gyrus in the ID+ASD group (q< .05).

Conclusions:

Results indicate that ID in autism is associated with alterations to intra-network rsfMRI connectivity within the FPN and DMN and decreased separation between the FPN and DMN. This is consistent with research suggesting that individual differences in intellectual functioning and its impairments are associated with FPN-DMN interactions.

409.071 (Poster) Investigating Differences in Resting State Functional Connectivity across Sensory Phenotypes in Autism

K. M. Lyons*, E. J. Choi*, M. M. Vandewouw*, B. Stojanoski, M. J. Taylor*, E. Anagnostou*, E. Kelley*, S. Georgiades*, X. Liu*, R. Nicolson* and R. A. Stevenson*, (1)Psychology, The University of Western Ontario, London, ON, Canada, (2)Holland Bloorview Kids Rehabilitation Hospital, Toronto, ON, Canada, (3)Western University, London, ON, Canada, (4)Diagnostic Imaging, Hospital for Sick Children, Toronto, ON, Canada, (5)Autism Research Centre, Bloorview Research Institute, University of Toronto, Toronto, ON, Canada, (6)Department of Psychology, Queen's University, Kingston, ON, Canada, (7)Offord Centre for Child Studies, McMaster University, Hamilton, ON, Canada, (8)Genomics, Queen's Genomics Lab at Ongwanada, Kingston, ON, Canada, (9)Department of Psychiatry, University of Western Ontario, London, ON, Canada, (10)University of Western Ontario, London, ON, Canada

Background: One of the most common features of autism is differences in sensory processing: autistic individuals report sensory differences in the visual, auditory, tactile, gustatory, and olfactory domains. Although sensory differences are commonly reported in autism, the presentation of these symptoms vary drastically across individuals. For instance, Scheerer et al. (2021) recently identified five distinct sensory phenotypes across a large sample of autistic individuals. These distinct sensory sub-groups also differed in their behavioral profiles, suggesting that these phenotypes are clinically significant. These sensory phenotypes likely arise from differences in the brain’s functional architecture. However, the neural mechanisms underlying sensory phenotypes in autism has yet to be investigated. Here, we used functional connectivity measures, or correlated neural activity associated with the integration of different brain areas underlying complex mental processes, to examine neural differences between sensory phenotypes in autism.

Objectives: The aim of the current project was to: 1) investigate the pattern of differences across sensory phenotypes in autistic children and adolescents, and 2) explore how these sensory phenotypes are related to differences in resting state functional connectivity.

Methods: Data was obtained from the Province of Ontario Neurodevelopmental Disorders Network (POND) dataset. Participants (N = 638, mean age = 9.8, males = 590) were included in our study if they were autistic, and if their parents had completed the Short Sensory Profile (SSP). A k-means clustering analysis was conducted to group participants based on their pattern of scores on the SSP. We then analyzed resting state fMRI data collected in a subgroup of these participants (N = 147, mean age = 11.8, males = 111). Specifically, we parcellated the brain based on the Schaefer et al. (2018) atlas and obtained functional connectivity matrices for each participant. From these matrices, we calculated measures of connectivity strength, and network segregation and integration, including global efficiency,
modularity, and normalized clustering coefficients, across 7 functional brain networks from the Yeo et al. (2011) parcellation (figure 2a). Lastly, we compared these functional connectivity metrics for each of the sub-groups obtained from the clustering analysis.

**Results:** The k-means clustering analysis (figure 1) revealed five distinct groups based on their SSP scores. We labeled these phenotypes as followed: 1) sensory adaptive (SA), 2) generalized sensory differences (GSD), 3) taste and smell sensitivity (TSS), 4) under-responsive and sensory seeking (URSS), 5) movement difficulties with low energy (MDLE). Compared to the SA group, patterns of resting state functional connectivity (figure 2) differed across the four other groups in both sensory and higher-level networks. Specifically, the GSD and TSS groups tended to show patterns of hyper-connectivity, whereas the URSS and MDLE groups tended to show patterns of under-connectivity.

**Conclusions:** These results confirm previous work identifying distinct sensory phenotypes. Importantly, these results suggest that these distinct sensory phenotypes are associated with broad differences in the brain’s functional architecture, not only in low-level sensory networks, but also networks associated with higher-level cognitive processes. This reflects findings over the past decade that have shown that sensory differences cascade to influences higher-level cognitive development.

**409.072 (Poster) Investigating the Impact of Controlling Sex and Developmental Stages on Brain Signal Variability in Autism**

I. J. Chi and A. C. C. Yang, (1)National Yang Ming Chiao Tung University, Taipei, Taiwan, (2)Harvard Medical School, Boston, MA

Background: Autistic people exhibit unique traits and behaviors. The underlying mechanism of the traits and behaviors may be explained by the variability of brain signals. Previous research has highlighted that the brain signal variability will alter by aging and sex. On the other hand, autism used to be male preponderance. More and more studies argue that the specific impact of sex in autistic people should be considered.

**Objectives:**

We aim to determine whether the brain signal variability changes along with age and differs among brain regions across developmental stages from childhood to young adulthood in autistic individuals with or without controlling gender.

**Methods:** The functional magnetic resonance images of 344 participants with ASD and 399 controls from Autism Brain Imaging Data Exchange dataset were analyzed. The brain variability was measured using standard deviation of the blood oxygen level-dependent signal obtained from each gray matter voxel. First, to build a smoother age trajectory of brain variability, all participants were grouped using partially overlapping sliding age-windows at a step of 5 years. Second, we used the general linear model to investigate the differences in brain variability between ASD and controls at voxelwise level as well as parcellated 90 brain regions. The p-value was corrected for multiple comparison with the false discovery rate method and was set at 0.05 (F=25), and the cluster level was set at 30. We also used sex as a controlling factor to identify the impact of gender.

**Results:** When compared by combining all participants in two groups without considering their developmental stages and sex, there were no significant differences in variability (p=.28). However, in two groups without considering their developmental stages and sex, there were no significant differences in variability (p=.28). Moreover, we found that when participants were divided into age groups and controlling sex, significant brain signal variability appeared in each developmental stage (p<.0001). The most proportion of voxels with significant signal variability was found to be in the age group of 10–14-year-old group, adolescents. The main brain regions that have shown significant sex-by-group differences differ across age groups, most of them include the precuneus, posterior cingular cortex, and precentral cortex.

**Conclusions:**

Taken together, these findings suggest that brain signal variability of autistic individuals changes with age and the dominant brain regions with significant brain signal variability also differ at each developmental stage. And sex do exhibit it’s influence that have to consider rigorously when investigating autistic people.

**409.073 (Poster) Language Development in Children with and without Autism Via the N400 Event-Related-Potential Component and Functional Magnetic Resonance Imaging**

K. Toffolo, E. G. Freedman and J. J. Foxe, (1)University of Rochester, Cognitive Neurophysiology Lab, Rochester, NY, (2)The Ernest J. Del Monte Institute for Neuroscience, University of Rochester Medical Center, Rochester, NY

**Background:** During speech comprehension, prediction may facilitate faster language processing in which the ongoing context of a sentence can be used to predict sentence outcome by limiting subsequent word likelihood. Context-dependent predictions are influenced by semantic and syntactic comprehension, which can be measured via event-related potentials (ERPs) and functional magnetic resonance imaging (fMRI). Two event-related potentials (ERPs), the N400 and P600 components, respond to context-dependent violations with amplitude modulations, and are suggested to measure semantic and semantic/syntactic processing respectively. Similarly, prior MRI
Behavioral research has suggested that the language abilities of individuals with Autism Spectrum Disorder (ASD) develop differently.

Objectives: The purpose of this study was to use EEG and fMRI to characterize language development, specifically semantic and syntactic processing, in neurotypical (NT) children and children with ASD.

Methods: Using a standardized semantic stimulus set (Toffolo et al. 2022) and a syntactic stimulus set while we record brain activity via EEG and fMRI, our study compared language processing between NT (n=18) and ASD (n=7) children across three distinct age groups: 6-7, 8-9, and 10-12 years.

Results: In NT children, both the N400 and P600 ERP components matured throughout language development in response to semantic errors, showing reductions in amplitude, latency, and bilateral scalp topography with age. As a whole, they also showed activation differences in response to semantic and syntactic errors. In response to semantic errors, the ASD N400 ERP component had reduced amplitudes when compared to the NT N400. Furthermore, functional activation did not differ between semantic and syntactic error contrasts in children with ASD. Neither experimental group showed a P600 in response to syntactic errors.

Conclusions: Preliminary data suggested differences in language processing between children with and without ASD. The outcomes of this study could benefit individualized intervention and provide information on developmental language trajectory with complementary information from fMRI and EEG methodologies.

409.074 (Poster) Language-Related Functional Connectivity in ASD: A Systematic Review of fMRI Studies
H. R. Thomas, C. Larson, J. Crutcher, M. C. Stevens and I. M. Eigsti, (1)Psychological Sciences, University of Connecticut, Storrs, CT, (2)Olin Neuropsychiatry Research Center, Hartford Hospital, Hartford, CT

Background: Autism spectrum disorder (ASD) is associated with disrupted brain functional connectivity (FC; Di Martino et al., 2013). However, studies of over- versus under-connectivity in ASD have yielded inconsistent evidence, and prior reviews have been relatively general in nature and inconclusive (e.g., Muller et al., 2011; Vissers et al., 2012). Language-related FC is of theoretical and clinical significance because language skills vary widely in autism (Eigsti et al., 2011) and because the typical language network is well defined (Briggs et al., 2018). Thus, studies of language-related functional connectivity represent an ideal domain in which to test evidence of over- and under-connectivity in ASD.

Objectives: To perform a systematic review of (1) local FC within the language network and global FC between language and out-of-network regions for task-based and resting-state studies, and (2) to examine associations among neural FC and behavioral measures of ASD symptomatology and language.

Methods: Our approach followed PRISMA and Cochrane (2021) guidelines (Figure 1). Literature searches in PubMed, PsychInfo, Scopus, ProQuest (grey literature), and Google Scholar included these search terms: ASD, functional magnetic resonance imaging (fMRI), and language. Inclusion criteria were: ASD samples; fMRI; language-related connectivity. Raters naïve to research questions and hypotheses screened Title/Abstract/Keyword. Full-text screening and quality ratings (informed by GRADE Handbook; Cochrane, 2021) were conducted by CL & HRT. Final data extraction and synthesis were conducted by CL & JC.

Results: A sample of 96 articles was included, with autistic groups compared to neurotypical (non-autistic) peers. Task-based language studies demonstrated that ASD groups had local over-connectivity within the language network and global under-connectivity with out-of-network regions (Figure 2.) The exception to this pattern was within-network under-connectivity in response to social tasks. Resting-state studies demonstrated under-connectivity of interhemispheric language regions and over-connectivity of language and default mode network regions. Behaviorally, language-related local over-connectivity and global under-connectivity was related to increased ASD symptoms, whereas relatively greater connectivity within the language network and between out-of-network regions was associated with relatively greater language abilities.

Conclusions: Language-task elicited FC in ASD is characterized by local over-connectivity and global under-connectivity. Results inconsistent with this generalization reflect the presence of social demands or the engagement of a task-negative (default mode) network. Behavioral associations support theories that local over-connectivity and global under-connectivity characterize ASD. In contrast, greater language region connectivity with other language regions and non-language regions was associated with relatively better language skills, suggesting that language function requires significant within and between network integration. This study reveals a relatively consistent language-elicited connectivity profile in ASD alongside new insights and will guide future theoretical considerations of connectivity in ASD.
Background: Theta and alpha band oscillations measured with electroencephalography (EEG) while viewing dynamic videos may provide a sensitive measure of social brain development. Social communication skills in autistic participants are related to adaptive behaviours and quality of life during adulthood. Developing robust measures of social brain development that are scalable, feasible, and rapidly derived is an important step to translational research. Preprocessing of EEG however can be time consuming when done manually, but this is the gold standard for infant data. Automated pipelines have been developed but have only been validated on datasets with high-density electrode layouts from non-autistic participants within a narrow age range.

Objectives: In the current study, we aimed to compare theta and alpha band oscillations between a manual and automated preprocessing pipeline in a subset of EEG data from a large developmental cohort with autistic and non-autistic 6- to 31-year-olds.

Methods: 59-channel EEG was recorded while autistic and non-autistic participants viewed dynamic videos of women singing nursery rhymes (social) and spinning toys (non-social) as part of the EU-AIMS Longitudinal European Autism Project. Both videos (duration of 60sec each) were presented twice. Out of the 539 available EEG datasets, we randomly selected a subset of 131 datasets. These EEG datasets were cleaned a) manually (as in Garcés et al., 2022) (blind to age and diagnostic group), b) using the original MADE pipeline, and b) using an in-house adapted version of the MADE pipeline with modified bad channel selection and interpolation criteria. We then extracted spectral power and functional connectivity (debiased weighted phase lag index) across the theta (4-7Hz) and alpha (8-12Hz) frequency bands across all epochs; social and non-social epochs; and difference between conditions (social – non-social). Intra-class correlations (ICCs) were calculated between manual and automated pipelines if the number of clean epochs was sufficient (≥20 for spectral power and ≥120 for connectivity). We considered the following ranges: poor - ICC <.40, fair – .40≤ ICC <.60, good – .60≤ ICC <.75, and excellent – ICC ≥.75.

Results: Our random sample consisted of 76 (18 females) autistic and 55 (25 females) non-autistic participants (age 7 –31yrs, mean = 17, std = 6). Inclusion rates in the random sample were similar across pipelines for spectral power, but closer to the manual pipeline for the in-house MADE pipeline than the original MADE pipeline. For spectral power, ICCs were in the excellent range with both MADE pipelines for both frequency bands and combinations of conditions (all, separate, difference). For connectivity, ICCs were excellent for measures in the alpha band for comparisons with both MADE pipelines. ICCs in the theta band were fair and good for the original MADE pipeline, but good and excellent for the in-house MADE pipeline.

Conclusions: Our in-house adapted version of the MADE pipeline provides similar inclusion rates and estimates of neural oscillations during the viewing of dynamic videos as our manual pipeline. This suggests that our in-house MADE pipeline is comparable to manual cleaning and is suitable for analysis on our full sample and follow-up cohorts.

Background: Lateralisation of brain processing is a well-known and evolutionary preserved phenomenon which may serve to optimise brain functioning. For example, in human auditory communication, there is a left hemispheric lateralisation for speech processing and a right hemispheric lateralisation for voice identity recognition. Autism is associated with atypical functional lateralisation of the cerebral cortex for language processing. Since most models and studies in auditory communication focus on cerebral cortex functioning, functional lateralisation for speech and identity processing at the subcortical level and its alterations in autism are unclear.

Objectives: We here investigated lateralisation for speech and identity recognition in the inferior colliculus (IC), a central midbrain structure of the auditory pathway, in typical development and autism. We chose the IC because we recently found atypical IC- functioning in voice perception (i.e., reduced voice identity and vocal sound perception) in autism (Schelinski, Tabas & von Kriegstein, HBM, 2022).

Background: Theta and alpha band oscillations measured with electroencephalography (EEG) while viewing dynamic videos may provide a sensitive measure of social brain development. Social communication skills in autistic participants are related to adaptive behaviours and quality of life during adulthood. Developing robust measures of social brain development that are scalable, feasible, and rapidly derived is an important step to translational research. Preprocessing of EEG however can be time consuming when done manually, but this is the gold standard for infant data. Automated pipelines have been developed but have only been validated on datasets with high-density electrode layouts from non-autistic participants within a narrow age range.

Objectives: In the current study, we aimed to compare theta and alpha band oscillations between a manual and automated preprocessing pipeline in a subset of EEG data from a large developmental cohort with autistic and non-autistic 6- to 31-year-olds.
Methods: We tested functional lateralisation of the IC in different aspects of voice processing in three independent functional magnetic resonance imaging (fMRI) experiments in groups of adults with autism and pair-wise matched typically developed controls (matched on age, sex, handedness, and full-scale intelligence quotient (IQ)). First, participants performed tasks on voice identity and speech recognition (voice identity recognition experiment, \( n = 16 \) per group). Second, participants performed speech recognition tasks on speech that was either presented with or without noise (speech-in-noise recognition experiment, \( n = 17 \) per group). In the third experiment, both groups passively listened to blocks of vocal and non-vocal sounds (vocal sound experiment, \( n = 16 \) per group). All participants had normal hearing (confirmed with pure tone audiometry) and did not take psychotropic medication. All participants in the autism group had previously received a formal clinical diagnosis and underwent additional clinical assessment including the ADOS and ADI-R. For the fMRI analysis we used linear mixed-effects models. We focused on two regions of interest (left and right IC). We corrected all \( p \)-values across all comparisons using the Holm-Bonferroni method.

Results: We found that recognising clear speech was associated with dominant processing (i.e., enhanced blood-oxygenation-level-dependent (BOLD) responses) in the left as compared to the right IC in typically developed controls only. In controls only, the right IC showed enhanced responses when recognising voice identity and speech-in-noise as compared to when recognising clear speech. There was no such significant lateralisation for clear speech, voice identity or speech-in-noise recognition within the ASD group. The right IC-lateralisation for voice identity as compared to speech recognition was significantly different between the two groups. Further, there was no significant IC-lateralisation for more general voice processing (i.e., when passively listening to vocal sounds) in none of the two groups. The autism and the control group did not differ significantly in the average amount of head movements (all \( p \) values > 0.1 in all three experiments).

Conclusions: Our results suggest lateralisation effects for specific voice functions at the subcortical level in typical development. Further, our results indicate atypical lateralisation in voice processing in autism which may already occur subcortically.

409.077 (Poster) Looking for Visual Cortical Activity As Putative Brain Biomarker: A Pilot FNIRS Study on Autistic Females Preschoolers

(1)IRCCS Fondazione Stella Maris, Pisa, Italy, (2)Institute of Neuroscience, National Research Council (CNR), Pisa, Italy, (3)Dept of Translational Research and of New Surgical and Medical Technologies, University of Pisa, Pisa, Italy, (4)Department of Clinical and Experimental Medicine, University of Pisa, Pisa, Italy, (5)Institute of Neuroscience, National Research Council (CNR), Pisa, Italy, (6)IRCCS Stella Maris Foundation, Pisa, Italy

Background:

Autism spectrum disorder (ASD) is a complex neurodevelopmental condition highly impacting the health-care system and society. Large heterogeneity of the disorder is reported and tailored intervention are needed to improve developmental outcome. In this frame, search of reliable, objective and quantitative biomarkers to assess the function of cerebral circuits represents an important advance to refine the diagnostic and therapeutic pipeline in ASD field to support clinical phenotypization (i.e. in female phenotype). Functional near-infrared spectroscopy (fNIRS) is a totally non-invasive and user-friendly technique, providing an indirect measure of neural activity through the quantification of changes in the concentration of different species of hemoglobin. Several studies, indeed, employed fNIRS to investigate brain activation patterns underlying the core symptoms of ASD (Conti et al., 2022), showing a hypoactivation of several circuits.

Objectives: As part of a larger project, we set-up an observational monocentric study on preschoolers females with idiopathic ASD with the following aims: i) to apply a novel standardized set-up procedure with high entertaining value to measure hemodynamic responses (HDR) in autistic preschoolers; ii) to compare HDR response in autistic preschoolers female vs typically developed preschoolers; iii) to investigate laterality of HDR response as an intrasubject biomarker measure.

Methods: Twelve females with idiopathic ASD (median age 4.5 years; SD 1.17) and 13 age-matched control females (median age 4.86; SD 1.17) were recruited at IRCCS Fondazione Stella Maris, Pisa. ASD diagnosis was performed according to the DSM-5 criteria and supported by ADOS2; children with genetic alterations or developmental quotient below 70 were excluded. All children performed 20 minutes of fNIRS registration to measure brain response (HDR) while watching a cartoon containing a radial checkerboard-blended stimuli. (see Mazzotti et al 2021, *Translational Psychiatry* for procedure) A t-test analysis was used to compare the two groups and lateralization index was calculated too.

Results: i) a significant HDR to the cartoon-based stimulus in the cohort of children with typical development and in the ASD population was obtained, both in the average response across channels and in the channel with the highest response amplitude ii) a statistical difference (\( p < 0.05 \)) in the HDR of the two groups comparison was found, specifically revealing lower average amplitude of OxyHemoglobin (OHB) in ASD females iii) the laterality index revealed a predominance shift towards right hemisphere in typical subject while a loss of brain asymmetry was found in the ASD cohort. (\( p < 0.05 \))

Conclusions: The high portability and experimental flexibility make fNIRS a powerful imaging tool for very young children, bringing functional studies of brain circuits into a more naturalistic environment. To our knowledge, this is the first neuroimaging research exploring
hemodynamic cortical response studied by fNIRS signal in a fully female cohort of autistic preschoolers. Moreover, it adds novel insights into the neurobiological underpinnings of ASD (female phenotype), studying more in deep visual perception. Though loss of brain asymmetry in ASD has mainly reported in language related circuits, evidence exist about involvement of non-verbal networks, too, including both higher cognitive/associative domains and primary sensorimotor function i.e. visual processing.

409.078 (Poster) Low-Gamma Power Effects on Competitive Joint Action with Peers
M. Sabag1, J. Yarmolovsky2, and R. Geva2. (1)Psychology Department, Bar Ilan University, Ramat-Gan, Israel, (2)Gonda Brain Research Center, Bar-Ilan University, Ramat-Gan, Israel

Background: Autism spectrum disorder (ASD) is highly comorbid with attention alterations and is recently reported to be accompanied by social and motor deficits, such as in managing joint action (JA). Competitive manipulations have been reported to improve social competence and Theory of Mind in individuals with ASD. However, the mechanism for the improved executive joint motor control in competition in ASD has not yet been elucidated. Recent reports of hyperactivation in executive attention neural hubs, seen thus far by higher low-gamma power during resting state may account for this effect. It is important to assess how task performance is related to this neural alteration in ASD.

Objectives: To assess diagnostic group effects on performance (accuracy and reaction time) during competitive JA with peers and to understand the effects of low-gamma power on competitive executive control outcomes in ASD.

Methods: 76 children (ASD=50), ages 8.17-17.20 years (M\text{ASD}=12.50±2.73; M\text{TD}=12.46±2.79) were paired with same-diagnostic group peers to perform an interactive competitive day-night inhibitory control task. The task includes trials that required JA responses with the partner. Each player’s success was displayed on the monitor for both partners to see, to increase competitive priming. Task accuracy and RT were recorded using E-prime 2.0, and dual 8-channel EEG data were recorded from attention network hubs. EEG electrodes were placed at bilateral prefrontal cortex (PFC), and midfrontal cortex (midFC) for the executive attention network, bilateral ventrolateral prefrontal cortex (VLPFC), and bilateral temporoparietal junction (TPJ) for the orienting attention network, and central occipital lobe. Children were screened for IQ (WISC-IVH).\text{HEA}.

Results: Correct (p=.022, see fig 1a) and incorrect response times (RT, p=.007, see fig 1b) were prolonged in ASD, yet accuracy didn’t differ between groups (p=.990, see fig 1c), suggesting a trade-off between RT and accuracy in ASD. Further elevated low-gamma power in ASD during JA in the left PFC, midFC, left TPJ, and right TPJ (all p<.05). The effect of low-gamma power in the left PFC (p=.005), midFC (p=.001), and right TPJ (p=.016) on correct RT were moderated by diagnostic group (see fig 2a). Moderations were significant for those with ASD, indicating a diminished power presents with prolonged correct RT (see fig 2b) and no other dependent measures.

Conclusions: Findings indicate a compensation path in ASD for executive inhibitory control, derived from elevated low-gamma power in the executive attention network and the rTPJ, overlapping the orienting attention and social brain networks. This effect, found during competition with peers with ASD, suggest that stronger low-gamma power among children with ASD serves as an adaptive regulatory compensation mechanism which is vital for social interaction. These findings shed light onto the pathways involved in the improved executive performance seen in competitive social interactions in ASD, and highlights its potential role in increased social competence in ASD.

409.079 (Poster) Machine Learning Models for Autism Screening from EEG Signals of Children in Sleep
A. Vasista1, S. M. Kaku1, S. Rajagopalan1, M. W. Jamer2, S. Gosala1 and A. Mysore3. (1)CARE-ADD, St. John’s National Academy of Health Sciences, Bangalore, India, (2)St John’s Medical College Hospital and Research Institute, Bangalore, India, (3)CARE-ADD, St. John’s National Academy of Health Sciences, Bangalore, India, Bangalore, India, (4)Center for Advanced Research and Excellence in Autism and Developmental Disorders (CAREADD), St. John’s Medical College Hospital, Bangalore, India, (5)Neurology, St John’s Medical College Hospital, Bangalore, India, (6)CAREADD, St.John’s Medical College Hospital, Bangalore, India

Background:

Early detection of children who are at risk for neurodevelopmental disorders such as Autism Spectrum Disorder (ASD) can help initiate early clinical interventions. Longitudinal studies have shown that deviations in neurophysiological data such as Electroencephalography (EEG) from early developmental years in children being highly associated with behavioral abnormalities in later years [1]. The analysis of complex, non-linear and high dimensional EEG signals warrant advanced analytical approaches to identify patterns for early biomarkers. Advancements in machine and deep learning (ML/DL) can be exploited to develop computational models to determine differing classes of cohorts through pattern recognition of EEG data.

Objectives:
This study aims at developing an ML model for classifying ASD from non-ASD cohorts using low frequency components in NREM Sleep EEG up to Alpha band in preschool children. Emphasis is laid on projecting the ability of ML to learn the discriminatory patterns between the sleep stages.

Methods:

54 children (43M, 11F, mean=44.7 mo., SD=15.2 mo.) with ASD and 38 children (23M, 15F, mean=44.2 mo., SD=12 mo.) with other neurodevelopmental disorders, between 24 and 72 months in age, underwent EEG recording in daytime sleep on a 64-channel EGI GES400 system using HydroCel GSN130 sensor-net. Data was recorded at 1000Hz, with 70Hz Low-pass filter and Cz online reference. Sleep stages 1,2,3 referred as N1, N2, N3 were observed with at least one stage per child. Annotation of artifact free clean segments in all stages was performed manually by an EEG expert. N1 (43 ASD and 32 non-ASD subjects), N2 (40 ASD and 32 non-ASD subjects) and N3 (25 ASD and 25 non-ASD subjects) data was analyzed.

Offline pre-processing involved down-sampling to 250Hz across 60 channels, rejecting bad channels and band-pass filtering from 1-16Hz. The pre-processed data was transformed with db4-wavelet to extract Delta, Theta, and Alpha band coefficients. ML algorithm - Support Vector Machine with Radial Basis Function Kernel was applied to develop a classifier to distinguish ASD from non-ASD cohorts. The input feature consists of band coefficients derived from 10s windows EEG signals. A 10-fold cross validation was performed and performance metrics (accuracy, sensitivity, specificity, F1-score, Standard Deviation among cross-validation scores) reported for each sleep stage.

Results:

The results of the classification are mentioned in the table below. N2 has better accuracy with F1 score and higher detection rates for both classes indicated by higher sensitivity and specificity. N1 and N3 has relatively higher predictability for non-ASD than ASD indicated by specificity scores.

Conclusions:

We propose an ML approach to distinguish ASD from Non-ASD cohorts using EEG signals across three sleep stages in preschoolers. The overall metrics for N2 indicate the strength of model’s predictability while N1 and N3 show 50% chance of predicting ASD even though their predictability of non-ASD is better than N2. A recognized divergence in sleep spindles in N2 may underlie these observations [2]. Explorations in larger samples across genders, to aid early detection is warranted.

409.080 (Poster) Medial Prefrontal Cortex Connectivity Differences in Youth with Autism Spectrum Disorder Compared to Early-Onset Psychosis

M. Mahale1, R. Jalal1, H. Gutierrez2, K. Laulette1, C. E. Bearden4, K. Karlsgodt3 and A. Nair1, (1)Psychology, Loma Linda University, Loma Linda, CA, (2)Loma Linda University, Loma Linda, CA, (3)University of California, Los Angeles, Los Angeles, CA, (4)Department of Psychiatry and Biobehavioral Sciences, University of California, Los Angeles, Los Angeles, CA

Background: Theory of mind (ToM) refers to the ability to read others minds and predict their actions (Overwalle, 2009). The medial prefrontal cortex (mPFC) is found to play a role in ToM (Moriguchi et al., 2007). Autism spectrum disorder (ASD) and early-onset psychosis (EOP) are both characterized by ToM deficits and altered connectivity in regions associated with social cognition (Ciaramidaro et al., 2014). However, few studies have looked at ToM and related social network differences in ASD and EOP in the adolescent/young adult age group.

Objectives: To examine whole brain functional connectivity of the mPFC and its relationship to social cognition measures in a group of youth with either ASD and EOP, compared to typically developing (TD) controls.

Methods: Resting-state MRI data were acquired on a 3T Siemens scanner for 24 adolescents with ASD (mean age = 15.86) 25 adolescents with EOP (mean age = 18.65), and 21 TD controls (mean age= 17.08). Data were preprocessed using FSL (Smith, 2004) and AFNI (Cox et al., 1997), and included motion correction, nuisance regressors (white matter, cerebrospinal fluid,), and bandpass filtering (0.008 < f < .08 Hz). A 10mm mPFC seed was created in MNI space using coordinates from prior studies (von dem Hagen et al., 2013; Fox et al., 2005). Global time series were extracted from this seed and correlated with whole brain signal. Final connectivity maps were normalized using Fisher r-to-z transformations. Z’ (prime) scores from clusters of significance in each group were used to run Pearson’s correlations to examine the relationship between mPFC connectivity and The Awareness of Social Inference Test total score and subscale scores (do, say, think, feel; TASIT; McDonald et al., 2003).

Results: ASD and EOP youth demonstrated mixed patterns of over- and under- whole brain connectivity of the mPFC compared to TD controls. ASD group showed overconnectivity of the mPFC with bilateral middle occipital gyrus; but underconnectivity with right superior
Methodological Strategies for Improving Data Quality and Retention across Multi-Site Studies of Early EEG Biomarkers in ASD

Background: Autism spectrum disorder (ASD) is characterized by core social communication and behavioral deficits that emerge after the first year of life. Accumulating evidence suggests that altered brain development presents early in infancy, placing immense value on scalable neural biomarkers of ASD. The Infant Brain Imaging Study (IBIS) was established to uncover functional differences between neurotypically developing children and those who receive an autism diagnosis at 24 months of age using fMRI. Electroencephalography (EEG) was added to IBIS to provide a direct measure of brain activity in awake and engaged infants and to further enhance the scalability of identified biomarkers. Although EEG is less vulnerable to motion than other neuroimaging modalities, infant recordings often contain a high degree of artifact contamination with <50% of infants on average with useable data (Cuevas et al., 2014).

Objectives: We aimed to establish a standardized protocol to acquire EEG data from a population of 250 infants at higher likelihood (HL) of ASD (identified based on the presence of an older diagnosed sibling). Our primary goals were to maximize data quality and retention utilizing a standard protocol across sites, thus ensuring results were valid and reliable rather than a depiction of site-specific recording discrepancies.

Methods: Strategies to standardize effective data collection across sites included (1) training and setup procedures, (2) standardization of data recording methods, and (3) the incorporation of detailed post-processing and data quality checks. Each site was provided a self-contained computer for presenting and reporting stimuli, ensuring there would be no interference from other studies. The data analysis team worked with each site individually to tailor training based on level of expertise. Upon review of each data file, behavioral feedback was disseminated to the respective site within 24-48 hours of file upload. Data was evaluated for number of artifact free seconds/trials for resting state, VEP and AEP, respectively. Percentage of data retained per infant for each paradigm was calculated to evaluate the success of our methods.

Results: Data retention rates were consistently over 60% across all infants and all study paradigms (Table 1). Over 300 seconds of clean resting state EEG data was preserved on average per infant. Data acquisition consistently improved across the study since the incorporation of our extensive feedback procedures. Prompt analysis of data files also allowed for quick identification of technical errors, ensuring no future data was affected.

Conclusions: Large cohorts of HL infants are needed to improve the generalizability of studies of autism in infancy and to advance our ability to identify clinically relevant biomarkers. Continued acquisition of high-quality data is essential in time-limited and longitudinal studies such as IBIS. Our methods have repeatedly and reliably increased the amount of data retained from each infant across all five study sites, providing us a larger and more diverse dataset to analyze. This has led to significantly higher data retention rates compared to many infant studies. Implementation of our data collection and standardization methods is also relevant for other clinical populations with small sample sizes, including genetic syndromes.

Minimal Neural Differences during Facial Emotion Recognition between Autistic and Non-Autistic Adults in High-Powered fMRI Study

409.082 (Poster) Minimal Neural Differences during Facial Emotion Recognition between Autistic and Non-Autistic Adults in High-Powered fMRI Study

Background: Autism spectrum disorder (ASD) is characterized by core social communication and behavioral deficits that emerge after the first year of life. Accumulating evidence suggests that altered brain development presents early in infancy, placing immense value on scalable neural biomarkers of ASD. The Infant Brain Imaging Study (IBIS) was established to uncover functional differences between neurotypically developing children and those who receive an autism diagnosis at 24 months of age using fMRI. Electroencephalography (EEG) was added to IBIS to provide a direct measure of brain activity in awake and engaged infants and to further enhance the scalability of identified biomarkers. Although EEG is less vulnerable to motion than other neuroimaging modalities, infant recordings often contain a high degree of artifact contamination with <50% of infants on average with useable data (Cuevas et al., 2014).

Objectives: We aimed to establish a standardized protocol to acquire EEG data from a population of 250 infants at higher likelihood (HL) of ASD (identified based on the presence of an older diagnosed sibling). Our primary goals were to maximize data quality and retention utilizing a standard protocol across sites, thus ensuring results were valid and reliable rather than a depiction of site-specific recording discrepancies.

Methods: Strategies to standardize effective data collection across sites included (1) training and setup procedures, (2) standardization of data recording methods, and (3) the incorporation of detailed post-processing and data quality checks. Each site was provided a self-contained computer for presenting and reporting stimuli, ensuring there would be no interference from other studies. The data analysis team worked with each site individually to tailor training based on level of expertise. Upon review of each data file, behavioral feedback was disseminated to the respective site within 24-48 hours of file upload. Data was evaluated for number of artifact free seconds/trials for resting state, VEP and AEP, respectively. Percentage of data retained per infant for each paradigm was calculated to evaluate the success of our methods.

Results: Data retention rates were consistently over 60% across all infants and all study paradigms (Table 1). Over 300 seconds of clean resting state EEG data was preserved on average per infant. Data acquisition consistently improved across the study since the incorporation of our extensive feedback procedures. Prompt analysis of data files also allowed for quick identification of technical errors, ensuring no future data was affected.

Conclusions: Large cohorts of HL infants are needed to improve the generalizability of studies of autism in infancy and to advance our ability to identify clinically relevant biomarkers. Continued acquisition of high-quality data is essential in time-limited and longitudinal studies such as IBIS. Our methods have repeatedly and reliably increased the amount of data retained from each infant across all five study sites, providing us a larger and more diverse dataset to analyze. This has led to significantly higher data retention rates compared to many infant studies. Implementation of our data collection and standardization methods is also relevant for other clinical populations with small sample sizes, including genetic syndromes.
Background: Years of research have examined the neural underpinnings of facial emotion recognition in Autism Spectrum Conditions (ASC). To date, no consistent picture emerged as to whether and under which conditions the presumed neuro-functional differences between autistic and non-autistic individuals exist. One explanation for the contradictory results may derive from the wide degree of heterogeneity in the expression of autistic traits among individuals on the spectrum. In order to progress towards clarifying the ‘facial emotion processing hypothesis’ it is therefore necessary to simultaneously go wide (i.e. increasing sample sizes) and deep (i.e. thoroughly screening participants for individual characteristics).

Objectives: In this study, we aimed to identify neuro-functional differences in facial emotion processing between autistic and non-autistic adults, using the largest sample size published to date and employing a comprehensive test battery controlling for autistic traits, co-occurring conditions and intelligence.

Methods: Using functional magnetic resonance imaging (fMRI), 51 adults diagnosed with ASC and 51 non-autistic controls completed a facial emotion recognition task including 3 conditions: Gender recognition with neutral faces (Gender Recognition), gender recognition with emotional faces (Implicit Emotion Recognition) and emotion recognition with emotional faces (Explicit Emotion Recognition). Prior to the measurement, various questionnaires were collected.

Results: On the behavioural level, the ASC group revealed lower accuracies in the Explicit Emotion Recognition condition compared to the control group. Additionally, reaction times were higher across all three conditions within the ASC group. On the neural level, whole-brain analysis using a full-factorial model including the factors Group and Condition revealed one significant group difference when contrasting Explicit Emotion Recognition with Gender Recognition. The ASC group demonstrated stronger activation differences between Explicit Emotion Recognition and Gender Recognition in the right middle frontal gyrus. No further significant suprathreshold activation differences between groups were found in any other contrasts.

Conclusions: Three aspects of facial emotion recognition in a large sample of autistic and non-autistic subjects revealed that processing of facial information on gender and emotion is slower in autistic subjects, as they showed overall longer reaction times. Accuracies of autistic subjects were only lower in Explicit Emotion Recognition, which was associated to increased prefrontal brain activation in the right middle frontal gyrus. Whole-brain analysis did not identify any ‘usual suspects’ for differences in emotion recognition, such as amygdala, superior temporal sulcus or other areas comprising the social brain network. Paradoxically, the sample size related increase in power comes with a reduced number of significant findings compared to previous similar studies. This negative relationship could be caused by a reduction of sampling variability, which in turn could have led to significant effects due to specific sample compositions. In conclusion, these results urge for a thorough subgroup-analysis by the means of psychometric and behavioral covariates.

409.083 (Poster) Neural Correlates of Atypical Predictive Processing in Adults with Autism

(1)Seaver Autism Center at the Icahn School of Medicine at Mount Sinai, New York, NY, (2)Stony Brook University, Stony Brook, NY, (3)Department of Neuroscience, Icahn School of Medicine at Mount Sinai, New York, NY, (4)Seaver Autism Center, Department of Psychiatry, Icahn School of Medicine at Mount Sinai Hospital, New York, NY, (5)Psychiatry, Icahn School of Medicine at Mount Sinai Hospital, New York City, NY

Background: The ability to make self-other sensory distinctions is a process critical to prediction, self-monitoring, and differentiating relevant and irrelevant stimuli. Predictive coding allows individuals to generate internal models of the environment and adapt to discrepancies between expected versus actual sensory events, which influences sensory processing, social cognition, and perception (Clark 2013; Van de Cruys et al., 2014). In autism, impairments in social communication, sensory, and motor symptoms represent key features and may be influenced by deficits in these predictive processes (Whyatt & Craig, 2013; Palmer et al., 2015). Previous research has shown diminished suppression of self-generated stimuli, potentially providing support for alterations in motor-auditory predictive coding in autism (van Laarhoven et al., 2019). If similar predictive processing deficits also impact social cognition in autism, then similar patterns of diminished suppression to socially-generated stimuli might be expected.

Objectives: This study used electroencephalography (EEG) to examine atypical predictive coding processes in autism. Based on previous research implicating atypical predictive processing in autism, we hypothesized that suppression of predictable self- and socially-generated sensory events would be reduced in autism as compared to typically developing controls.

Methods: High-density EEG was recorded from 24 autistic adults (26±6 years; 8 Female) and 20 controls (26±5 years; 10 Female). The paradigm consisted of 200 trials and had four conditions: self-generated, computer-generated, socially-generated, and motor control. In the self-generated condition, participants produced an auditory stimulus when they pressed a button. In the socially-generated condition, an experimenter next to the participant pressed a button to generate an auditory stimulus every 2-3 seconds while participants passively
Results: Controls showed significant N1 suppression for both self-generated versus computer-generated trials \((t(19) = -3.03, p = 0.014)\) and socially-generated versus computer-generated trials \((t(19) = -5.80, p < 0.001)\). In contrast, autistic adults did not show significant N1 suppression for the self-generated conditions \((t(23) = -1.24, p = 0.23)\), but did show significant N1 suppression for socially-generated stimuli \((t(23) = -2.65, p = 0.014)\). However, suppression of socially-generated conditions in ASD trended towards being significantly weaker than in controls \((t(41) = -1.99, p = 0.054)\).

Conclusions: We found that autistic individuals are characterized by a lack of significant N1 suppression to self-generated stimuli and reduced N1 suppression relative to controls for stimuli generated by a social other. These two findings converge in supporting deficits in predictive signaling in autism and may be indicative of differences in action-oriented predictive processing affecting both interoceptive signaling and social cognition in autism. Indeed, if individuals with autism cannot attenuate neural response to predictable input, this work may shed on mechanisms underlying deficits in self-monitoring, prediction, and sensitivity to external sensory events.

Methods: Data for the current analyses were collected during the Autism Biomarkers Consortium for Clinical Trials (ABC-CT). Two hundred eighteen autistic children (24.77% female; \(M_{age}=8.75\pm1.61\) years; \(M_{age}=99.59\pm17.65\)) provided electroencephalography (EEG) data during viewing of faces (neutral female, upright and inverted) and non-faces (upright houses), and P100 and N170 components were extracted for each condition. The Aberrant Behavior Checklist and the Child and Adolescent Symptom Inventory-5 were used to measure irritability and generalized anxiety (GA), respectively. Multiple linear regressions were performed to examine whether irritability scores predicted P100 and N170 amplitude and latency to faces and non-faces.

Results: Regression models with irritability, GA, age, sex, and IQ as predictors were significant for P100 amplitude to upright faces \((F(5,201)=5.43, p<.001, R^2=97.1\%)\) and houses \((F(5,208)=3.59, p=.004, R^2=5.72\%)\) and N170 latency to upright \((F(5,201)=7.55, p<.001, R^2=13.73\%)\) and inverted faces \((F(5,200)=5.35, p<.001, R^2=9.59\%)\). Children with higher irritability trended towards lower P100 amplitudes to upright faces \((\beta=0.77, t=1.73, p=.086)\) and inverted faces \((\beta=-0.87, r=1.81, p=.071)\). Higher irritability also predicted longer N170 latencies to upright \((\beta=4.02, t=1.85, p=.066; trend level)\) and inverted faces \((\beta=6.26, r=2.36, p=.019)\), while children with higher GA trended towards shorter N170 latencies to upright \((\beta=0.26, r=1.73, p=0.085)\) and inverted faces \((\beta=0.34, r=1.82, p=.070)\). There were no relationships between irritability and P100 amplitude to inverted faces, N170 latency to houses, or P100 latency or N170 amplitude in any condition \((all p>.10)\).

Conclusions: Hypotheses were partially supported. In a sample of autistic children, higher irritability predicted lower P100 amplitudes to upright faces and houses, suggesting that higher irritability may relate to generally reduced attention allocation. Higher irritability predicted longer N170 latencies to upright and inverted faces, contrasting prior irritability research conducted with a non-autistic sample. Moreover, higher irritability predicted shorter N170 latencies to faces. These results suggest that variability in irritability and anxiety may account for some of the heterogeneity in face perception in autistic children.
INSAR 2023 ANNUAL MEETING ABSTRACTS

409.085 (Poster) Neural Engagement during Social Approach and Avoidance in Autistic Adults without Intellectual Disability
M. Lin¹, S. Kirsch², S. Guendelman², C. Kaufmann², S. Maier³, L. T. van Elst and I. Dziobek, (1)Unter den Linden 6, Humboldt-Universität zu Berlin, Berlin, Germany, (2)Humboldt-Universität zu Berlin, Berlin, Germany, (3)University Medical Center - University of Freiburg, Freiburg, Germany, (4)Humboldt-Universitaet zu Berlin, Berlin, Germany

Background:
Successful human interaction involves not only correct recognition but also an appropriate reaction to facial affect. Autism spectrum condition (ASC) has been associated with a decreased desire to approach positive social cues as well as a lack of automatic avoidance of negative social cues. Previous studies have observed such discrepancies on a behavioural level; meanwhile, the investigation of the neural underpinnings has received limited attention.

Objectives:
In this study, we aimed to untangle the differential impact of autism on social approach-avoidance processes, by examining the neural and behavioral responses during explicit approach-avoidance ratings towards positive and negative social cues.

Methods:
Using functional magnetic resonance imaging (fMRI), 43 adults diagnosed with ASC and 48 non-autistic controls completed two explicit social approach-avoidance rating tasks. Participants rated their approach-avoidance tendencies towards 90 trials of happy, neutral, and angry faces (a) via a 3-button choice (approach, no tendency, or avoidance) during fMRI scan and (b) on a 9-point Likert scale outside the scanner.

Results:
On the behavioural level, the two groups differed only on the approach-avoidance ratings of happy faces but not the ratings of neutral or angry faces, i.e., the ASC group rated happy faces as less approachable than the control group. On the neural level, whole-brain analysis with t-contrasts directly comparing the two groups for each condition revealed significant group differences, again, only for the happy (versus neutral) condition. The ASC group demonstrated stronger activation in the cerebellum, fusiform gyrus, inferior and medial frontal cortex, and medial superior frontal cortex during the perception and imagination of approaching or avoiding happy faces. No suprathreshold activation in the angry (versus neutral) was observed when contrasting the two groups. Region-of-interest analysis demonstrated marginally increased activation of the left caudate in the ASC group compared to the controls.

Conclusions:
Reduced social approach tendencies were found in autistic adults, which were also reflected in stronger neural activation of a widespread network during the approaching of happy faces. Those regions have been associated with motor and cognitive control, planning, and especially inhibitory control when selecting between actions, suggesting that adults on the spectrum may engage in more response suppression process when envisioning themselves approaching others. Meanwhile, autistic adults do not avoid negative social cues more than their peers, either on a behavioral level or a neural level.

Note. The data collection and analyses of this study will continue after the submission. Therefore, upon acceptance, a larger sample size and further analyses (e.g., parametric modulation, neural-behavioral correlations) may be included.

409.086 (Poster) Neural Processing of Phonological Information in Kindergarteners with ASD and the Relation to Reading Outcomes
B. Manning¹, K. Hosseini², E. Yang³, G. Buzzell² and S. H. Kim⁴, (1)Medical Social Sciences, Center for Autism and the Developing Brain at Weill Cornell Medical College, Chicago, IL, (2)Florida International University, Miami, FL, (3)Korea University, Seoul, Korea, Republic of (South), (4)Psychiatry, Center for Autism and the Developing Brain, White Plains, NY, Korea, Republic of (South)

Background: Very little is known about which factors contribute to academic success for children with autism spectrum disorder (ASD). Phonological processing is a foundational skill for reading development (Wagner & Torgesen, 1987), but the link between phonological processing and reading skills in children with ASD has not been studied in depth using both behavioral and electrophysiological methods.

Objectives: (1) To examine the relation between neural processing of phonological information and reading ability in kindergartners with ASD; (2) to determine how this relation differs between typically developing (TD) children and children with ASD; (3) to explore how this relation changes from kindergarten entry to exit in children with ASD.
Methods: 56 children (28 ASD; 28 TD) completed an “Old/New” ERP paradigm at kindergarten entry; 38 children with ASD also completed the paradigm at exit. Children also completed reading subtests from the Woodcock Johnson-IV (WJ-IV) Tests of Achievement. EEG activity was recorded while children listened to two rhyming pseudowords /gibu/ and /bidu. In an initial sensitization block, children heard one token repeated 50 times. In the second block, 100 tokens were randomly presented, including 50 “new” and 50 “old” tokens. We first conducted a Generalized Linear Mixed Model (GLMM) with P1 EEG amplitude as the dependent variable. Stimulus (old vs. new), group (ASD vs. typical), and reading achievement levels (WJ-IV Letter-Word Identification and Passage Comprehension standard scores), and their interactions were included as independent variables. Analyses controlled for sex, nonverbal IQ, and age. For children with ASD, we also examined the interaction between timepoint (kindergarten entry vs. exit), stimulus (old/new) and reading achievement levels.

Results: Results revealed a marginally significant three-way-interaction between Letter-Word Identification, stimulus, and group (p = .08) (Figure 1). To further examine the three-way interaction, we conducted post-hoc tests for children with “lower” and “higher” Letter-Word ability, using a median split. Results revealed that, among children with ASD with “lower” Letter-Word ability, P1 amplitude was significantly greater for new compared to old stimuli (p = .03). There was no significant difference between old and new stimuli for typically developing children (p = .70) or children with ASD with “higher” Letter-Word ability (p = .76). The three-way interaction between Passage Comprehension standard score, stimulus, and group was not significant (p = .16). Longitudinal analyses also revealed a marginally significant three-way interaction between time, stimulus, and reading achievement in children with ASD (Letter-Word: p = .06; Passage Comprehension: p = .04). Post hoc tests revealed that the difference between old and new stimuli in children with ASD was significantly greater at kindergarten entry compared to kindergarten exit (Letter-Word: p = .07; Passage Comprehension: p = .04).

Conclusions: Results indicate that the neural measure of one’s ability to process unfamiliar nonword stimuli may predict reading abilities in kindergarteners with ASD. This association was strongest at kindergarten entry. Given that children with ASD showed an atypical neural pattern of phonological processing compared to typical peers, targeting this skill prior to kindergarten will be critical to promote reading achievement.

409.087 (Poster) Neural Response to Social and Monetary Reward in Autism Spectrum and Comorbid Internalizing Symptoms
S. Barkley, T. C. Day, M. D. Lerner and B. D. Nelson, (1)Stony Brook University, Stony Brook, NY, (2)Department of Psychology, Stony Brook University, Stony Brook, NY

Background: The social motivation hypothesis posits that core social deficits of autism are due to atypical reward processing (Chevallier et al., 2012). Research has indicated that individuals with autism exhibit decreased reward-related brain activation in response to social (i.e., domain-specific) and potentially nonsocial (i.e., domain-general) feedback (Clements et al., 2018). In addition, autism is highly comorbid with internalizing psychopathology—which has also been linked to abnormal neural reward response (Bress et al., 2012; Kessel et al., 2015). Inconsistent previous findings may be due to the complexity of internalizing behavior, which may be better captured through symptom dimensions. It is unclear if autism-related deficits in neural reward sensitivity are impacted by comorbid internalizing symptoms.

Objectives: This study utilized electroencephalography to examine the relationship between neural reward response and autism symptoms in young adults. We hypothesized that 1) individuals with greater autism symptoms would exhibit smaller social and monetary neural reward response, and 2) internalizing symptom dimensions would moderate this relationship, producing greater neural reward response attenuation for those with elevated autism and multiple dimensions of internalizing symptoms.

Methods: The sample included 114 18-30-year-old students (Table 1). Participants self-reported autism symptoms via the Social Responsiveness Scale, Second Edition (SRS-2). Participants self-reported distress and fear/obsession symptoms via the Inventory of Depression and Anxiety Symptoms — Expanded Version (IDAS-II). In the social reward task, participants guessed which peer ‘liked’ a photo of them. In the monetary reward task, participants guessed which door contained a monetary prize. Tasks were matched on trial structure, timing, and feedback, with 60 trials and equal correct/incorrect outcomes. Continuous EEG was recorded using the BioSemi ActiveTwo system, digitized with a 1024Hz sampling rate. Feedback-locked epochs were extracted 200ms before feedback onset. The reward positivity (RewP), an event-related potential component indexing reinforcement learning and reward system activation, was calculated as the mean activity at FCz electrode, 250-350ms following feedback. Domain-specific RewP was calculated as the residual for social independent of monetary reward, and vice versa. Domain-general RewP was calculated by averaging social and monetary RewP. Hierarchical regression was used to examine the interactions between autism, distress, and fear/obsession symptoms in relation to RewPs.

Results: For domain-specific RewP, there were no significant effects involving autism, distress, and fear/obsession symptoms. For domain-general RewP, results indicated a trend main effect such that greater autism symptoms related to a smaller RewP (β = .25, t = -1.92, p = .057). There was also a significant interaction (β = .001, t = 3.73, p < .001) such that the negative association between autism symptoms and domain-general RewP was greatest with high fear/obsessions and low distress, or vice versa (Figure 1).

Conclusions: This study suggests greater autism symptoms relate to blunted neural response to social and nonsocial reward in young adults. These findings support prior research evaluating the social motivation hypothesis, suggesting that reward dysregulation underlies autism features. The interaction between autism, fear/obsessions, and distress dimensions indicates that reward processing is further dysregulated in individuals with autism and specific internalizing symptom combinations. This finding has important implications, as individuals with
autism-related social impairments often develop internalizing psychopathology in adolescence.

409.088 (Poster) Personal Relevance and Emotional Face Perception in Autism Spectrum Conditions
M. Bayer, I. Dziobek and K. T. Boegl. (1)Berlin School of Mind and Brain, Humboldt-Universitaet zu Berlin, Berlin, Germany, (2)Clinical Psychology of Social Interaction, Humboldt-Universität zu Berlin, Berlin, Germany

Background:
Difficulties in social interaction are one of the core features of Autism Spectrum Conditions (ASC). Neuroimaging research has shown that these difficulties are accompanied in alterations in the neural processing of faces in general, and of emotional facial expressions in particular, although previous results are heterogeneous.

Objectives:
In this study, we aimed to investigate the role of personal relevance in face processing in ASC. In non-autistic participants, personal relevance (i.e. faces of relevant others) has been shown to increase activations in the core and extended face processing network. We hypothesize that personal relevance in ASC might have the same effect, and might thereby also enhance emotion processing, i.e., that the personal relevance of a face might be a crucial moderator in the processing of an emotional facial expression. Thus, we expect to replicate reduced or absent effects of emotional facial expressions in response to stranger’s faces, whereas these effects might be preserved in response to personally relevant faces.

Methods:
Participants with ASC and matched controls (N=23 per group, mean age 32.9 years) performed an emotion recognition task on photographs of a personally relevant person and a matched stranger, displaying fearful, happy, and neutral facial expressions, while we recorded simultaneous EEG-fMRI.

Results:
Both groups showed significantly increased hemodynamic activity for relevant faces compared to stranger’s faces in the core and extended face processing network, including fusiform gyrus, medial PFC and precuneus, with no significant group differences. Crucially, emotion effects in ASC were limited to relevant faces, while the control group showed emotion effects to both relevant and unknown faces. In EEG data, group differences were evident in early sensory processing, with increased P1 amplitudes to relevant vs. stranger’s faces being observed only for the non-autistic group. Later processing showed effects of personal relevance and emotion without any group differences.

Conclusions:
Our results indicate preserved processing of faces and emotional facial expressions in ASC, specifically for personally relevant faces. Thus, face processing in ASC seems to be characterised by a higher specificity, rather than a general processing dysfunction or alteration. However, there is evidence for alterations of early sensory processing of faces in ASC, in line with previous findings. Our results further speak to the importance of accounting for personal relevance in face processing, in order to allow for the investigation of real-life social information processing.

409.089 (Poster) Potential Neural Correlates of Audiovisual Speech Processing in Autistic and Non-Autistic Youth: A Pilot fMRI Study

Background: Autistic youth demonstrate differences in processing multisensory stimuli, particularly audiovisual speech. For example, autistic individuals tend to be less attuned to the temporal relations between auditory and visual speech components, as indicated by wider temporal binding windows (a wider time interval over which paired auditory and visual stimuli are perceived as a synchronous percept). Prior research has identified several key brain regions involved in multisensory speech processing, including the superior temporal sulcus (STS) and insula, in neurotypical adults. However, it is unclear if activations in these regions are consistent in temporal processing of audiovisual speech in autistic and non-autistic youth.
Objectives: This pilot study applied functional magnetic resonance imaging (fMRI) with a simultaneity-judgment audiovisual speech task to a sample of autistic and non-autistic youth to begin to characterize the neural substrates of temporal processing of audiovisual speech in this population.

Methods: Thirty-eight participants (n = 18 autistic, 20 non-autistic) completed the study. Groups were matched on chronological age, biological sex, and gender. A 3-Tesla fMRI scanner equipped with a 32-channel head gradient coil was used to acquire a high-resolution anatomical scan and to measure BOLD signals from functional scans. During the event-related runs, participants completed a simultaneity judgment task, wherein participants were presented with a neutral-faced adult female speaker saying the syllable “ba,” presented either synchronously or asynchronously (stimulus-onset asynchronies of ±400 ms) and asked to indicate whether they perceived each trial to be synchronous or asynchronous. Images were processed and analyzed using FMRIB’s Software Library. Anatomical and functional images were mapped onto standard Montréal Neurological Institute (MNI) space with 2 mm isotropic voxels, and functional images were smoothed using a Gaussian kernel (FWHM = 5 mm). A general linear model was used to model the fMRI time series using a double gamma hemodynamic response function (HRF), which included regressors of interest plus first temporal derivatives for the four contrasts: synchrony > rest, asynchrony > rest, synchrony > asynchrony, and asynchrony > synchrony. Additional regressors of no interest accounted for artifacts of head motion. A mixed-effects FLAME1 model was used for group level analyses, generating maps for within and between group analyses with a cluster threshold of z > 3 and p < .05.

Results: Results for non-autistic youth were consistent with prior findings in non-autistic adults, with similar key regions involved in temporal audiovisual speech processing, including the posterior STS and anterior insula. Autistic youth, however, demonstrated responses in fewer of these key multisensory regions, with responses limited to visual and motor cortices. Results in several regions associated with audiovisual speech processing, such as the medial temporal gyrus, anterior temporal lobe, and anterior insula, varied according to several participant characteristics, including age, task accuracy, and nonverbal IQ.

Conclusions: These results suggest that there may be differences in the neural mechanisms of audiovisual speech processing in autistic youth and highlight the need to account for participant characteristics when investigating the neural bases of multisensory processing in autistic individuals. Future directions for research and clinical implications will be discussed.
The identification of early biomarkers that can support clinical judgements represents one of the main challenges for researchers, in order to detect as early as possible a risk of autism and start promptly treatments and interventions that can divert the atypical neurodevelopment trajectory. Ultimately, identifying the specific pattern of neuronal development in ASD can give important support to the early diagnostic procedures, that have the potential to change the development of these children. The use of the EEG for the study of children at high risk of developing ASD could be of help in this endeavor.

409.091 (Poster) Quantifying Neural Sensitivity for Subtle Changes in Vocal Identity and Expression Using Frequency-Tagging EEG in Adult Men with and without Autism

Background: Voices convey important social information, such as the identity and emotional state of the speaker. Autistic people may have difficulties processing socio-affective vocal cues, but behavioural findings are inconsistent.

Objectives: Here, we introduce an innovative and robust EEG paradigm that allows to quantify the implicit neural sensitivity for subtle socio-communicative vocal cues at the individual subject-level, and we contrast responses in adults with and without autism spectrum disorder (ASD).

Methods: We examined the neural sensitivity of 27 adult men with ASD and 25 neurotypical controls (matched on age, sex and IQ) to rapidly and implicitly detect subtle changes in vocal identity and vocal expression, using frequency-tagging EEG. Via a series of oddball paradigms, we presented a periodic stream of highly variable vocal utterances at 4 Hz, with an oddball every 3 or 4 utterances (thus at 4/3=1.33 Hz). To examine neural sensitivity to vocal identities, different neutral utterances of the same speaker were presented at base rate, periodically interleaved with neutral utterances of different speakers at oddball rate. To examine neural sensitivity to vocal expressions, base rate utterances of neutral voices were periodically interleaved with an expressive utterance (angry, fearful, happy, and sad, in separate sequences). These distinctive frequency tags for base rate and oddball stimuli allowed direct and objective quantification of the neural identity-discrimination or expression-categorization responses. To determine the impact of low-level acoustic cues aside of the target social cues, we also administered identical sequences with phase and amplitude scrambled utterances, a manipulation which rendered the vocal identity and emotion unrecognizable but largely preserved the acoustic characteristics.

Results: Both paradigms yield robust oddball responses in every participant, thereby offering a reliable quantitative index of the neural sensitivity for these important socio-communicative vocal cues. Importantly, oddball responses for sequences of scrambled utterances were significantly lower or even absent, demonstrating that differences in low-level acoustic features are not the main drive of the observed neural discrimination responses. For the vocal identity discrimination paradigm, we found significantly reduced oddball responses in the autistic versus neurotypical group, indicating substantial difficulties discriminating speakers and segregating speech streams. For the vocal expression discrimination paradigm, we did not observe any differences between both participant groups.

Conclusions: We applied, for the first time, an auditory frequency-tagging EEG paradigm to pinpoint neural sensitivity for changes in vocal identity and expression. We found that male adults can implicitly differentiate vocal emotions and speaker identity in a stream of utterances. While the brains of autistic adults are as sensitive as those of neurotypical controls to selectively categorize emotionally expressive vocal utterances, they are significantly less responsive towards differences in speaker identity. In light of the fast, implicit, double-objective and robust nature of this new EEG approach, it may open up perspectives for clinical applications, in particular in paediatric and nonverbal populations.

409.092 (Poster) Reduced Dynamic Functional Connectivity between the Anterior and Posterior Components of the Temporal Parietal Junction May Drive the Association between Attention and Mentalising in Autism.
C. Mevorach1, L. Bravo Balsa1 and A. Abu-Akel1, (1)School of Psychology, University of Birmingham - Centre for Human Brain Health, Birmingham, United Kingdom, (2)School of Psychological Sciences, University of Haifa, Haifa, Israel

Background: Previous studies have consistently reported atypical performance in ASD compared to typically developing (TD) groups during Theory of Mind (ToM) or mentalising tasks, as well as reduced activation and functional connectivity (FC) of the neural network underpinning ToM including in the Temporal Parietal Junction (TPJ). Attention atypicality in orienting, disengaging and reorienting of attention, have also been consistently demonstrated in ASD. Here too, studies have shown atypical activation in regions associated with attention orienting and reorienting (including in the TPJ). It is possible that attention reorienting is intrinsically linked to difficulties in mentalising as the ability to disengage and shift attention to new stimuli could be needed for the development of ToM. Thus, the right TPJ is likely an important interaction point between the mentalising and attention orienting functions in ASD, specifically the interaction between anterior (raTPJ; attention) and posterior (rpTPJ; mentalising) subdivisions of the region.

Objectives: Here we focused on resting state Functional Connectivity (FC) between the raTPJ and rpTPJ as a window into the relationship between attention reorienting and social cognition in ASD compared to TD adults. Since previous static FC studies resulted with both hyper- and hypo-connectivity in ASD compared to TD adults. Since previous static FC studies resulted with both
connectivity states between networks at different time points. We ask whether in ASD there is reduced dynamic FC between the anterior and posterior TPJ and whether this is linked to symptomatology in ASD.

Methods: Dynamic independent component analysis (dyn-ICA) was used to assess general variability in FC of the raTPJ and rpTPJ in two resting-state fMRI adult datasets from the ABIDE database, with the first (ASD = 14; TD = 15) serving as exploratory and the second (ASD = 29; TD = 29) as replication. We also assessed specific connectivity states (from highly negatively to highly positively correlated) in the replication dataset using a sliding-window approach to explore the associations between connectivity states and ASD symptom severity (measured with the Social Responsiveness Scale; SRS).

Results: Our results demonstrate a reduced dynamic FC in ASD compared to TD adults in the exploratory dataset (t = -2.34, p = 0.03, Cohen’s d = 0.88), which was also evident in the replication datasets (t = -2.21, p = 0.03, Cohen’s d = 0.60). Furthermore, increased dynamic FC in ASD predicted decreased behavioural symptoms (β(se) = -138.51(54.91), t = -2.52, p = 0.018, η² = 0.197). Additional regression analyses revealed that for ASD, decreased symptom severity was predicted by engagement of the highly positive state, but engagement of the highly positive state predicted increase in symptoms.

Conclusions: Dynamic FC between the raTPJ and rpTPJ appears to be important in ASD and is perhaps driven by an increased engagement of a highly positively correlated functional state. Previous research points to an antagonistic relation between the attention and mentalising networks and it is therefore plausible that increased positive connectivity in the TPJ and reduced alterations and changes of connectivity states underlie attention and mentalising atypicalities in autism.

409.093 (Poster) Sensory Processing and Visual Evoked Potentials in Individuals in with and without Autism Spectrum Disorder: The Gendaar Study

M. Santhosh, H. M. Borland, K. Pelphrey, S. J. Webb and G. A. Consortium, (1)Center for Child Health, Behavior and Development, Seattle Children’s Research Institute, Seattle, WA, (2)Autism and Neurodevelopmental Disorders Institute, University of Virginia School of Medicine, Washington, DC, (3)Psychiatry and Behavioral Sciences, University of Washington, Seattle, WA, (4)Seattle Children’s Research Institute, Seattle, WA

Background: Sensory processing issues are prevalent in autistic individuals with over 96% autistic children reporting either hypo or hyper sensitivity in multiple domains and often persist into young adulthood (Marco et al., 2011). Visual evoked potentials (VEP) collected via EEG recordings are a reliable measure of early stage visual processing and provide an understanding of the workings of the visual processing system. Previous studies have shown a decrease in P100 amplitude from VEP in autistic adolescents and young adults (Kovarski et al., 2016) but not in autistic children (Webb et al., 2022).

Objectives: The goal of this project is to (1) look at group and gender differences in sensory sensitivities and visual evoked potentials P100 and N100 amplitude and (2) relationship between sensory processing and basic visual processing (P100, N100) in adolescent and young adults with and without autism.

Methods:

196 participants (ASD = 95) ages 12-26 years from the NIH funded ACE GENDAAR study were included in the preliminary analysis. Autism diagnosis was confirmed via the ADOS-2. Participants viewed videos of flickering checkerboards displayed for 500 msec with a central red fixation point while high density EEG was collected for a total of 200 trials. Analysis focuses on the midline occipital region (average of electrodes 70, 74, 75, 82, 83), primary dependent variable is P100 amplitude and secondary variable is N100 amplitude.

Participants also completed the sensory profile self report, a 60 item questionnaire that reported on different sensory sensitivities with questions 17-26 focused on visual processing. Raw scores were calculated for visual processing questions and for sensory sensitivity and sensory avoiding quadrants.

Results:

Preliminary analysis showed no group differences in visual processing raw scores (t = 4.83, p > 0.05), but showed significant differences in sensory sensitivity (t = 5.94, p < .05) and sensory avoiding (t = 8.08, p = 0.05). Sex differences were observed in sensory sensitivity (t = -3.49, p < .05) and sensory avoiding (t = -2.89, p < .05) for autistic group but not for TD (all ps > .05). Secondary analysis will focus on the subset of samples that provided valid EEG data for VEP P100 and N100 amplitude and sensory processing scores (visual processing raw, sensory sensitivity and sensory avoiding). Standard scores from sensory sensitivity and sensory avoiding will be grouped into hyper (scores between 41 - 75) and hypo sensitivity (scores between 15 - 26). We expect (1) autistic group to show reduced P100 and N100 amplitude based on previous research in adolescents and young adults and (2) individuals with higher hypersensitivities to have reduced amplitude and vice versa.

Conclusions:
Preliminary analysis showed autistic groups scoring higher in sensory sensitivities and sensory avoiding quadrants as consistent with previous research but not in the visual processing sub section. Autistic females scored higher in sensory sensitivity and sensory avoiding quadrants indicating the variability in sensory concerns for autistic males and females. Next steps will focus on the secondary analysis of how visual evoked potentials might integrate with sensory processing behaviors.

409.094 (Poster) Sex Differences in Atypical Predictive Processes from Low Spatial Frequencies in ASD: Evidence from Mismatch Responses to Filtered Faces.
A. Lacroix1, S. Harquel2, M. Mermillod3, M. I. Garrido4, L. Barbosa5, L. Vercueil6, D. Alleysson7, F. Dutheil8, K. Kovarski9 and M. Gomot10,
(1)LPNC, Grenoble, France, (2)Defitech Chair in Clinical Neuroengineering, Center for Neuroprosthetics and Brain Mind Institute, EPFL, Geneva, Switzerland, (3)LPNC, Univ. Grenoble Alpes, Univ. Savoie Mont Blanc, CNRS, Grenoble, France, (4)Melbourne School of Psychological Sciences, University of Melbourne, Melbourne, VIC, Australia, (5)Univ. Grenoble Alpes, Univ. Savoie Mont Blanc, CNRS, LPNC, Grenoble, France, (6)Fralin Biomedical Research Institute at VTC, Virginia Tech, Roanoke, VA, (7)Grenoble Institut Neurosciences, InsermU1216, CHU Grenoble, Grenoble, France, (8)Université Clermont Auvergne, CNRS, LaPSCo, CHU Clermont-Ferrand, WittyFit, Clermont-Ferrand, France, (9)UMR 930 INSERM, University of Tours, Tours, France, (10)INSERM Grand Ouest, Tours, France

Background:
Fast visual recognition in non-autistic adults relies on coarse information conveyed by Low Spatial Frequencies (LSF), which possibly triggers predictions. Atypical predictive processes have been observed in autistic individuals. In visual perception, this might be related to a bias toward local information conveyed by High Spatial Frequencies (HSF). By reducing predictions in autism, this bias might impair facial processing. Additionally, sex differences have been reported in autism, including during attention to faces, but need further investigation.

Objectives:
The objective of the present study was to investigate if autistic individuals have impaired predictive processes from LSF during face processing and if there were sex differences.

Methods:
The Mismatch Response (MMR) being an electrophysiological correlate of the prediction error, an oddball paradigm was employed in 40 autistic and 48 non-autistic individuals while recording their scalp activity with a 96-EEG channels cap. An unfiltered face was used as the standard stimulus, whereas HSF and LSF-filtered faces were deviants. Assuming that LSF were at the root of predictive processes, a smaller prediction error (i.e., smaller MMR) to deviants containing only LSF compared to deviants containing only HSF was expected in non-autistic individuals. In contrast, this difference was expected to be reduced in autism.

Results:
Cluster statistics and ERP analyses on MMR over parieto-occipital areas both revealed that LSF-filtered face deviants lead to a smaller prediction error than HSF-filtered face deviants in two time-windows (130-230 ms and 350-450 ms after stimulus onset). However, cluster statistics show that this difference was reduced in autism during the second time window (p clustered = .03). Planned comparisons on ERP showed that the difference in amplitude between HSF-MMR and LSF-MMR was significant in autistic males and females irrespective of the time window (all p < .006) but not significant in autistic males, while in autistic females, it was significant in the early part (130-230 ms; p < .001) but not in the late part (350-450 ms).

Conclusions:
These findings confirm the predictive role of LSF in non-autistic individuals and highlight atypical predictive mechanisms from LSF during face processing in autistic individuals. Additionally, it emphasizes sex differences in autism, in line with recent research. These differences might contribute to better social skills in autistic females and confirm the need for sex stratification in autism research.

409.095 (Poster) Social Functioning in Male and Female Adults with Autism Relies on Similar but Not Identical Neural Mechanisms
A. P. Key, D. Jones, M. E. Klemencic and B. A. Corbett,
(1)Vanderbilt Kennedy Center; Dept. of Hearing and Speech Sciences, Dept. of Psychiatry and Biological Science, Vanderbilt University Medical Center, Nashville, TN, (2)Vanderbilt Kennedy Center, Vanderbilt University Medical Center, Nashville, TN, (3)Psychiatry and Behavioral Sciences, Vanderbilt University Medical Center, Nashville, TN

Background: Due to higher incidence of autism diagnosis in males than females, research on biological sex differences has been limited. Recent findings suggest distinct strengths and difficulties in males vs. females with autism. The neural mechanisms underlying sex-related
Objectives: This study aimed to characterize biological sex differences in social cognition in adults with autism by examining neural responses associated with sensory-perceptual processing and spontaneous memory for social and nonsocial stimuli.

Methods: Brain responses to social and nonsocial stimuli were evaluated using visual event-related potentials (ERPs) in 41 adults (17 female, 24 male) with ASD (age 18-35 years, M=24.43 years). All subjects passively viewed 200 color photographs depicting unfamiliar faces and house facades with equal probability. One face and one house were randomly selected and repeated throughout the session (50 repetitions/stimulus type) while the rest were shown only once (50 single presentations/stimulus type). To encourage attention to the screen, participants were asked to press a button in response to an unrelated visual probe (a cartoon drawing; 10 trials). Bilateral occipitotemporal N170 response (130-190ms) amplitude and latency were used to evaluate sensory-perceptual processing. Parietal ERP amplitudes (300-500 ms, 500-800ms) evaluated spontaneous detection of stimulus repetition. Autism Diagnostic Observation Schedule (ADOS-2) and Social Responsiveness Scale (SRS-2) scores provided behavioral measures of autism symptomatology and social difficulties in daily life.

Results:

Brain-behavior correlations indicated that in females, prolonged N170 responses to faces vs. houses. However, only females evidenced neural specialization previously reported in typical populations, with faster N170 responses over the right vs. left hemisphere. Conversely, only males consistently elicited shorter N170 latencies in response to faces than houses. Consistent with prior evidence of reduced incidental memory for faces in autism, neither males nor females exhibited the parietal ERP amplitude enhancement in response to repeated vs. non-repeated faces in the 300-500ms interval. Analysis of the general memory response (500-800 ms) revealed that males but not females detected stimulus repetition, reflected by the reduced ERP amplitude compared to the non-repeated trials, indexing reduced allocation of processing resources.

Conclusions: These findings suggest that adults with autism process social stimuli using the neural mechanisms previously reported in children with autism and in neurotypical populations. Biological sex differences in brain-behavior associations highlight the possible source of variable clinical presentation: females recruit both sensory-perceptual and memory processes for more adaptive functioning, while males rely on sensory-perceptual processes alone.
Results: Twenty-eight participants have been consented to date with n=11 in progress or complete and recruitment/retention that is ongoing and steadily improving. We estimate enrollment of at least 12-15 more participants over the next 6 months. The current preliminary sample includes both males and females with ASD (mean age=5.67,SD=3.01), all of whom exhibited some language delay and high RRB severity as indexed by the CYBOCS-ASD total score (mean=13.00,SD=2.00). Controlling for differences in N-acetylaspartate, changes in the ACC ranged from 3%-16% for Glu (mean=7.79,SD=7.21) and 1%-15% for Glx (mean=5.73,SD=7.64). Changes in the striatum ranged from 0.5-8% for Glu (mean=4.42,SD=5.58) and 0%-22% for Glx (mean=11.01,SD=15.57). Additional control variables are being evaluated.

Conclusions: We observed differences in absolute levels of glutamate in cortical and striatal regions following NAC administration compared to placebo. These findings are in line with the prominent theory that an excitation to inhibition imbalance may underlie the pathophysiology of some aspects of ASD and suggest the previously reported benefits of NAC for RRB in children with ASD may be related to changes in excitatory neurotransmission in CSC. Our next study will examine these relationships in a randomized, controlled trial.

409.097 (Poster) The Dual Effect of OT on Social Perception in Adolescents with ASD: A MEG Study of Neural Connectivity

A. Korisky1,2, I. Gordon1 and A. Goldstein2, (1)Gonda multidisciplinary brain research center, Bar Ilan University, Ramat Gan, Israel, (2)Gonda Brain Research Center, Bar-Ilan University, Ramat Gan, Israel, (3)Department of Psychology, Bar-Ilan University, Ramat-Gan, Israel, (4)Department of Psychology, Bar-Ilan University, Ramat Gan, Israel

Background:

Autism Spectrum Disorder is a neurodevelopmental condition characterized by difficulties in the social domain. In addition to clinical symptomology, studies have shown that individuals with ASD tend to present atypical patterns in face perception. Several studies have shown that oxytocin (OT), a naturally occurring hormone that relates to social communication in mammals, can modulate social behaviors in ASD. However, the mechanism underlying the effects of OT, especially during the early stages of perception, is relatively unknown.

Objectives:

The current work focused on the effects of single-dose OT on the early perceptual processing of social and non-social cues in adolescents diagnosed with ASD. Using magnetoencephalography (MEG), we first investigated the effect of OT on three neural components that relate to face perception: M100, M170, and M250. Next, we examined whether the effects of OT were reflected also in the spatial domain by investigating connectivity patterns between social-related regions, in alpha and gamma neural bands.

Methods: Twenty-five adolescents with ASD participated in a wall-established social task during a randomized, double-blind placebo-controlled MEG and OT administration study. Participants arrived at the lab twice and received an acute dose of intranasal OT or placebo in each session. During each scan in the MEG, participants were asked to identify pictures of social and non-social stimuli. Additionally, 23 typically developing (TD) adolescents performed the same task in the MEG as a benchmark that allowed us to better characterize neural regions of interest and behavioral results for this age group in this task.

Results:

Our results show a dual effect of OT such that single-dose administration impacts in a differential manner on the early perception of social and non-social perception. Throughout social processing, an administration of OT enhances the neural response during the M170 time window in the medial frontal cortex and modulates the connectivity between this region and the fusiform cortex. In addition, OT enhances the overall neural reactivity and increases attention toward the upcoming stimuli regardless of their content.

Conclusions:

The current study highlights the complexity of the effects of OT during early perceptual stages in ASD. By providing a new model composed of both social-related influence and modulation of the overall attention, we provide a new platform for exploring and establishing novel treatments for early attentional phases in ASD.

409.098 (Poster) The First Application of OPM-MEG Technology in Determining Emotional Face Responses in Very Young Children with and without Autism

J. Sato1, K. Safar2,3, K. de Villa1, J. Devasagayam1, R. Hill1, M. J. Brookes1,2, E. Anagnostou1,2,3, J. A. Brian1,2,4 and M. J. Children, Toronto, ON, Canada, (11) Program in Neuroscience & Mental Health, The Hospital for Sick Children, Toronto, ON, Canada, (12) Department of Pediatrics, University of Toronto, Toronto, ON, Canada, (13) Holland Bloorview Kids Rehabilitation Hospital, Toronto, ON, Canada, (14) Department of Psychology, University of Toronto, Toronto, ON, Canada, (15) Department of Medical Imaging, University of Toronto, Toronto, ON, Canada

Background: In the last decade the role of functional connectivity in the brain has become the main model for understanding brain development, function, and dysfunction. It is well established that adolescents and adults with autism spectrum disorder (ASD) show atypical brain oscillatory activity underpinning critical aspects of cognition and social functioning. Magnetoencephalography (MEG) is the ideal method for measuring functional connectivity, affording far better spatial resolution than other neurophysiological approaches. But MEG has historically shown poor reliability in children under 5 years. However, a recent and innovative optically pumped magnetometers (OPMs) system, is a new, wearable MEG technology that yields a four-fold increased sensitivity compared to classic MEG and nine-fold increased sensitivity over EEG to gamma. OPMs are also uniquely tolerant of head movement, which is a significant advantage when scanning young children. We are the first to scan very young children with OPMs, advancing our understanding of early brain development in autism.

Objectives: Using OPMs we are presenting our initial investigations of evoked responses and functional connectivity in young children (3-4-year-olds) diagnosed with ASD and typically developing (TD) controls.

Methods: OPM data were recorded using a whole-head, 40-dual-axis zero-field magnetometers during the presentation of emotional faces (to elicit evoked responses) in 8 TD (3 males) and 2 children with ASD (2 males). For the evoked fields to the face stimuli, we focused on occipital and fusiform source-space analyses, filtered between 3-40Hz. Functional connectivity to faces using network-based statistics will also be performed in the larger cohort of children with and without ASD.

Results: Our preliminary findings show a clear response to emotional faces in TD children, with M100 seen in the calcarine cortex with a peak amplitude of 5.21nAm±3.11 and latency at 110.38ms±14.78, and a M170 in the fusiform gyri with an amplitude of -14.03nAm±5.71 and latency at 186.88ms±27.46. These latencies are expected to emotional faces at this age. The children with ASD also showed evoked responses to the faces with greater amplitudes and longer latencies than the TDs, showing a M100 in the calcarine cortex with an amplitude of 9.82nAm±4.89 and a latency at 145ms±7.07, and M170 in the fusiform with an amplitude of -22.59nAm±15.03 and latency at 204ms±41.01. For the connectivity analyses, we expect greater connectivity in children with ASD, particularly in gamma, which is thought to reflect an imbalance in excitatory and inhibitory synaptic transmission.

Conclusions: This is the first OPM-MEG study to be performed in young children at the age of diagnosis, who could otherwise not be reliably scanned using MEG. With these data, we will be able to determine if source-space responses to faces, gamma band dysfunction and/or connectivity abnormalities are present at early diagnosis, as well as the relations of these measures of brain function to behaviour, across the autism spectrum. Although we have 10 participants to date in the 3-4-year age range, we have also completed testing on 7 younger children (1–2-year-olds); we expect to have data from >90 children by May 2023, including equal numbers with and without ASD.

409.099 (Poster) The Longitudinal GAMMA Band EEG Activity in Autistic Children
J. Lauttia1, S. Yrttiaho1, T. M. Helminen1, K. Eriksson2 and A. Kylliainen3. (1) Faculty of Social Sciences/Psychology, Tampere University, Tampere, Finland, (2) Faculty of Social Sciences/Psychology, Tampere University, Tampere, FINLAND, (3) Department of Pediatric Neurology/Faculty of Medicine and Health Technology, Tampere University and Tampere University Hospital, Tampere, Finland

Background: It has been suggested that in children with autism spectrum disorder (ASD), the cortical brain activity would show an imbalance between excitation and inhibition, which is reflected in atypically high baseline gamma activity. Previous research in gamma band have, however, been conflicting. In some of the studies, heightened gamma activity has not been found, whereas in some studies it has. A part of the research has also shown age-related changes in gamma band activity during the development.

Objectives: The study aimed at investigating longitudinal gamma band EEG activity in autistic children, typically developing children and children with intellectual disability without ASD. The specific aim was to investigate whether the baseline gamma band EEG is atypical in autistic children and whether it is a consistent finding longitudinally.

Methods: Nineteen autistic children (2.5–5.6 years), 19 typically developing children (TD, 2.4–5.8 years) and 17 children with intellectual disability without ASD (ID, 3.5–6.2 years) participated in the study. The baseline EEG was recorded in two different time points with 24 months in-between. EEG was recorded when the children watched a 3-minute video of a person building with Lego bricks. The gamma band activity (24.4–44.0 Hz) was analyzed in central and parietal areas to avoid myogenic artefacts. The group differences were analysed with nonparametric tests due to non-normal distributions and small sample size.

Results: In the first measurement point, the groups differed statistically in parietal gamma band EEG activity (Kruskal-Wallis, H=6.917, p=.031) but not in central gamma band EEG (H=2.841, p=.242). Children with ASD had more increased parietal gamma band power than
TD children (Mann-Whitney U=64,000, p=.027) and children with ID (U=52,000, p=.021). TD and ID groups did not differ in parietal gamma band EEG activity (U=108,000, p=.868).

At 24-months follow-up, the groups no longer differed in either parietal (H=622, p=.718) or central (H=1.488, p=.475) gamma band EEG activity.

For ASD children, both parietal (Wilcoxon Z=−2.040, p=.041) as well as central (Z=−3.296, p=.001) gamma band EEG were statistically larger in the first measurement point, compared to the second. For TD and ID children, the central gamma band EEG was higher in the beginning than in the follow-up (TD Z=−2.906, p=.004; ID Z=−2.803, p=.005), but parietal gamma band EEG showed no difference between the two time points.

Conclusions: The present results suggest that the gamma band activity changes over time in early childhood. The study supports previous studies by showing that the gamma band activity is higher in early development in children with ASD as compared to children with TD and with ID without ASD. However, the autism-specific difference seems to evaporate during the development. The present findings warrant further longitudinal studies with larger samples and multiple measuring points.

409.100 (Poster) Infant Resting State Functional Connectivity Networks Associated with Language Development in a Sample at High and Low Familial Likelihood of ASD

Background: Although much is known about the neurobiology of language in children and adults, relatively little is known about individual differences in the infant brain related to language development. Functional connectivity studies have demonstrated that regions classically associated with language show increased connectivity across the first few years of life (Gao et al. 2015) and are potentially related to later language outcomes (Emerson et al., 2016). As increasing evidence suggests that language is subserved by more broadly distributed regions in the adult brain, whole-brain studies are needed to explore relationships between infant brain networks and emerging language skills. Additionally, there is a need to examine broad measures of language function as well as granular measures of infant vocalizations to establish a comprehensive understanding of the underlying neurobiology.

Objectives: To identify functional brain networks associated with language development in the first two years of life in participants from the Infant Brain Imaging Study, a prospective study of infants at high and low familial likelihood for autism spectrum disorder, representing a broad range of language development.

Methods: Resting state functional connectivity MRI (fcMRI) was collected from sleeping infants at 6 (n = 95), 12 (n = 119), and 24-months (n = 141) using gradient-echo echo-planar image acquisition on cross-site calibrated 3T Siemens TIM Trio scanners. Cross-sectional fcMRI enrichment analyses were conducted to identify infant functional brain networks (Figure) associated with distinct language measures. These included standardized performance-based scores (Mullen Scales of Early Learning Expressive Language [MSEL-EL] and Receptive Language [MSEL-RL]), parent-reported vocabulary (MacArthur Communicative Development Inventories [M-CDI] Words and Gestures Produced and Understood), and granular measures of vocalization behavior coded from audio-visual recordings (speechlike rate, canonical babbling ratio (CBR) and proportion of vocalizations socially directed). fcMRI enrichment analysis addresses multiple comparison problems by identifying networks with an increased density of connections associated with behavior (Eggebrecht et al., 2017). Only network pairs that demonstrate a strong enrichment signal and pass a stringent machine learning, linear regression and PCA-based secondary vetting procedure are reported (Hawks et al., 2021).

Results: See Table for a complete list of significant brain-behavior associations. MSEL-EL was consistently associated with frontoparietal control network (FPC) and Default Mode Network (DMN) connectivity at 6 and 24 months. The MSEL-RL was associated with connectivity involving somatomotor, FPC, or both networks across 6, 12, and 24 months. Parent report measures of vocabulary (M-CDI) broadly showed convergence of network involvement with lab-based measures. Granular vocalization measures yielded a small number of...
specific relationships at 12 months, with CBR associating with DMN connectivity and proportion of vocalizations directed associating with Visual network connectivity.

Conclusions: Findings indicate that across the first two years of life, language development is associated with widespread functional connectivity in the brain, with particularly strong associations with FPC and DMN, and to a lesser extent the SMN and Visual Network. Widespread involvement of brain networks supports a distributed model of language processing, while consistent involvement of a smaller set of networks suggests a degree of specialization and generates testable hypotheses for future studies.

**409.101** (Poster) Visual Evoked Potential Differences in Infants Later Diagnosed with Autism

**L. D. Yankowitz**, C. L. Wilkinson, H. Tager-Flusberg and C. A. Nelson; (1)Laboratories of Cognitive Neuroscience, Boston Children's Hospital/Harvard Medical School, Boston, MA, (2)Department of Developmental Medicine, Boston Children's Hospital / Harvard Medical, Boston, MA, (3)Department of Psychological and Brain Sciences, Boston University, Boston, MA, (4)Department of Developmental Medicine, Boston Children's Hospital, Boston, MA

Background: There is evidence that the Visual Evoked Potential (VEP), which indexes low-level sensory processing of visual stimuli in primary visual cortex, is altered in ASD. For example, the P1 component was smaller in a sample of adolescents and adults with ASD relative to typically developing peers (Kovarski et al., 2016). Evidence is more mixed in children, with reports of reduced P1 amplitude (Kovarski et al., 2019) and latency (Milne, 2011), though these occurred in the context of increased intra-participant, inter-trial variability in ASD, and group amplitude and latency effects were reduced or eliminated after accounting for this variability (Kovarski et al, 2019, Milne et al., 2011). The VEP matures rapidly over the first two years of life (Kos-Pietro et al, 1997). Thus, there may be developmental influences on ASD-related differences in the VEP, necessitating study of the VEP in infants later diagnosed with ASD. Two questions remain unknown: 1) When in development do differences in VEP associated with ASD emerge? 2) Can differences in VEP be detected before a diagnosis of ASD is made?

Objectives: To understand the early development of VEP in ASD by examining VEP amplitude, latency, and variability in infants later diagnosed with ASD.

Methods: Pattern reversal VEP was measured in 12-month-old infants participating in two concurrent longitudinal studies (see Table). Between 2-3 years of age, infants were either diagnosed with ASD as part of the longitudinal study evaluation, or by community diagnosis by clinical psychologist. VEP was compared between infants with (ASD, n=17) and without (noASD, n=50) later diagnoses of ASD. Infants with unknown diagnostic outcome or elevated familial likelihood but no ASD outcome were not included. ANCOVAs controlling for study and number of segments included after segment rejection were applied to assess group differences in mean amplitude of N1, P2, and N2; N1-P1 and P1-N2 difference; latency of N1, P1, and N2; and inter-trial median absolute deviation (i.e., variability) in P1 amplitude and latency. Correlations between component amplitudes and MSEL Visual Reception scores were assessed.

Results: Infants later diagnosed with ASD had a larger mean P1 amplitude compared to infants not later diagnosed (p<0.05), as well as a larger N1-P1 complex (p<0.05, see Figure). No significant differences were detected in peak latencies, although the N2 latency trended toward being slightly later in infants later diagnosed with ASD (p = 0.055). Across all infants, more negative N1 amplitude was associated with higher 12-month MSEL VR (r = -0.3, p = 0.013).

Conclusions: By 1 year of age, infants later diagnosed with ASD show differences in the VEP compared to infants not later diagnosed, though the nature of these differences (increased P1 and N1-P1 amplitudes) is not consistent with prior reports of differences in older children. Notably, in typical development P1 amplitude declines during this age range, suggesting the possibility that the ASD group has delayed maturation of the VEP. Future research will be needed to determine whether the inconsistency in findings reflects a developmental change or characteristics associated with the sample or task.

**409.102** (Poster) Dataset-Specific Developmental Trajectories of Brain Structure and Function in Neurodevelopmental Conditions: Implications for Replicability

**M. M. Vandewouw**, Y. (. Ye), J. Croshie, R. Schachar, A. Iaboni, S. Georgiades, R. Nicolson, E. Kelley, M. Ayub, J. Jones, M. J. Taylor, J. P. Lerch, E. Anagnostou and A. Kushki; (1)Autism Research Centre, Bloorview Research Institute, Holland Bloorview Kids Rehabilitation Hospital, Toronto, ON, Canada, (2)Institute of Biomedical Engineering, University of Toronto, Toronto, ON, Canada, (3)Engineering Science, University of Toronto, Toronto, ON, Canada, (4)Department of Psychiatry, The Hospital for Sick Children, Toronto, ON, Canada, (5)Department of Psychology, University of Toronto, Toronto, ON, Canada, (6)Department of Psychology and Behavioural Neurosciences, McMaster University, Hamilton, ON, Canada, (7)Department of Psychology, University of Western Ontario, London, ON, Canada, (8)Centre for Neuroscience Studies, Queen's University, Kingston, ON, Canada, (9)Department of Psychology, Queen's University, Kingston, ON, Canada, (10)Department of Psychiatry, Queen's University, Kingston, ON, Canada, (11)Program in Neuroscience & Mental Health, The Hospital for Sick Children, Toronto, ON, Canada, (12)Department of Psychology, University of Toronto, Toronto, ON, Canada, (13)Diagnostic Imaging, The Hospital for Sick Children, Toronto, ON, Canada, (14)Department of Medical Imaging, University of Toronto, Toronto, ON, Canada, (15)Department of Medical Biophysics, University of
Background: Neurodevelopmental conditions (NDCs) are associated with disruptions in brain growth and development. With the brain’s structure and function undergoing complex changes throughout childhood and adolescence in both typical and atypical development, many investigations of NDCs attempt to control for age-related effects in their analyses. However, these effects may differ between datasets, challenging the replicability and generalizability of findings.

Objectives: We determined whether the developmental effects in NDCs differed between two independently collected datasets: the Province of Ontario Neurodevelopmental Network (POND) and Healthy Brain Network (HBN).

Methods: Functional magnetic resonance imaging (fMRI) data were extracted for POND and HBN participants (5-19 years old) who were diagnosed with Autism Spectrum Disorder (ASD), Attention-Deficit/Hyperactivity Disorder (ADHD), or Obsessive-Compulsive Disorder (OCD), or who were neurotypical (NT). Functional connectomes were constructed using five-minutes of resting-state data (POND: movies or Inscapes, HBN: fixation-cross) and used to extract the functional connectivity strength of 232 cortical and subcortical regions classified into eight canonical resting-state networks. Normative modeling (controlling for diagnosis) was used to characterize the dataset- and sex-specific developmental trajectories. A bootstrapping approach was used to compare the sex-specific trajectories between datasets. For each iteration (N=10,000), a normative model was constructed using 80% of a primary dataset (e.g., POND), and deviation scores (the degree to which an individual deviates from the normative range of the primary dataset) were extracted for the remaining data (e.g., remaining 20% of POND and alternate dataset, HBN); median deviation scores were computed across all iterations. Differences in median deviation scores between the primary and alternate datasets were evaluated using ANCOVAs, covarying for diagnosis and holding significance at p<0.05.

Results: After propensity matching on age, sex, and head motion, 551 POND (164 ADHD, 217 ASD, 60 OCD, 110 NT) and 551 HBN (374 ADHD, 66 ASD, 11 OCD, 100 NT) participants were included. In both datasets, age explained more variance in functional connectivity strength in females than males in all resting-state networks, particularly the salience and subcortical networks. Age explained more variance in POND than HBN in all networks except the salience network; largest differences were observed in the frontoparietal control and subcortical networks. For females, significant differences in deviation scores between datasets were observed in 24% and 39% of brain regions when normative models were constructed using HBN and POND, respectively, as the primary dataset, with more pervasive effects observed in males (97% and 91% of regions, respectively). In both sexes, when HBN was used as the primary dataset, functional connectivity strength was underestimated for POND participants, while connectivity strength was overestimated for HBN participants when normative models were constructed from POND; largest effects were observed in subcortical regions.

Conclusions: This study is critical in demonstrating that developmental trajectories of functional connectivity strength in NDCs can differ between independently collected datasets. Thus, age is an essential consideration when seeking replicable findings across datasets. Next steps include examining how different age-correction techniques impact findings and their replicability.

409.103 (Poster) Frequency-Specific Differences in Rich-Club Organization in Neurodevelopmental Conditions

M. M. Vandewoude1,4, J. Crosbie1, R. Schachar1, A. Jaboni1, S. Georgiades1, R. Nicolson1, E. Kelley1, M. Ayub1, J. Jones1, A. Kushki1, J. P. Lerch1,4, M. J. Taylor1,4, and E. Background: A set of highly connected brain regions called the “rich-club” play a vital role in integrating information across the functional connectome and support a wide range of cognitive functions. Functional magnetic resonance imaging (fMRI) has been used to relate disruptions in rich-club organization to neurodevelopmental disorders (NDDs) such as autism spectrum disorder (ASD) and attention-deficit/hyperactivity disorder (ADHD). Magnetoencephalography (MEG) can provide important information about the neural dynamics underlying the disruptions in rich-club organization in NDDs.
Objectives: This study will be the first to use MEG to investigate rich-club organization in a large sample of children and adolescents with and without NDDs. We quantify rich-club organization in different frequency bands known to support distinct cognitive functions and examine diagnostic differences and interactions with age and sex.

Methods: Resting-state MEG data were obtained from 539 children and adolescents (4-19 years of age) diagnosed with ASD (N=214) or ADHD (N=107), or who were neurotypical (NT; N=218); diagnostic groups were matched on age, sex, and data quality. Functional connectivity networks were constructed for each of the canonical frequency bands (theta: 4–7Hz, alpha: 8–14Hz, beta: 15–29Hz, low gamma: 30–55Hz, and high gamma: 65–80Hz). Rich-club coefficient curves were constructed for each network and statistical significance was assessed. The area under the curve of significant rich-club coefficients was used to quantify each network’s rich-club organization. Linear regression models were used to investigate main effects of diagnosis, age, sex, along with their interactions, on the rich-club organization in each frequency band, holding significance at $p<0.05$, with Tukey post-hoc comparisons for simple effects and simple slopes.

Results: In theta ($F(2, 527)=5.60, p=3.93\times10^{-3}, \eta_p^2=0.02$) and high gamma ($F(2, 527)=8.67, p=1.98\times10^{-4}, \eta_p^2=0.03$), the three-way interaction between age, sex, and diagnosis was significant. In both bands, while the NT children and adolescents showed a significant age-by-sex interaction, with rich-club organization decreasing with age in the females and no significant change with age in the males, neither the NDD females nor males showed significant changes in rich-club organization with age. In alpha, the three-way interaction was again significant ($F(2, 527)=6.76, p=1.26\times10^{-2}, \eta_p^2=0.03$); however, in this band, while the males in all three diagnostic groups showed increasing rich-club organization with age, only the ASD females showed a similar relation, with the NT and ADHD females showing no change with age. In beta, the age-by-diagnosis interaction was significant, with controls showing a weaker, but still significant, positive relation between age and rich-club organization compared to both NDDs. No significant main effect of diagnosis nor its interactions were significant in low gamma.

Conclusions: While the existing fMRI literature reports altered in rich-club organization in NDDs compared to typical development, we, for this first time, established the complex and frequency-dependent nature of these disruptions. Next steps include investigating the associations of rich-club organization with behaviour across the diagnostic groups.

409.104 (Poster) Disruptions in Amygdala-Prefrontal Connectivity Are Associated with Severity of Anxiety and Modulated By Levels of Social Impairment in Autistic Children

K. Ibrahim1, A. Pusok1, K. Wee1, J. Zhong1, C. Kalvin2 and D. G. Sukhodosky2. (1)Yale Child Study Center, Yale University School of Medicine, New Haven, CT, (2)Yale Child Study Center, Yale University, New Haven, CT, (3)Child Study Center, Yale University, New Haven, CT

Background: Co-occurring anxiety is prevalent among children with autism spectrum disorder (ASD) and represents a common reason for referral to mental health services. On a neural level, anxiety is associated with disruptions in the functional integrity of brain networks involved in emotion processing and regulation, particularly the amygdala-prefrontal cortex circuit. In autism, the majority of studies have focused on task-based fMRI, and less is known regarding the relationship between intrinsic functional connectivity and anxiety in ASD, which is measured during resting-state fMRI.

Objectives: The present study examined whether disruptions in amygdala-prefrontal connectivity during resting-state fMRI differentiates children with ASD and co-occurring anxiety relative to unaffected controls. We then tested if the severity of social impairment moderates the relationship between amygdala-prefrontal connectivity and anxiety severity in ASD.

Methods: This cross-sectional study included a well-characterized sample of 103 5- to 15-year-old children: 74 with ASD (M age = 11.6 years; SD = 1.8 years; 17 female) and 29 typically developing (M age = 11.5 years; SD = 1.8 years; 11 female). Children completed 12 minutes of resting-state fMRI. A diagnosis of ASD was confirmed with the Autism Diagnostic Interview-Revised (ADI-R) (Le Couteur et al. 2003) and/or the Autism Diagnostic Observation Schedule-2nd edition (ADOS-2) (Lord et al. 2012). All children with ASD had a diagnosis of an anxiety disorder (generalized anxiety disorder, separation anxiety disorder, or social anxiety disorder) based on the Anxiety Disorders Interview Schedule. Standard imaging preprocessing and analysis was conducted using FSL FEAT. Amygdala region-of-interest were created using FreeSurfer segmentations to reflect individual-specific neuroanatomy. The parent-rated MASC-2 and SRS-2 were used as continuous measures of anxiety and social functioning, respectively, in dimensional analyses.

Results: Relative to controls, children with ASD showed hyper-connectivity between the right amygdala and right orbitofrontal cortex (peak MNI coordinates: 22 16 -20; p = 0.01, z=4.36) (Figure 1A). In dimensional analyses conducted within the ASD group (n=74), level of social impairment severity was then found to moderate the relationship between anxiety severity and connectivity between the amygdala and dorsal anterior cingulate (peak MNI coordinates: 24 16 -18, p=0.008, z=4.29)—a region implicated in emotion generation (Figure 1B). That is, increasing levels of anxiety severity was associated with decreasing amygdala-dorsal anterior cingulate connectivity for children with ASD and lower severity of social impairment ($\text{SRS T score} < 74$), but the opposite for children with higher severity of social impairment ($\text{SRS T score} \geq 74$) (a median split T score of 74 on the SRS-2 was used to form social impairment subgroups). All findings remained significant after accounting for potential covariates (IQ, age, SRS, psychotropic medication status). We also conducted a whole-brain, exploratory analysis of brain structure to test the congruency of intrinsic connectivity findings with neuroanatomy. A similar pattern
was found in which severity of social impairment moderated the relationship between cortical thickness in the lateral prefrontal cortex and anxiety severity.

Conclusions: Findings suggest that disruptions in amygdala-prefrontal connectivity is associated with anxiety in children with ASD, which may be moderated by the level of social impairment.

409.105 (Poster) Large-Scale Networks of Anxiety in Autistic Children Based on Intrinsic Functional Connectomes

K. Ibrahim, J. E. Richards, A. L. Hogan and J. Roberts, (1)Loyola University Chicago, Chicago, IL, (2)University of South Carolina, Columbia, SC, (3)Department of Communication Sciences and Disorders, University of South Carolina, Columbia, SC, (4)Department of Psychology, University of South Carolina, Columbia, SC

Background: Disruptions in frontoparietal and frontolimbic networks supporting the cognitive control of emotion (emotion regulation) are implicated in childhood anxiety. However, the association between connectivity among large-scale functional networks and anxiety severity in children with autism spectrum disorder (ASD) remains unclear.

Objectives: The current study investigated whether the functional organization of the connectome predicts severity of anxiety in autistic children during resting-state fMRI. Here, we used a machine learning connectivity approach (known as connectome-based predictive modeling, CPM) to identify intrinsic networks predictive of anxiety.

Methods: This cross-sectional study included a sample of 74 children with ASD ages 8-15 years (17 females). ASD diagnosis was confirmed with the ADI-R and/or ADOS-2. Severity of anxiety was indexed by the total score on the clinician-rated Pediatric Anxiety Rating Scale (PARS). During fMRI participants completed 12 minutes of resting-state (i.e., viewing a blank screen with a cross-hair). Connectome-based predictive modeling with internal cross-validation was conducted to identify resting-state networks predictive of anxiety severity. Leave-one-out cross-validation was used, where a single subject’s predicted value (“left-out” participant) is created using data from all other participants (N-1) as the training dataset. Permutation testing was conducted to generate null distributions for significance testing. Virtual lesioning was used to test the robustness of large-scale networks in predicting anxiety severity.

Results: Intrinsic connectivity was predictive of anxiety (r=0.4, RMSE = 2.1, p=0.006, permutation testing, 1000-iteration, one-tailed) with both positive and negative networks emerging as significant (i.e., hyper- and hypo-connectivity predicting anxiety, respectively) (Figure 1A). High-degree nodes that were predictive of anxiety in every iteration of the model included the left dorsolateral prefrontal cortex, right orbitofrontal cortex, right insula, left temporal pole, and right supramarginal/angular gyrus. All findings remained significant after accounting for potential covariates (IQ, age, severity of social impairment using the Social Responsiveness Scale total score, severity of disruptive behaviors using the CBCL Externalizing Behavior Problems score, gender, and psychotropic medication status). Figure 1B summarizes connectivity within and between large-scale neural networks. Overall, connectivity was identified within and between large-scale networks implicated in cognitive control (medial frontal, frontoparietal), social functioning (default mode, salience), emotion generation (subcortical), and sensory control/movement (sensorimotor, visual, cerebellar) (Figure 1B). As a check on the construct specificity of findings for anxiety symptoms in ASD, we then tested whether the CPM model predicted disruptive behaviors after accounting for the shared covariance with anxiety. Even when intrinsic connectomes predicted anxiety, the model did not predict severity of disruptive behaviors (p = 0.8). Next, to check model robustness at a network-level, we systematically removed or “lesioned” each of the canonical networks. We found that the model predicting anxiety remained significant even when removing single canonical networks (e.g., medial frontal, default mode, salience), emphasizing the complexity of the intrinsic functional connectome in predicting behavioral phenotypes in ASD.

Conclusions: Connectivity between large-scale functional networks may contribute to the variability in anxiety in autistic children, suggesting a broader network dysfunction. These findings have potential to advance identification of neuroendophenotypes predictive of childhood anxiety in ASD that can inform individualized, targeted treatments.

409.106 (Poster) Neural Correlates of Face Processing in Children with Fragile X Syndrome and Autism Spectrum Disorder

M. W. Guy, J. E. Richards, A. L. Hogan and J. Roberts, (1)Loyola University Chicago, Chicago, IL, (2)University of South Carolina, Columbia, SC, (3)Department of Communication Sciences and Disorders, University of South Carolina, Columbia, SC, (4)Department of Psychology, University of South Carolina, Columbia, SC

Background: Atypical neural responses to face stimuli have been well-documented in children with autism spectrum disorder (ASD). However, much of this research excludes additional participant groups that are also impacted by varying degrees of ASD symptoms. In the current study, we investigated neural correlates of social information processing among children with ASD, as well as children with fragile X syndrome (FXS) and unaffected siblings of children with ASD (ASIBs). FXS is single gene disorder often characterized by intellectual impairment. Approximately 60% of preschoolers with FXS also meet diagnostic criteria for ASD (Roberts et al., 2020). Additionally, ASIBs are often impacted by the broader autism phenotype, in which they display higher rates of subclinical ASD symptoms than observed in the general population (e.g., Ozonoff et al., 2014).
Objectives: We aimed to examine differences in neural responses to social and non-social stimuli in heterogeneous groups of participants impacted by ASD, including children with ASD, children with FXS, and unaffected ASIBs.

Methods: Participants included children with ASD (N = 36, 35 males, age M = 5.6 years), children with FXS (N = 19, 13 males, age M = 6.2 years), and non-ASD younger siblings of children with ASD (N = 23, 16 males, age M = 5.5 years). A group of children with typical development were also included (N = 28, 23 males, age M = 5.2 years). Event-related potentials (ERPs) were measured in response to photographs of upright and inverted faces and houses. A behavioral support protocol was utilized to promote successful data collection (Guy, Black, et al., 2021). The P1, indicative of stimulus orienting, and N170, reflecting specialized face processing, ERP components were examined.

Results: There was a difference in the amount of usable data collected across groups: ASD (trials M = 159), FXS (trials M = 127), ASIB (trials M = 221), TD (trials M = 206). As presented in Figure 1, there was a main effect of group on P1 amplitude, F(3, 6696) = 37.00, p < .01, η2 = .02. As presented in Figure 2, there were main effects of stimulus type, F(1, 159) = 6.26, p = .01, η2 = .03, and group, F(3, 6675) = 90.35, p < .01, η2 = .04, on N170 amplitude. There were no differences between the groups in the latency of the P1 or N170 ERP responses. However, the group average N170 ERP for the ASD participants appeared to occur later than for the other three groups.

Conclusions: These results show distinct differences between the ERP responses of the children with familial ASD (ASD, ASIB) compared to the FXS children. The similarity of the ASD and ASIB responses suggest a common genetic or environmental origin of the reduced response to faces. The FXS children have a high incidence of ASD outcomes, but demonstrate a unique pattern of responses in this study. These results suggest increased activation during face processing in the FXS participants, both in sensory orienting (P1) and face processing (N170).

409.107 (Poster) The P1 Event-Related Potential Response Is Associated with Sensory Responsivity in Infants with Fragile X Syndrome and High Familial Risk for Autism

M. W. Guy, S. Conte, A. L. Hogan, A. Bursalioglu, J. E. Richards and J. Roberts, (1)Loyola University Chicago, Chicago, IL, (2)University of South Carolina, Columbia, SC, (3)Department of Communication Sciences and Disorders, University of South Carolina, Columbia, SC, (4)Department of Psychology, University of South Carolina, Columbia, SC

Background: Atypical sensory processing and sensory responsivity is widely reported in research on autism spectrum disorder (ASD) and fragile X syndrome (FXS) and may result from atypical neural processing, signal integration, or gating. Examination of sensory processing in infancy could provide insight into the development of atypical sensory responsivity within these disorders. Event-related potentials (ERPs) are valuable for investigating relations between neural correlates of sensory processing and emerging behavioral sensory responsivity. In particular, the infant P1 ERP component is associated with visual sensory orienting, providing a sensitive index to examine early occurring neural responses in relation to observed behavioral sensory responsivity.

Objectives: To investigate neural correlates of sensory processing in 12-month-old infants at high-risk for ASD in relation to clinical measures of sensory responsivity concurrently and as a predictor of sensory responsivity in early childhood.

Methods: Twelve-month-old infants with FXS (n=15), siblings of children with ASD (i.e., ASIBs; n=21), and low-risk control (LRC) infants (n=21) participated in an ERP study including presentations of familiar and novel faces and toys (Guy et al., 2018). Group differences in P1 amplitude were investigated. The Sensory Experiences Questionnaire (SEQ) total score was used to assess sensory responsivity in participants at 12 months and early childhood (M = 43.15 months). SEQ scores were analyzed in relation to P1 responses.

Results: The groups differed on P1 amplitude, F(2, 972) = 55.97, p < .001, η2 = .10. Amplitude was greater among participants with FXS, M = 18.39µV, than ASIBs, M = 10.71µV, or LRC participants, M = 11.01µV. At 12 months of age, there was an interaction of SEQ score and participant group on P1 amplitude, F(2, 864) = 5.16, p = .006, η2 = .03. Higher SEQ scores at 12 months were associated with greater concurrent P1 amplitude responses for ASIBs, however, the opposite pattern was observed in LRC infants, and no relation was seen for infants with FXS. In predicting SEQ scores during early childhood from 12-month-olds’ ERPs, there was an interaction of SEQ score, group, and stimulus type, F(4, 882) = 2.45, p = .045, η2 = .01. Among participants with FXS, greater amplitude P1 was associated with higher SEQ scores across stimulus type, while LRC participants showed relations between P1 amplitude and SEQ varied based on stimulus type. There were no significant effects of SEQ scores in early childhood for ASIBs.

Conclusions: High-risk infant groups demonstrated unique patterns of P1 activation, which were uniquely associated with sensory responsivity concurrently during infancy and as a predictor during early childhood. Although infants with FXS demonstrated greater P1 amplitude responses than ASIBs or LRC infants, greater SEQ scores were observed only as a predictor of elevated sensory responsivity in early childhood. In contrast, elevated sensory responsivity was associated with greater P1 amplitude during infancy for ASIBs, despite not displaying elevated atypical P1 responses. Results indicate that P1 amplitude is associated with sensory responsivity, but that the nature and developmental timing at which these relations are observed varies based on risk group.
Background: Previous neuroimaging research has suggested altered structural brain connectivity and brain microstructure in autism. However, this work largely examined such white matter differences by using the conventional microstructural model, diffusion tensor imaging (DTI). The DTI model has well-established limitations as it cannot resolve crossing fibers. One promising microstructural model that addresses the limitations of DTI is the tensor distribution function (TDF). TDF accurately accounts for complex fiber configurations and can be easily applied to the ‘single-shell’ acquisitions commonly used in autism research for diffusion-weighted magnetic resonance imaging (dMRI). Recent work examining normative aging has also indicated that TDF may capture brain microstructure differences more sensitively than DTI. Yet, no studies to date have used the TDF model to characterize white matter microstructure in individuals with autism.

Objectives: Investigate white matter microstructure alterations in autism using the advanced diffusion model, TDF, and the conventional model, DTI.

Methods: We analyzed single-shell dMRI data from 472 participants (78.4% male; 4-64 years old) across 10 datasets, including 276 participants with autism and 196 neurotypical controls; all data is publicly available through the NIMH Data Archive (NDA) and the Autism Brain Imaging Data Exchange (ABIDE). Preprocessing of the dMRI scans included eddy current correction, distortion correction, and fitting the TDF and DTI models. From the TDF, we derived an advanced measure of fractional anisotropy (TDF-FA). Metrics derived from DTI included fractional anisotropy (DTI-FA), mean diffusivity (DTI-MD), axial diffusivity (DTI-AD), and radial diffusivity (DTI-RD). Diffusion-weighted MRI indices were projected to a standard white matter skeleton using FSL’s tract-based spatial statistics, and mean values for each dMRI metric were extracted from 20 bilateral white matter regions of interest (ROIs). The advanced harmonization approach, ComBat, was used to correct for scanner-related variability across datasets. Group-level analyses investigated white matter differences between the autism and neurotypical groups when including the following nuisance covariates: age, sex, and the interaction between diagnostic group and age; full-scale IQ was also included as a nuisance covariate in follow-up analyses. A false discovery rate of 5% was used to correct for multiple comparisons across ROIs.

Results: Autism was associated with widespread alterations in white matter microstructure that suggest weaker structural connectivity, including lower TDF-FA and DTI-FA, as well as increased DTI-MD and DTI-RD; no significant differences were observed in DTI-AD. More specifically, TDF-FA exhibited significant reductions in autism across the full white matter, as well as in commissural, limbic, association, and projection tract regions (Cohen’s $d$=0.20-0.45). DTI-FA, DTI-MD, and DTI-RD displayed significant alterations in autism primarily in the full white matter and commissural and limbic tract regions (Cohen’s $d$=0.23-0.44). Results were similar when statistically adjusting for full-scale IQ.

Conclusions: Here we used the advanced method, TDF, to demonstrate widespread white matter microstructure differences in autism. As these alterations were not limited to a specific type of tract or area of the brain, these findings reveal the diffuse nature of structural brain differences in autism and underscore the importance of considering both higher- and lower-order brain regions when dissecting the neural underpinnings of autism.
Background: Autism is characterised by difficulties in social communication, restricted and repetitive behaviours, and sensory processing. These symptoms are thought to originate from differences in brain structural development, which are accompanied by genetic variation. Accordingly, to develop support strategies for clinical needs in autism, a better understanding of neuroanatomical development, and its associated genetic features, is essential.

Objectives: The objective of this study was to examine how neurotypical and autistic people differ in their patterns of neuroanatomical development, and how those differences relate to clinical and genetic variation, at both the group- and individual level. To make our results maximally applicable across the autism spectrum, we leveraged one of the largest and most heterogeneous autism datasets: AIMS-2-TRIALS LEAP.

Methods: We analysed longitudinal (2 timepoints separated by ~12-24ms) neuroanatomical (structural magnetic resonance imaging) data of 386 individuals (neurotypical=172, autism=214, 6-30yrs). First, we used partial least squares regression analysis to identify spatial patterns of neuroanatomical development in cortical thickness and surface area that differed between neurotypical and autistic participants. We established the robustness of our results using leave-one-out cross-validation. Second, we explored these patterns’ clinical and genomic (leveraging the Allen Human Brain Atlas) correlates.

Results: At the group-level, developmental differences between neurotypical and autistic people were driven most by lower-order (e.g., primary sensorimotor cortex) and least by higher-order (e.g., prefrontal cortex) regions (see Figure 1). At the individual level, a more ‘neurotypical’ developmental pattern correlated with fewer social difficulties, and more typical sensory processing. Also, developmental patterns were associated with biological processes (metabolic pathways and inflammation) and cell-types (e.g., immune cells and GABAergic neurons) implicated in (a)typical (neuro)development.

Conclusions: Our results suggest that the development of the neural substrates of lower-order, sensorimotor processing plays a crucial role in autism; and may be primary to the subsequent (a)typical development of higher-order regions and the neurocognitive functions they subserve. Once externally validated, our results may inform the development of personalised support strategies that target these structures and their associated functions.
primarily in rostral middle frontal, superior frontal, and superior parietal regions. Autistic children showed comparable degrees of both regional accelerated and decelerated cortical surface expansion. However, compared to non-autistic children, autistic children exhibited increased surface area at both Times 1 and 4, primarily in lateral occipital, inferior temporal and parietal regions. Significant sex differences in cortical surface expansion were observed. For example, within the rostral middle frontal gyrus autistic males exhibited accelerated expansion while autistic females exhibited decelerated expansion compared to non-autistic participants of the same sex, with opposite effects observed primarily in frontal regions.

Conclusions: Altered cortical development in autistic children results in age dependent differences compared to non-autistic children. Biological sex can significantly modulate the direction and degree of these effects. Additional work is required to parse how individual variability in cortical development is associated with specific autistic phenotypes.

310.004 (Oral) Examining the Replicability of Brain Structure Similarly Networks across Data from the Province of Ontario Neurodevelopmental Disorders Network (POND) and the Healthy Brain Network (HBN)

Y. Sadat-Nejad, J. Crosbie, R. Schachar, A. Iaboni, S. Georgiades, R. Nicolson, E. Kelley, M. Ayub, J. Jones, M. J. Taylor, J. P. Lerch, E. Anagnostou and A. Kushki, (1)Autism Research Centre, Holland Bloorview Kids Rehabilitation Hospital, Toronto, ON, Canada, (2)University of Toronto, Toronto, ON, Canada, (3)Department of Psychiatry, The Hospital for Sick Children, Toronto, ON, Canada, (4)Autism Research Centre, Holland Bloorview Kids Rehabilitation Hospital, Toronto, ON, Canada, (5)Offord Centre for Child Studies, McMaster University, Hamilton, ON, Canada, (6)Department of Psychology, University of Western Ontario, London, ON, Canada, (7)Department of Psychology, Queen’s University, Kingston, ON, Canada, (8)Department of Psychiatry, Queen’s University, Kingston, ON, Canada, (9)Diagnostic Imaging, Hospital for Sick Children, Toronto, ON, Canada, (10)Wellcome Centre for Integrative Neuroimaging, University of Oxford, Oxford, ON, United Kingdom, (11)Autism Research Centre, Bloorview Research Institute, University of Toronto, Toronto, ON, Canada, (12)Autism Research Centre, Bloorview Research Institute, Toronto, ON, Canada

Background: Autism spectrum disorder (ASD), Attention-deficit/hyperactivity disorder (ADHD), and Obsessive-compulsive disorder (OCD) are highly overlapping, and exhibit significant within-condition heterogeneity. To characterize this, the discovery of data-driven clusters that transcend diagnostic boundaries has received significant attention. However, the replicability of such clustering solutions across datasets remains a challenge.

Objectives: As a first step in understanding replicability challenges across multiple datasets, our objective was to compare the structure of participant-networks derived from structural MRI across two datasets (POND and HBN) using network theoretic measures.

Methods: We analyzed structural MRI from: Province of Ontario Neurodevelopmental Disorders (POND) network (POND; n=647; age=12.1±3.25, 28% female, 42% ASD, 30% ADHD, 10% OCD, 18% TD) and the Healthy Brain Network (HBN; n=628; age=10.9±3.53, 32% female, 10% ASD, 77% ADHD, 3% OCD, 9% TD). T1-weighted images were processed with CIVET pipeline to extract area, cortical thickness, cortical volume and subcortical volume according to automated anatomical labeling atlas (AAL). We used ComBat harmonization to correct for scanner effects, linear regression to correct for sex effect, and the best fit from linear, quadratic, or cubic polynomial models for age effects. A subsample from each dataset was extracted using propensity matching for age and sex, resulting in 504 from each set (POND: n=504, age=11.15±3.06, 29% female, 41% ASD,32% ADHD, 10% OCD,17% TD; HBN: n=504, age=10.9±3.21 29% female, 10%ASD, 78% ADHD,3%OCD, 9%TD). The data were then used to create participant similarity networks for bothPOND and HBN: First, principal component analysis (PCA) was applied to reduce the dimensionality of cortical thickness, surface area, and cortical and subcortical volume data. Next, we constructed participant similarity networks using the Chebyshev distance and scaled exponential similarity kernel. The surface area, thickness, and volume networks were fused with similarity network fusion (SNF) to obtain a network representing participant similarities across all brain measures. Lastly, the participant networks were thresholded at the 50th percentile to remove weak connections. The constructed networks were compared using clustering coefficient (tendency to make clusters), average betweenness centrality (characterises information flow), radius (characterises compactness of the network) and maximum clique (largest fully connected subgroup).

Results: Despite differences in proportion of diagnoses across datasets, both networks demonstrated moderate clustering tendency (clustering coefficient: POND=0.32, HBN=0.59), low average betweenness centrality (POND=0.002, HBN=0.001), and an equal radius of two. For both datasets, there was a significant age difference between the maximum clique and the rest of the network (age difference: POND:3.5±0.10, HBN: 2.0±0.69, p-corr<0.0004), but no significant differences in sex proportion, autism traits, or ADHD symptoms.

Conclusions: The POND and HBN datasets demonstrated similar network properties, which may be promising for replicability studies. Our results suggest older participants contributed to forming cliques in similarity networks, highlighting the importance of considering age in clustering studies.

Objectives: Our objective is to identify biologically relevant sub-groups in a cohort of individuals with ASD by linking their neuroanatomical phenotypes to the neuroanatomy of 150 mouse models.

Methods: We used three data sets: 1. T1w MRI scans from over 700 individuals in the POND Network, 2. T2w MRI scans from over 4000 mice across 150 studies of genetic mouse lines related to ASD, and 3. Whole-brain mouse and human gene expression data from the Allen Institute for Brain Science.

Creating neuroanatomical clusters. We registered the MRI scans together separately in either species. Using absolute and relative volume information, we computed effect size maps with respect to controls. We then used similarity network fusion (Wang et al., 2014) and spectral clustering to identify neuroanatomical clusters in each species.

Linking clusters across species. We linked the similarity between mouse and human clusters using a gene expression common space as in Beauchamp et al. (2022). We first created representative maps by averaging the effect size images for mice (individuals) in each cluster. We then masked each map by thresholding for the top 20% of voxels. We created a gene expression signature for every cluster by averaging the expression of 2835 homologous genes over all voxels in the mask. Finally, we correlated the expression signatures of each mouse and human cluster.

Annotating biological pathways. For each mouse cluster, we first expanded the set of single genes into gene neighbourhoods by using the STRING database (https://string-db.org) to identify one-hop protein-protein interactions. We then used the Reactome database (https://reactome.org/) in combination with gene annotations from the Bader Lab (https://baderlab.org) to evaluate the over-representation of pathways in each cluster. The clusters were annotated with pathways that were significantly over-represented.

Results: We identified multiple highly-correlated (r > 0.80) mouse and human clusters. Using a 5-cluster solution, we identified a match (r = 0.92) between a human cluster and a mouse cluster enriched for signaling by Wnt and MAPK family signaling. The clusters are characterized by volume increases in the cortex and decreases in hind brain structures like the pons, and medulla.

Conclusions: The heterogeneity of ASD suggests that the current diagnostic classification does not reflect a unique biological category. The identification of sub-groups with convergent biology is crucial for the development of effective therapies. While many approaches are possible, the combination of preclinical studies using mouse models and novel data-driven methods for linking brains across species provides a promising avenue towards this goal.
Longitudinal MRI studies in infancy have identified early brain markers of autism spectrum disorder (ASD) as early as 6 months of age, prior to the onset of the hallmark diagnostic symptoms. Age-specific behavioral associations with these brain markers have also been demonstrated in the first two years of life. This research highlights that brain changes are detectable in infancy and clinically significant, suggesting potential therapeutic windows and targets for early intervention.

Objectives:

This presentation will provide an overview of brain markers detected in the first year of life in infants who developed ASD, and monogenic syndromes associated with ASD. One such brain marker will serve as an illustrative example of leveraging both longitudinal neuroimaging in infants, and mechanistic studies in rodent models, to elucidate underlying pathophysiological mechanisms and inform the design of potential clinical trials.

Methods:

Longitudinal MRI scans and behavioral assessments from 6-24 months of age were conducted in infants from two harmonized studies: infants at high familial likelihood for ASD from the Infant Brain Imaging Study (N=308; 61% male); and infants with monogenic syndromes that have different associations with ASD – fragile X syndrome and Angelman syndrome – from a parallel infant MRI study (N=29; 65% male). Rodent models of these monogenic conditions were studied to establish face validity between the infant populations and their corresponding mouse model (N=15 each group), and to investigate the pathophysiology underlying the infant neuroimaging markers.

Results:

Several anatomical brain markers were identified as early as 6 months of age in infants who later developed autism including: increased cortical surface area growth; aberrant white matter development; and excessive volume of extra-axial CSF (EA-CSF) surrounding the brain. In three independent cohorts, children with ASD had excessive EA-CSF from 6 months to 4 years (18% greater than controls; p<.005). Excessive EA-CSF was detectable at 6 months (prior to the onset of behavioral symptoms), was correlated with severity of specific later symptoms (p<.01), and predicted diagnosis of ASD two years later (AUC=.70). These findings were extended to infants with fragile X syndrome and Angelman syndrome, and these genetic conditions also had excessive EA-CSF (p<.001). Studies to date in fragile X rodent models also showed excessive EA-CSF (thereby establishing face validity with infants) (p=.02), deficient CSF circulation (p<.001), and impaired clearance of accumulating neuroinflammatory proteins (p=.006).

Conclusions:

The convergence of studies in idiopathic ASD, monogenic syndromes associated with ASD, and rodent models, can serve as a framework for: (1) reverse-translating neuroimaging findings in children to the underlying mechanisms in preclinical models; and (2) forward-translating this research to inform the design of clinical trials. For example, several clinical trials for these monogenic syndromes are delivering targeted therapeutics via intrathecal CSF circulation; however, aberrant CSF circulation may adversely affect pharmacodynamics and drug biodistribution throughout the central nervous system. Finally, since brain markers in ASD are detectable by 6 months and are prognostic of later outcome, this elicits a conversation about the possibility of presymptomatic prediction of ASD diagnosis, thereby enabling early supports that may improve quality of life.
Background:
Various neuroimaging studies have explored variations in brain structure and function associated with autism. There is probably a common neurobiology of autism reflected in different imaging modalities and the potential linkage between brain structure and function variations has been largely hypothesized.

Objectives:
We aim to integrate brain structural and functional imaging with linked independent component analysis (LICA) to further understand the neural substrate of autism. Next, we aim to unravel the brain-behavior relationships in a general univariate and in a multivariate way.

Methods:
We studied 164 individuals with autism and 145 typically developing individuals, aged between 7 and 30 years, in a deeply phenotyped autism dataset – the EU-AIMS LEAP cohort. LICA was utilized to simultaneously factorize all subjects’ voxel-based morphometry (VBM) data, fractional anisotropy (FA) data, and 4 ICA-derived resting-state functional networks into 70 independent components (ICs) of spatial variations. These 4 networks are primary visual network, somatosensory network, anterior salience network (SN) and anterior default mode networks (DMN) previously generated from a larger cohort of the same dataset. A Generalized Linear Model was used to examine case-control differences and univariate multimodal brain-behavior associations. Next, Canonical Correlation Analysis (CCA) was performed to respectively explore the aggregated effects between all multimodal ICs of structure-function covariations and subscales of ADI and ADOS, and the Social Responsiveness Scale (SRS), Repetitive Behavior Scale-Revised (RBS) and Short Sensory Profile (SSP) in autism. The statistical significance of CCA was determined by permutation testing (10,000 times). Age, gender, IQ, site, and motion were included as covariates in all analyses.

Results:
Ten out of 70 ICs were defined as multimodal (no single modality’s contribution>50%). Multimodal IC58 was found to show a significant diagnostic group effect (b=-0.166, FDR corrected, p=0.020, Figure 1). The first three contributors of this IC were anterior SN, anterior DMN and VBM (contributions>15%) with autism diagnosis related variations in bilateral frontal areas, cingulate gyrus, and lateral occipital cortex (LOC). The convergence of the regions in IC58 suggests the consistency in the organization across different modalities. Additionally, we found a significant univariate correlation between multimodal IC37 and SSP in autism group (r=0.227, FDR corrected, p=0.042, Figure 2) showing that higher participant loadings of IC37 are related to better sensory responses in individuals with autism. In this IC there is involvement of visual areas (LOC, lingual gyrus) and white matter tracts (anterior thalamic radiation, corticospinal tract and superior longitudinal fasciculus) that play a crucial role in (visual-)sensory processing. We found no significant multivariate CCA association pattern in the current study.

Conclusions:
Our study provides spatial patterns of linked structural-functional features and identified a multimodal pattern associated with autism diagnosis, highlighting a covariation pattern of brain regions previously implicated in autism. The convergence of some brain regions in this autism-related IC furthermore suggests that the variations of the functional connectivity probably relate to their gray matter volume variations. Finally, we established a brain-behavior connection in autism emphasizing that the role of these brain areas relates to variations in sensory behaviors in autism, which need further investigation.

320.004  (Oral) Parsing the Neuroconnectional Landscape in Autism Via Cross-Species fMRI
M. Pagani1,2, V. Zerbi1,2, A. Galbusera4, N. Wenderoth3, T. Xu5, M. P. Milham5, A. Di Martino5 and A. Gozzi6, (1)Istituto Italiano di Tecnologia, IIT@UNITN, Rovereto, Italy, (2)Child Mind Institute, New York, NY, (3)Neural Control of Movement Lab, ETH Zurich, Zurich, Switzerland, Zurich, Switzerland, (4)Istituto Italiano di Tecnologia, Functional Neuroimaging Lab, Centre for Neuroscience and Cognitive Systems, Rovereto, Italy, (5)Child Mind Institute, New York, NY, (6)Istituto Italiano di Tecnologia, Istituto Italiano di Tecnologia, Rovereto, Italy

Background: Brain imaging studies in individuals with autism have revealed disrupted or aberrant patterns of functional connectivity as measured with resting-state fMRI (rsfMRI). Great heterogeneity in the manifestation of these alterations exists across patient cohorts. However, the origin and etiopathological significance of these heterogeneous findings remain unclear. Leveraging recent implementation of rsfMRI mapping in the mouse, we recently showed that different genetic models of autism exhibit distinct or even divergent patterns of...
rsfMRI connectivity. This result suggests that heterogenous functional connectivity in autism may encode for etiologically-relevant information.

**Objectives:** Here we used cross-species rsfMRI to probe if dominant patterns of dysconnectivity observed in 19 different genetic models of autism can be identified and decoded in rsfMRI scans of patients with idiopathic autism (ABIDE I and II).

**Methods:** *Mouse rsfMRI.* A total of 286 mice with 19 autism-related genetic alterations and 290 control littermates underwent rsfMRI mapping at 7T. Twelve etiologies were scanned at IIT Rovereto (Italy) and 7 etiologies were scanned at ETH Zürich (Switzerland). rsfMRI connectivity mapping was carried out by using global connectivity mapping. *Human rsfMRI:* Global connectivity mapping was carried out on \( n=1123 \) individuals with ASD and \( n=1166 \) controls (6-30 yo) from ABIDE1 (Di Martino et al., 2014) and ABIDE2 (Di Martino et al., 2017). Replicability of findings was assessed by splitting our sample into discovery and replication datasets.

**Results:** Consistent with our recent work (Zerbi et al., 2021), we found that all the 19 genetic models of autism imaged exhibited atypical rsfMRI connectivity, defining a pseudo-continuous landscape of connectivity alterations. Dominant cross-etiological convergences were however notable, revealing two dominant patterns of network alterations characterized by subcortical hyperconnectivity and striato-cortical hypoconnectivity, respectively.

Guided by our mouse results, a region-specific decoding of rsfMRI connectivity in idiopathic autism (ABIDE I and II) revealed two groups of patients recapitulating hyper- and hypoconnectivity patterns identified in the rodent database. Notably, these patterns of dysconnectivity were highly reproducible in a discovery and replication design, and exhibited robust enrichment for genes dysregulated in autism. Moreover, the two clusters were characterized by partly dissociable symptom severity profiles, and gene transcriptional signatures.

**Conclusions:** Our results suggest that neuroconnectional heterogeneity in idiopathic autism can be parsed into distinct, etiologically-relevant subtypes.

**POSTER SESSION — BRAIN STRUCTURE (MRI, NEUROPATHOLOGY)**

**410 - Brain Structure (MRI, neuropathology)**

### 410.108 (Poster) A Meta-Analysis of Longitudinal Total Brain Volume Trajectories in Autism

*S. Ashley1, K. Merritt1, P. Letrondo1, P. Laguna2, A. Reichenberg3 and A. David1, (1)UCL, London, United Kingdom, (2)Cardiff University, Cardiff, United Kingdom, (3)Seaver Autism Center, Department of Psychiatry, Icahn School of Medicine at Mount Sinai, New York, NY*

**Background:** Early brain overgrowth is a replicated neurophenotype associated with autism. Overgrowth occurs in approximately 20% of cases and may originate from disrupted cell proliferation during prenatal development (Courchesne et al., 2020; Fombonne et al., 1999). However, longitudinal brain development in autism, from infancy to adulthood has not been systematically charted.

**Objectives:** To conduct a meta-analysis of longitudinal growth trajectories of total brain volume (TBV) in autism compared to controls.

**Methods:** Four electronic databases were searched from inception through January 2022: PubMed, PsycINFO, Embase and Web of Science. Studies were eligible if they: 1) compared individuals with a diagnosis of autism spectrum disorder with typically developing controls; 2) collected mean and standard deviation measurements for TBV; 3) used a longitudinal neuroimaging design. The primary outcome measures were Hedges’ \( g \) effect size calculations for volume and annualized rate of change (ARC). Meta-regressions were performed for age, IQ, and gender. Data were pooled using random-effects models and risk of bias was assessed using an adapted version of the Joanna Briggs Checklist for Cohort studies.

**Results:** Eight studies were included in the meta-analysis, representing 559 individuals with autism and 3635 controls. Mean ages ranged from 6 months to 30 years and all but one study had \( >80\% \) males. There was a non-significant effect of TBV across all timepoints, but meta-regressions revealed a significant relationship between age and TBV (\( F = 22.67, p < .0001 \)), with overgrowth restricted to early years and reduced volume during adulthood in autism. Growth patterns significantly differed between groups, with slower ARC in autism compared to controls (\( g = -0.23, p = 0.001 \)). IQ, but not gender, was significantly related to TBV.

**Conclusions:** Findings from this meta-analysis indicate that TBV alterations in autism are age-dependent, with brain overgrowth during early childhood, slower rates of change across mid to late childhood, and reduced volumes in adulthood. Such changes across development may reflect a compensatory biological response to initial overgrowth or may signal advanced aging and degenerative processes occurring within the brain. More precise mapping of growth and relative brain size in the autism spectrum and their underlying mechanisms should help inform early diagnosis and interventions to mitigate the possible effects of atypical developmental trajectories.
410.109 (Poster) Abnormal Myelination of the Uncinated and Inferior Longitudinal Fasciculi Is Associated with Language Impairment in Phelan-McDermid Syndrome

F. Cucinotta, E. Mormina, M. Briguglio, L. Turriziani, A. Ricciardello, F. Granata and A. M. Persico, (1)IRCCS Centro Neurolesi "Bonino-Pulejo", Messina, Italy, (2)Department of Biomedical and Dental Sciences and of Morphofunctional Imaging, University of Messina, Messina, Italy, (3)Interdepartmental Program "Autism 0-90", "G. Martino" University Hospital, University of Messina, Messina, Italy, (4)Villa Miralago, Center for the treatment of eating disorders, Cuasso al Monte, Italy, (5)Child & Adolescent Neuropsychiatry, Dept. of Biomedical, Metabolic and Neural Sciences, University of Modena and Reggio Emilia, Modena, Italy

Background: Phelan-McDermid syndrome (PMS) is caused by chr. 22q13 deletions, disruptive point mutations in the SHANK3 gene, or rearrangements involving chr. 22 yielding a ring chromosome. Clinically, PMS is mainly characterized by severe intellectual disability, as well as frequent deficits in expressive and receptive language. Structural brain differences underlying language impairment in PMS have not yet been investigated.

Objectives: (1) to characterize the major white matter tracts involved in language processing, including the uncinated fasciculus (UF) and the inferior longitudinal fasciculus (ILF), in PMS; (2) to investigate the relationship between language skills and the integrity of the UF and ILF white matter tracts.

Methods: DTI tractography was performed to analyze UF e ILF in 26 PMS patients, (mean age 11.8±9.3, range 2-36 yrs; M:F=11:15). Whole-brain connectivity was generated for each subject using a probabilistic streamline tractography algorithm, and automatically defined regions of interest were used to map the UF and ILF. Indices of fractional anisotropy (FA) and mean diffusivity (MD) were correlated with: (a) age, (b) expressive language, (c) receptive language, (d) language developmental profiles, (e) comorbid autism spectrum disorder (ASD), (f) chr 22q13 deletion size. Nonparametric analyses were performed and additional multivariate analyses are under way.

Results: (1) A statistically significant increase in FA and decrease in MD was recorded in the ILF of 10 post-puberal, as compared to 16 pre-puberal PMS cases (p<0.01), whereas in the UF significant differences were observed only for reduced MD (P<0.01), but not for increased FA (P=0.5-0.2 for left and right hemispheres, respectively; (2) Lack of expressive language and severe impairment in receptive language were associated with FA reduction and MD increases in ILF and UF of both hemispheres (all p-values <=0.01). Moreover, PMS patients who never acquired language skills displayed significantly lower FA and greater MD for both tracts (all p-values <=0.05), compared to patients with delayed language development or with regression of acquired language, who do not differ from each other. Chr. 22q13 deletion size is significantly associated with expressive and receptive language skills (p=0.040 and p=0.005, respectively), but not with FA and MD in the ILF and UF, which are also not associated to presence/absence of ASD.

Conclusions: This study combines clinical phenotyping with DTI tractography to investigate the neurobiological role of the SHANK3 gene in axons and myelin formation, as well as its correlation with language impairment. Significant decreases in FA and increases in MD of both right and left UF and ILF are associated with expressive and receptive language deficits in PMS. This confirms an important role of UF and ILF in verbal language development and socio-communication skills, although no significant difference between ASD and non-ASD patients was recorded. Finally, the significant association between chr 22q13 deletion size and language development suggests that other genes located in the telomeric region of chr 22q may contribute to phenotypic variability in PMS, in addition to SHANK3.

410.110 (Poster) Brain Morphometric Differences between Adolescents with Autism Spectrum Disorder and Neurotypical Adolescent in Uruguay

Background:

Autism spectrum disorder (ASD) refers to a neurodevelopmental disorder characterized by impairment in social communication and restricted repetitive behaviors and interests. In children and adolescents diagnosed with ASD, multiple structural and functional variations have been identified in sMRI as well as in IMRI, compared to neurotypical population. Nevertheless, the growing neuroimaging literature in ASD has not yet identified neuroanatomical or functional markers that specifically and consistently accompany an ASD diagnosis. The limitations to advance in this field are multiple, making international efforts and collaboration between scientists fundamental to achieve better results; in this context is that we initiate our project.

Objectives:
Our purpose is to contribute to define more consistently the neuroanatomical features of ASD in adolescents, and considering that the amount of evidence that comes from South American population is scarce, we aim to establish to what extent the variations in sMRI described in the international literature are also identified in our patients.

Methods:

Participants included are 7 adolescents with an ASD diagnosis done by doctoral-level clinicians based in DSM-5 criteria and 10 neurotypical age-matched controls. None of them have medical, neurologic or genetic illness. All participants provided informed consent. To the ASD sample the Autism Diagnostic Observation Schedule (ADOS) was administered and the Raven test was applied to both samples. Images were acquired with a 3.0-Tesla MRI (General Electric Discovery 750W) for the ASD sample while a 1.5 Tesla MRI (General Electric Signa Voyager) for the neurotypical sample. We compared volumetric parameters in both scanners in order to be sure there were not significant differences in image acquisition between them. Morphological sequences were done (3D T1) without sedation in all cases.

Results:

We used Freesurfer software for the automatized parcellation and SPSS for the statistical analyses. We found that bilateral globus pallidus and right amygdala have significant bigger volume and left nucleus accumbens smaller volume in ASD sample compared with the neurotypical sample; left globus pallidus [Neurotypical vs ASD, volume (mm3) mean ± SE = 2193.9 ± 99.665 vs 2457.6 ± 65.338]; right globus pallidus [Neurotypical vs ASD, volume (mm3) mean ± SE = 2144.2 ± 81.560 vs 2425.9 ± 80.599]; right amygdala [Neurotypical vs ASD, volume (mm3) mean ± SE = 1744.5 ± 58.886 vs 1889.7 ± 26.816]; left nucleus accumbens [Neurotypical vs ASD, volume (mm3) mean ± SE = 831.01 ± 45.259 vs 709.44 ± 25.033].

Conclusions:

To our knowledge, this is the first study in our country to describe the brain morphometric characteristics in adolescents with ASD. Interestingly, although to date there is no consensus as to how they vary, the altered subcortical structures in our study are the same as those described internationally.

410.111 (Poster) Associations between a Novel Motor Imitation Task and Cerebellar Regional Volumes in Children with and without ASD

R. Santra', M. R. Plotkin', L. Rice', B. Tuncgenc', R. Robinson', C. Pacheco', R. Vidal', D. Crocetti and S. H. Mostofsky', (1)Center for Neurodevelopmental and Imaging Research, Kennedy Krieger Institute, Baltimore, MD, (2)Psychology, University of Nottingham, Nottingham, MD, United Kingdom, (3)Neuroscience Institute at Children's Hospital Colorado, Aurora, CO, (4)Johns Hopkins University, Baltimore, MD, (5)Johns Hopkins School of Medicine, Kennedy Krieger Institute, Baltimore, MD

Background: Imitation of others’ actions is widely understood to be crucial to social-communicative development, starting in infancy and beyond. Impaired motor imitation is commonly observed in autism spectrum disorder (ASD) and has been hypothesized to contribute to its core features. Addressing the lack of reliable methods for assessing motor imitation, we recently developed a novel Computerized Assessment of Motor Imitation (CAMI), which applies innovative and highly-reliable computer vision methods to a brief (one minute), engaging motor imitation videogame; finding that CAMI robustly distinguishes ASD children from typically developing (TD) controls (Tuncgenc et al., 2021). The brain-basis of these autism-associated impairments in imitation remains unclear. Multiple lines of evidence implicate cerebellar abnormalities in the pathophysiology of autism; however, associations of the cerebellum with motor imitation has not yet been studied, including in autism.

Objectives: We aim to apply an innovative regional cerebellar parcellation developed in our laboratory to examine associations of regional cerebellar grey matter volumes (GMV) with motor imitation skill and with autism symptom severity.

Methods: Participants included 85 children (40 ASD, 45 TD), aged 8-12 years. Imitation performance was assessed using CAMI in which children imitated unfamiliar dance moves of a video avatar in three one-minute trials. The CAMI algorithm, validated by comparisons with human coding, automatically computes the spatial and temporal differences between child and avatar movements, returning an overall imitation score from 0 (very poor), to 1 (perfect). See Figure 1. T1 images were processed using Automatic Cerebellum Anatomical Parcellation using U-Net with Locally Constrained Optimization (ACAPULCO), a convolutional neural network (CNN)-based cerebellar parcellation method yielding 17 cerebellar subregions. ACAPULCO-derived CNNs were then generated using a manually-derived pediatric cerebellar atlas developed in our laboratory.

Results: Consistent with published findings, t-test revealed that, compared to TD children, ASD children showed significantly worse CAMI performance (p<0.001). Among ASD children, Pearson correlation revealed a significant association between poorer CAMI performance and higher (more severe) Autism Diagnostic Observation Schedule scores (r=-0.40; p=0.012).
M ANCOVA co-varying for total cerebral volume and scanner model revealed no significant effects of diagnosis on regional GMVs. Partial correlations within ASD group revealed significant positive associations in bilateral lobule IX (Left: r=0.45; p=0.011, Right: r=0.45; p=0.006) and lobule X (Left: r=0.34; p=0.043, Right: r=0.35; p=0.035), such that smaller GMVs were associated with worse CAMI scores in the TD group, smaller right lobule VIII (r=-0.39; p=0.011) and left Crus II/VIIB (r=-0.37; p=0.016) were associated with better CAMI scores. See Figure 2.

Conclusions: Our preliminary findings reveal associations between regional cerebellar GMVs and autism-associated motor imitation impairments, assessed using CAMI. For ASD children, worse imitation is associated with smaller GMV in bilateral lobules IX and X, cerebellar regions thought to provide tertiary contributions to both cognitive and motor control. In contrast, for TD children, better imitation is associated with smaller GMV in right lobule VIII and left CrusII/VIIB, regions contributing to motor and spatial-cognitive functions, respectively. These patterns suggest that the cerebellum may differentially contribute to motor imitation, and resulting social-communicative development, in ASD vs. TD children.

410.112 (Poster) Atypical Early Cortical Development Related to Idiosyncrasy in Gaze Patterns in Preschoolers with Autism

Background: Human brains are hard-wired to preferentially orient to social cues. In normal development, social orientation is automatic and allows the accumulation of social experience leading to fine-tuning of more complex social and cognitive skills. A striking hallmark of Autism Spectrum Disorders is reduced orientation to social stimuli from the earliest age (Jones et al., 2013). Brain mechanisms underlying the atypical social attention deployment remain elusive.

Objectives: Our aim with the present study was to tackle the cerebral underpinnings of the atypical social information processing in preschoolers with autism.

Methods: This study involved 41 children with autism (9F) aged 1.97-5.99. Images were acquired in natural nocturnal sleep at Campus Biotech, Geneva, Switzerland. Children of various developmental and sleep profiles were included, following the extensive at-home training to habituate to the MRI sounds. Cortical surfaces were reconstructed using the Freesurfer 7.1 and were manually inspected and edited. Vertex-wise GLM analyses were deployed to probe for the relation between brain morphology and behavioral phenotype. The supratentorial brain volume, age and gender were used as covariates and correction of results for multiple comparisons was done using Monte Carlo simulations. The gazing pattern was measured using unique a method of unbiased quantification of divergence from the normative gazing pattern we developed (Kojovic et al, 2020). The moment to moment idiosyncrasy in looking behavior was obtained while viewing one episode of the French cartoon “Trotro” lasting 2'53” (Lezoray, 2013) in a session preceding the MRI session.

Results: The moment-to-moment divergence from the normative social gazing patterns was strongly related to the atypical gyriﬁcation pattern in an array of regions falling along dorsal and ventral visual processing streams. More divergent visual behavior was seen with more cortical folding in region involving top-down attention network (dmPFC & dACC), areas involved in processing body form and motion (EBA+STS), passive scene viewing (PPA) and face processing (FG). More symptoms in social affect domain co-occured with more cortical folding in region involving mentalizing network (TPJ+dPCC), processing body form and motion (EBA), language (IFG) and salience network (Ins).

Conclusions: Our preliminary findings reveal associations between regional cerebellar GMVs and autism-associated motor imitation impairments, assessed using CAMI. For ASD children, worse imitation is associated with smaller GMV in bilateral lobules IX and X, cerebellar regions thought to provide tertiary contributions to both cognitive and motor control. In contrast, for TD children, better imitation is associated with smaller GMV in right lobule VIII and left CrusII/VIIB, regions contributing to motor and spatial-cognitive functions, respectively. These patterns suggest that the cerebellum may differentially contribute to motor imitation, and resulting social-communicative development, in ASD vs. TD children.

410.113 (Poster) Brain Morphometry Mechanisms on the Abnormal Empathizing-Systemizing Difference in Children with Autism Spectrum Disorder
N. Pan1, S. Huang2, L. Lin2, X. Wang3, J. Jing4 and X. Li4, (1)Sun Yat-sen University, Guangzhou, China, (2)Department of Child Healthcare, Affiliated Foshan Maternity and Child Healthcare Hospital, Southern Medical University, Foshan, China, (3)Key Laboratory of Brain, Cognition and Education Science, Ministry of Education, China; Institute for Brain Research and Rehabilitation, and Guangdong Key Laboratory of Mental Health and Cognitive Science, South China Normal University, Guangzhou, China

Background: Behavioral research showed that children with autism spectrum disorder (ASD) had higher empathizing-systemizing difference than normal children, however, there is no research report on the neuroanatomical mechanisms on the empathizing-systemizing difference in children with ASD.

Objectives: To our knowledge, this would be the first study to quantify the brain morphometry underlying the empathizing-systemizing difference in children with ASD and TD children by structural magnetic resonance imaging (sMRI).
Methods: Participants comprised 41 children with ASD and 39 typically developing (TD) children aged 6-12 years. Empathizing-systemizing difference was estimated using D score from the Chinese version of Children’s Empathy Quotient and Systemizing Quotient. We quantified brain morphometry, including global and regional brain volumes and surface-based cortical measures (cortical thickness, surface area, and gyrification) via sMRI. We estimated associations between the empathizing-systemizing difference and brain morphometry by hierarchical linear regression models in children with ASD and TD children, respectively.

Results: D score was negatively associated with amygdala gray matter volume ($\beta = -0.16; 95\% CI: -0.30, -0.02$). There was a negative association between D score and gyrification in left lateral occipital cortex (LOC) in children with ASD while a positive association between D score and gyrification in right fusiform in TD children. Moderate analyses demonstrated significant interactions between D score and diagnosed group in amygdala gray matter volume ($\beta = 0.19; 95\% CI: 0.04, 0.35$) and left LOC gyrification ($\beta = 0.11; 95\% CI: 0.05, 0.17$), but not in right fusiform gyrification ($\beta = 0.08; 95\% CI: -0.02, 0.17$).

Conclusions: Neuroanatomical variation in amygdala volume and gyrification of LOC could be potential biomarkers for the empathizing-systemizing difference in children with ASD, but not in TD children. Our findings contribute to provide direct neural mechanism support to the E-S and EMB theory and large-scale neuroimaging studies are necessary to test the replicability of our findings.

410.114 (Poster) Caudate Volume at 12 Months of Age Is Related to School-Age Behavioral Profiles at 8-13 Years in Children with Fragile X Syndrome

Background: Fragile X syndrome (FXS) is a heritable genetic condition resulting in behavioral and brain differences throughout life and increased diagnosis of autism spectrum disorder (ASD) over the general population. Research has unveiled distinct patterns of behavioral and brain development between infants with FXS and infants at high familial likelihood for ASD, with recurrent ASD (HL-ASD). Recent findings demonstrate enlarged caudate volumes in infants with FXS compared to HL-ASD (specific to FXS – not influenced by comorbid ASD) emerging at six months and continuing through two years of age. Caudate enlargement may underlie behavioral features of FXS, such as reduced adaptive behaviors and increased repetitive behaviors. A unique longitudinal dataset spanning brain imaging in infancy and behavioral data a decade later can help elucidate relationships between early brain markers and later behavioral outcomes in FXS.

Objectives: To characterize relationships between caudate volume in infancy and behavioral profiles of adaptive and repetitive behavior at 8-13 years in a preliminary sample of children with FXS.

Methods: Structural MRIs were collected between 6-24 months of age in a longitudinal study of brain and behavior in FXS. Segmentation of MRIs generated volumes of subcortical structures for 23 infants (5 female). This sample is currently being recruited for a follow-up study collecting behavioral data at school-age (8-13 years old). In response to the COVID-19 pandemic and to increase participation accessibility for FXS families living across the country, behavioral follow-up was conducted remotely with parents, including the Vineland Adaptive Behavior Scale, 3rd edition (VABS) administered by a trained data collector via video conference and an online adapted version of the Repetitive Behavior Scale – Revised (RBS-R) questionnaire. Correlations compared caudate volume at 12 months (the timepoint with the most available MRI data) with the behavioral measures at 8-13 years old for the currently enrolled subset of the sample with VABS (n = 6) and RBS-R (n = 5) data at this point in data collection.

Results: As expected, enlarged caudate volume in infancy was related to both poorer adaptive behaviors and greater repetitive behaviors at school-age. Caudate volume negatively correlated with the VABS Adaptive Behavior Composite (ABC; $r = -0.36$) such that increased caudate volume related to decreased adaptive behaviors. Caudate volume positively correlated with the RBS-R ($r = 0.30$) such that increased caudate volume related to elevated repetitive behaviors. Although the magnitude of the correlation was strong, the statistic did not reach significance, owing to the limited sample collected at the time of submission.

Conclusions: These preliminary results reveal proof of principle for establishing longitudinal relationships between distinguishing brain features in infancy with school-age behavioral characteristics in FXS. Data collection is ongoing and by time of conference we aim to have greater power to detect significant effects (approximately double the current sample size). If observed patterns persist, these longitudinal relationships could represent a novel link between an early brain feature of FXS and behavioral outcomes a decade later. Longitudinally delineating phenotypic profiles of genetic etiologies such as FXS can contribute to unraveling heterogeneity in autism.

410.115 (Poster) Clinical Correlates of Gabaergic Interneuron Pathology in the Autistic Prefrontal Cortex

V. Martinez-Cerdeno, B. Dufour, E. McBride and P. Juarez, (1)Pathology & Laboratory Medicine, UC Davis, Sacramento, CA, (2)Psychiatry and Behavioral Sciences, UC Davis / Shriners’ Hospital of Northern California, Sacramento, CA, (3)UC Davis, Sacramento, CA, (4)Department of Pathology and Laboratory Medicine, UC Davis / Shriners’ Hospital of Northern California, Sacramento, CA

Background: There is growing evidence that abnormalities in the autonomic prefrontal cortex (PFC) are associated with autism spectrum disorder (ASD). This region is critical for the regulation of autonomic and executive functions and is implicated in the pathophysiology of ASD. Understanding the underlying mechanisms is crucial for developing targeted interventions. This study aimed to investigate clinical correlates of interneuron pathology in the autistic PFC using advanced imaging techniques.

Methods: We performed ultra-high-resolution diffusion MRI (dMRI) and ultra-high-field 7T MRI of the brain. The dMRI data were analyzed to quantify the degree of fiber tract integrity, while the 7T MRI data were used to examine brain morphometry. We performed statistical analyses to identify significant correlations between these imaging parameters and clinical measures.

Results: Our findings revealed altered interneuron morphology in the autistic PFC, with increased fiber tract integrity and reduced volumes of certain subcortical structures. These changes were associated with specific clinical features, such as impairments in social interaction and communication.

Conclusions: The observed correlations suggest a potential role of altered interneuron pathology in the autistic PFC in the regulation of autonomic and executive functions. These findings highlight the importance of interneuron pathology in the PFC as a potential target for future therapeutic interventions in ASD.
Background: Cortical inhibitory interneurons include a wide variety of subpopulations that are classified based on their morphology, marker expression, and electrophysiological properties. One class is the PV+ Ch cell that we found is numerically decreased in the prefrontal cortex in ASD. Ch cells are fast-spiking GABAergic interneurons that are involved in the generation of gamma oscillations generated by the cortex. In particular, synaptic inhibition from Ch cells controls the firing rate of pyramidal cells, synchronizes spikes within populations of neurons, and participates in cortical executive functions.

Objectives: Determine types of interneurons that may be altered in the cerebral cortex in ASD.

Methods: Immunostaining of postmortem brain tissue and statistical analysis.

Results: We found that there is a decrease in the PV+ Ch cells in in ASD. We also found a decreased amount of GABA\textsubscript{A}R\textsubscript{2α} in the pyramidal cell proximal axon -target of Ch cells synapses-, and a reduced Ch bouton size -probably indicating a decrease in the number of synapsis per bouton- in the prefrontal cortex in ASD. We concluded that Ch cells play an important role in the cortical circuitry dysfunction in ASD. We next assessed the relationship between interneuron pathology with the severity of ASD symptomology and the presence of ASD comorbidities. Using patient ADI-R scores, we found a significant correlation between the severity of interneuron loss in the orbitofrontal cortex with the severity of stereotypic motor behaviors in ASD subjects. We found that while all ASD subjects showed a significant and reduction in PV+ interneurons, ASD with intellectual delay showed reduction in total interneuron number relative to non-intellectual delay ASD.

Conclusions: Through this retrospective study, we identified that distinct patterns of GABAergic interneuron pathology in the ASD prefrontal cortex are associated with specific types of ASD symptomology and comorbidities and highlighted the importance of GABAergic dysfunction in the neurobiology of ASD.

410.116  (Poster) Early Differences in Sensory Structures in the Neonatal Brain

A. Javed, D. Fenchel, D. Batalle, A. D. Edwards and G. McAlonan, (1)Department of Forensic and Neurodevelopmental Sciences, Institute of Psychiatry, Psychology and Neuroscience, Kings College London, Institute of Psychiatry, Psychology & Neuroscience, London, United Kingdom, (2)Department of Forensic and Neurodevelopmental Sciences, and the Sackler Institute for Translational Neurodevelopment, Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, United Kingdom, (3)Department of Forensic and Neurodevelopmental Sciences, Institute of Psychiatry, Psychology and Neuroscience, King’s College London, London, United Kingdom, (4)Neonatal Unit, Evelina London Children’s Hospital, London, United Kingdom, (5)NIHR-Biomedical Research Centre for Mental Health at the Institute of Psychiatry, Psychology and Neurosciences, King's College London, London, UNITED KINGDOM

Background:

Sensory difficulties are at the core of Autism Spectrum Conditions (ASC) and related neurodevelopmental conditions. Up to 90% of ASC individuals report sensory difficulties (Robertson et al., 2017).

Despite the vast amount of literature suggesting sensory difficulties cause great difficulty for neurodevelopmental conditions, relatively little is known about their neuroanatomical basis. Magnetic Resonance Imaging (MRI) have provided evidence in adulthood suggesting neuroanatomical differences in sensory regions in ASC (Habata et al., 2021). However, adult (and childhood studies) make it difficult to untangle primary from secondary brain changes associated with ASC. Given that sensory features are among the earliest signals of ASC in infancy, the development of sensory systems in the postnatal period is crucial to understand.

Objectives:

Here, we tested the hypothesis that the volume of key sensory brain regions is altered at birth in neonates with a higher likelihood of atypical neurodevelopment. We compared how sensory regions correlated with each other between groups to understand how these regions are connected and grow together.

Methods:

92 new-born infants underwent T2-weighted sequences on a 3T MRI scanner. 37 infants (23M and 14F) born at an average of 39.02 (SD=1.94) weeks gestational age (GA) and scanned at an average 42.10 (SD=1.81) weeks postmenstrual age (PMA) were classified as higher likelihood (HL) of neurodevelopmental infants if they had a first-degree relative with ASC and/or Attention Deficit Hyperactivity Disorder (ADHD). 55 infants (25M and 30F) born at an average 39.80 (SD=1.32) weeks GA, scanned at 42.31 (SD=1.40) weeks PMA were classified as lower likelihood (LL) with no family history of neurodevelopmental conditions. Neonates with significant physical health conditions and/or clinically relevant incidental MRI brain anomaly were excluded.
Primary sensory grey matter volumes examined included the occipital lobe (OL) (containing the visual cortex), the insula (gustatory cortex) posterior superior temporal gyrus (PSTG) (auditory cortex), and thalamus (relaying sensory information).

The equality of independent inter-correlations (left and right regions) were examined by transforming Pearson’s correlations to Fisher-z scores (Snedecor et al., 1980). Multiple comparisons were controlled using the False Discovery Rate method (BH95) with a at 5%.

Results:

There were no significant between group differences in sex, age at birth and age at scan. General linear models were run on individual regions of interest, with total brain tissue volume, GA at birth, PMA at scan, sex and sex*risk as co-variates. The results revealed no differences between HL and LL sensory volumes.

We found that the correlation between left OL and right PSTG (LL r=0.528, HL r=0.813) (z=2.49, p=0.013) was significantly smaller in the LL group compared to the HL group however this did not survive FDR.

Conclusions:

Our preliminary findings revealed no significant differences when comparing HL and LL sensory region-of-interest volumes. However, inter-regional correlations indicated a larger correlation in HL-group between the left OL and right PSTG (auditory cortex). This suggests that sensory information may be processed and integrated differently in the visual and auditory domain in neurodevelopmental conditions in early development. However, this warrants further investigation on how these regions develop longitudinally.
The current study and imply a potentially more pronounced role for the right hemisphere in language development in autism. Increased lobule IX GMV in right-handed autistic preschoolers (p
< .001, k=1303). Within ASD, voxel-wise regressions with phenotypic measures revealed that increased GMV in right lobule IX (p
< .001, k=261), and left lobule I-V (p
< .001, k=85) were associated with greater social-communicative (SRS-2) impairment. Right lobule IX was also associated with more severe motor (PANESS) (p
< .001, k=403), repetitive/restrictive behavior (RBS-R) (p
< .001, k=168), and overall ASD symptoms (ADOS-2) (p
< .001, k=274). These relationships were driven by ASD boys.

Conclusions:

Complementary approaches investigated autism-associated differences in cerebellar structure, including VBM and an innovative ROI approach. While ROI analyses revealed no effects of diagnosis, voxel-wise methods revealed that ASD girls showed localized clusters of increased lobule IX GMV. VBM further revealed that decreased lobule IX GMV was associated with more severe core autism traits, particularly within ASD boys. Our findings suggest sexually dimorphic patterns of cerebellar structure and associations with symptom severity in ASD children. The predominance of VBM (vs ROI) findings suggests the presence of more localized alterations in cerebellar structure that may be less detectable using ROI-based approaches.

Examine the Role of White Matter Microstructures in Language Development in Autism

Background: Language abilities are highly variable in autistic children and can range from above average abilities to severe language difficulties (e.g., Baird & Norbury 2016). It is unclear what underlies this heterogeneity. Investigating neuro-anatomical microstructures in white matter pathways known to be involved in typical language development can provide us with more information regarding their role in language heterogeneity in autism and can help us disentangle neural and behavioral mechanisms impacting language abilities in autism.

Objectives: To clarify the role that white matter microstructures in known language pathways play in the language development of autistic preschoolers.

Methods: As part of the multisite Preschool Brain Imaging and Behaviour Project (PIP), receptive and expressive language abilities of 59 preschoolers (n autistic = 25, n non-autistic = 34) were examined using the Mullen Scales of Early Learning (MSEL) and a spontaneous language sample (including mean length of utterance). Note that this is only a subset of data from one out of five data acquisition sites and data from other sites will be added. Participants were invited to undergo an MRI scan during their natural sleep, which included diffusion tensor imaging (DTI) to characterize white matter microstructures. Group differences between the autistic and non-autistic group were assessed and partial correlations between language variables and white matter microstructures while controlling for age were investigated. Mixed effects regression will be employed on the larger sample to estimate the relationship between white matter and language abilities.

Results: Non-parametric group differences indicated significantly lower expressive and receptive language scores on all language measures in the autistic group compared to the non-autistic group. No significant group differences were observed for any of the variables characterizing white matter microstructures. Whole sample partial correlation analyses to characterize the continuous sample revealed significant negative associations between expressive language and mean diffusivity in the anterior segment of the right arcuate fasciculus (p = .40, p < .05). When examining the different groups, for the autistic preschoolers only, a significant, positive association was observed between expressive language and fractional anisotropy (p = .84, p < .01) and a negative association between expressive language and radial diffusivity (p = .77, p < .01), both in the long segment of the right arcuate fasciculus.

Conclusions: Results indicate that for our whole sample, higher language abilities were associated with lower mean diffusivity in the arcuate fasciculus, which is in line with previous work indicating language impairment in school-aged autistic children and non-autistic children with language difficulties to be associated with elevated values of mean diffusivity (Nagae et al., 2011; Vydrova et al., 2015). Associations between right arcuate fasciculus microstructures and expressive language in our autistic group are a novel finding of the current study and imply a potentially more pronounced role for the right hemisphere in language development in autism.
Background: Maximum grip strength may be indicative of brain-body communication efficiency (Carson, 2018) and is associated with the prominence of autism-related features (Travers et al., 2015; Kern et al., 2011). During childhood, grip strength is similar in autistic and non-autistic individuals, but in adulthood grip strength and its neural correlates are differ based on diagnosis (Travers 2015; Travers 2017). However, the neural correlates of grip strength in autistic children are unknown, making it unclear if the differing neural mechanisms driving diagnostic differences during adolescence are present from early childhood or arise concurrently with behavioral differences. Additionally, it is unclear how brain-behavior relationships are influenced by co-occurring attention-deficit/hyperactivity disorder (ADHD), which has been shown to be a meaningful source of neural heterogeneity within the autistic population (Yerys et al., 2019). In non-autistic adults, maximal grip strength is associated with microstructural properties of the lateral grasping network (LGN), proprioception input network (PIN), and cerebellar modification network (CMN) (Schulz et al., 2012; Koppelmans et al., 2015). Yet, we do not know if relationships between brain structure and grip strength are similar in non-autistic and autistic children or how co-occurring ADHD features may influence these relationships.

Objectives: 1) Characterize the microstructural neural correlates of grip strength in autistic and non-autistic children. 2) Evaluate to microstructure-grip relationships within autistic children with and without elevated ADHD features.

Methods: Bimanual maximum grip strength and diffusion weighted imaging data were collected from 132 children (62 autistic; 6.02-10.97 years). Vanderbilt NICHDQ scores were used to determine the presence of elevated ADHD features (37 autistic children). Multi-shell DWI were acquired using a 3T GE Scanner and processed with TiDi-Fused imaging (Guerrero-Gonzalez et al., 2022). Bilateral white matter pathways of the LGN, PIN, and CMN, (Figure 1) were delineated using probabilistic tractography. Weighted median free water elimination-corrected fractional anisotropy (FWE-FA) was calculated in each bilateral tract. General linear models predicted tract-specific FWE-FA from grip strength, group (autistic vs non-autistic OR autistic-elevated ADHD vs autistic non-elevated ADHD), and their interaction while accounting for age, sex, and head motion. Results were corrected for multiple comparisons using FDR.

Results: 1) Significant grip strength main effects were found in the LGN and PIN across autistic and non-autistic children. No significant grip strength-by-group interaction effects were found (Figure 1A). 2) Neural correlates of grip strength were distinct in autistic children with and without elevated ADHD features (Figure 1B), as indexed by significant grip-by-group interaction effects in the PIN and CMN (Figure 2).

Conclusions: Results suggest that for maximal grip, autistic and non-autistic children rely similarly on core motor networks (LGN) but differentially on proprioceptive input and cerebellar feedback. Alternative network reliance may depend on the presence of co-occurring ADHD features, indicating that brain-body communication may be distinct in autistic sub-populations. Importantly, these group-specific neural mechanisms contribute to similar grip force, suggesting equal network efficiency. These results have implications for understanding the neurobiological underpinnings of motor differences in autistic children and may impact how we interpret and assess motor behaviors in autistic sub-populations.

Background: The 16p11.2 BP4-BP5 deletion confers high risk for autism spectrum disorder (ASD) and is one of the pathogenic variants most frequently diagnosed in the clinic. Morphometric studies using T1-weighted magnetic resonance imaging (MRI) have revealed large and pervasive volumetric alterations in 16p11.2 CNV carriers. However, the specific neuroanatomical mechanisms underlying such changes, as well as their developmental trajectory, are still unclear.

Objectives:
To characterize brain microstructural connectivity and network organization patterns in young children sharing a deletion of the 16p11.2 locus, the same mechanism and genetic risk factor to develop ASD.

Methods:

We explored differences in structural brain connectivity in a cross-sectional study involving 24 young children carrying a 16p11.2 deletion and 66 typically developing children between 2 and 8 years of age. Diffusion MRI data was collected to compute intra-axonal volume fraction and its developmental modelling. We also computed network node metrics such as node strength, closeness, betweenness, efficiency, clustering and participation coefficient.

Results:

Estimated bundle-specific intra-axonal volume fraction revealed large effect size alterations in microstructural connectivity (0.96 to 1.95 Cohen's d). Weighted graph metrics in 16p11.2 deletion children showed significantly higher global efficiency and betweenness. Areas exhibiting altered connectivity metrics in 16p11.2 deletion children were previously associated to a spectrum of brain functions, including language (superior temporal sulcus, transverse temporal and supramarginal gyri), motor skills (precentral gyrus and inferior parietal lobule), and socio-emotional processing (superior temporal sulcus and rostral anterior cingulate).

Conclusions:

Our results shed light on the neuroanatomical basis of the previously reported increase of white matter volume in volumetric studies. The alterations of structural connectivity present in 16p11.2 deletion children are also in line with evidence of altered number of neurons, axonal diameter and synaptic function in 16p11.2 mice models, deviating the maturation of specific neuronal circuits from typical neurodevelopmental trajectories. Future work is warranted to determine how these alterations contribute to the emergence of symptoms observed in young children diagnosed with autism and other neurodevelopmental disorders.

410.121 (Poster) Sensory Profiles Are Linked to Brain Morphometry in Autism

Background:

Autism is a very diverse and heterogeneous clinical condition. This heterogeneity is particularly apparent in sensory processing where alterations can range from hypo- to hyperreactivity, with effects on all sensory domains.

Objectives:

We assumed that the biological underpinnings of these alterations would manifest themselves already on the structural brain level. Hence, we wanted to unravel if morphological brain patterns are linked to sensory processing profiles in autism. Further, we were interested if sensory processing profiles might be an eligible candidate to stratify the autism spectrum.

Methods:

We used canonical correlation analyses to unravel underlying patterns between sensory processing profiles and vertex-wise estimates of cortical and subcortical volumes of 204 autistic participants ($M_{age} = 16.12, SD = 5.34$, range = 7 – 31 years, 29% female). Sensory processing profiles were assessed using the Short Sensory Profile.

Results:
Our results show that sensory profiles were associated with structural brain features ($RV$-coefficient $= 0.06$, $p = .002$). Comparing participants with low levels of sensory alterations to participants with high levels, our analyses suggest that the underlying brain volume patterns were different between those groups (Tucker’s congruence coefficient $= .72$). Despite those differences on a morphological level, our findings indicate that for the clinical phenotype, i.e., the sensory processing profiles, there is a common, underlying latent factor underlying both groups. Exploratory analyses showed that this latent factor was associated with scales assessing repetitive behavior ($r = .61$) and ADHD symptomatology ($r = .47$) in our sample.

Conclusions:

We conclude that sensory processing is an important aspect to stratify and describe the autism spectrum. As we can show that the differences between sensory processing groups are already manifest on a structural brain level, we argue that alterations in sensory processing are not only due to a different brain functioning but seem to have a biological underpinning in brain morphology. Underlining the associations between sensory processing and clinical symptoms like repetitive behavior and ADHD, our findings are also of practical clinical relevance and might spark future research within this domain.

410.122 (Poster) Neural Correlates of Speech Onset Delay in Autistic Males: A Follow-up, Voxel-Based Morphometry Study

Y. C. Wang¹ and S. S. F. Gau, (1)Department of Psychiatry, National Taiwan University Hospital, HsinChu branch, Hsin-Chu, Taiwan, (2)Graduate Institute of Clinical Medicine, College of Medicine, National Taiwan University, Taipei, Taiwan, (3)Department of Psychiatry, National Taiwan University Hospital & College of Medicine, Taipei, Taiwan

Background:

Autism spectrum disorder (ASD) is a severely impairing neurodevelopmental disorder but lacks a biomarker for early detection or diagnosis. In addition, heterogeneity within the diagnostic entity hinders searching the brain mechanism of ASD. Speech onset delay, commonly seen in autistic children, predicts long-term outcomes and could serve as a potential phenotype marker of subgrouping ASD. However, the specific neural correlates of speech onset delay in ASD remain unknown; for example, no consistent results from previous structural MRI studies. Despite some evidence showing the importance of the age effect, very few studies focused on the developmental change either based on longitudinal data or considering the age differences in cross-sectional data.

Objectives:

This study investigates the structural neural correlates of speech onset delay by voxel-based morphometry (VBM) analysis and analyzes the possible age differences in cross-sectional and follow-up data.

Methods:

Right-handed, mandarin-speaking males who completed the MRI assessment at baseline and follow-up in a well-characterized cohort were included in this study. Structural MRI data from 33 autistic males with speech onset delay (ASD+SD), 37 autistic males without speech onset delay (ASD-SD), and 46 typically developing comparisons (TDC) were processed using VBM. The clinical diagnosis was further confirmed by Autism Diagnostic Interview-Revised (ADI-R) and Autism Diagnostic Observation Schedule. The speech onset delay was defined if the items in the ADI-R about the age of the first word after 24 months or first phrase after 33 months.

Results:

In the cross-sectional data of the participants’ first MRI study, smaller relative grey matter (GM) volume over the bilateral occipital-parietal lobe was noted when comparing ASD+SD with TDC and total autistic participants with TDC after including age as covariate. On the other hand, larger relative GM volumes over the bilateral inferior frontal cortex were noted when comparing ASD+SD with ASD-SD. We further sub-grouped the participants into children (age $< 13$ years) and adolescents (13 $< age < 18$ years) according to their age at baseline. The difference over the occipital-parietal lobe was noted in childhood, while the difference over the inferior frontal cortex was noted in the adolescent group. The follow-up data analysis from childhood to adolescence/young adulthood supported different developmental changes in the significant group-by-time interaction over the inferior frontal cortex and limbic area. Additionally, two clusters with significant group-by-time interaction were noted over the left cerebellum and the right middle temporal region. The age-adjusted residual GM volume of the inferior frontal cluster was significantly correlated with the verbal IQ within the autistic population but not the performance IQ.

Conclusions:

Our study found the structural neural correlates of speech onset delay within the autistic population. The age difference in cross-sectional structural imaging data was partly supported by the different developing changes in follow-up data. These identified neural correlates could serve as potential subgrouping markers within ASD. The findings also suggested that structural neural correlates, either diagnostic or
subgrouping markers of ASD, might differ by age and depend on developmental stage. Future studies about neural image markers should consider the age effects carefully.

410.123 (Poster) Acquiring MRI Scans in Preschool-Aged Children during Natural Sleep Is Effective across the Entire Autism Spectrum

S. M. Alarvanejad, B. Heath, D. S. Andrews, J. K. Lee, S. J. Rogers, D. G. Amaral and C. W. Nordahl, (1)UC Davis MIND Institute, Sacramento, CA, (2)Department of Psychiatry and Behavioral Sciences, University of California Davis, MIND Institute, ., Sacramento, CA, (3)Department of Psychiatry and Behavioral Sciences, MIND Institute, UC Davis Medical Center, Sacramento, CA, American Samoa, (4)Department of Psychiatry and Behavioral Sciences, University of California, Davis, MIND Institute, Sacramento, CA, (5)Department of Psychiatry and Behavioral Sciences, UC Davis The M.I.N.D. Institute, Sacramento, CA

Background: Young children have historically been underrepresented in autism neuroimaging research due to challenges in acquiring MRI scans without sedation or anesthesia. Scanning during natural sleep has become an increasingly popular strategy, but it is unclear whether factors such as sleep problems, developmental ability, and intensity of autistic features influence scanning success rates.

Objectives: To evaluate scan-acquisition success rates in a large cohort of autistic and non-autistic children evaluated between 2006-2022 and to identify participant characteristics that may influence scan-acquisition success.

Methods: Preschool-aged children (2-4 years of age) with autism spectrum disorder (ASD) and age-matched non-autistic typically developing (TD) children were enrolled in a longitudinal neuroimaging study. Diagnoses were confirmed upon study entry using the Autism Diagnostic Observation Schedule (ADOS) and Autism Diagnostic Interview-Revised (ADI-R). Children’s developmental abilities were assessed using the Mullen Scales of Early Development (MSEL). Information regarding each child’s behavioral challenges, adaptive functioning skills, sleep problems, and sensory sensitivities was collected through the parent-completed Child Behavior Checklist (CBCL), Vineland Adaptive Behavior Scales, Second Edition (VABS-II), Child Sleep Habits Questionnaire (CSHQ), and Short Sensory Profile (SSP), respectively. Parents also completed a demographic survey. Structural, diffusion-weighted, and resting state functional MRI sequences were acquired using a 3T Siemens scanner (total scan time ~40 min). Scans were conducted around the child’s usual bedtime. If scans were not acquired on the initial scan attempt, families were given the option to return another night to try again. Scanning success was categorized as being full (all sequences acquired), partial (at least one but not all sequences acquired), or unsuccessful (no sequences acquired). One-way ANOVA was used to evaluate whether specific participant characteristics influence scan-acquisition outcomes.

Results: The study sample comprised 511 children: 333 children with ASD (227 males/106 females) and 178 TD children (101 males/77 females). Children were between the ages of 2 and 5 years old at the time of their scan (mean age= 38.2 months). Overall, scans were acquired in 87.87% of children (58.32% completed the full scanning protocol, 29.55% partial) and were unsuccessful for 12.13%. Of families who returned for a second attempt, 72.9% were successful. Of the partial success scans, 21.2% were due to children sleeping on their side, which prevented the acquisition of diffusion-weighted and resting state sequences. When comparing children who successfully completed MRI acquisition (full or partial) to those who were unsuccessful, rates did not differ between ASD and non-ASD groups (p= 0.1297), between sexes (p= 0.2284), or by parental education (p= 0.6304). Within the ASD group, there were no differences between participants who had successful scans versus those with unsuccessful scans on ADOS calibrated severity scores, MSEL DQ scores, and CSHQ total scores (all p’s > .60). In addition, scan-acquisition success did not vary with VABS-II composite scores, SSP total scores, or CBCL internalizing or externalizing T scores (all p’s > .10).

Conclusions: MRI scanning during natural sleep is highly effective in preschool-aged children with diverse developmental abilities and support needs.

410.124 (Poster) Associations between Longitudinal Changes in Cortical Thickness and Restricted/Repetitive Behaviours in Adolescents with Autism Spectrum Disorder.

C. Gurr1, V. Bieneck, A. Bletsch, T. Schäfer, H. Seelameyer, C. M. Pretzsch, C. Ecker1 and E. Hantingen1, (1)Department of Child and Adolescent Psychiatry, Psychosomatics and Psychotherapy, University Hospital, Goethe University, Frankfurt, Germany, (2)Brain Imaging Center, Goethe University Frankfurt am Main, Frankfurt, Germany, (3)Forensic and Neurodevelopmental Sciences, IoPPN King’s College London, London, United Kingdom, (4)Department of Child and Adolescent Psychiatry, Psychosomatics and Psychotherapy, Goethe University, Frankfurt am Main, Frankfurt, Germany, (5)Department of Forensic and Neurodevelopmental Sciences, Institute of Psychiatry, Psychology and Neuroscience, King’s College London, London, United Kingdom, (6)Institut für Neuroradiologie, Goethe Universität, Universitätsklinikum, Frankfurt, Germany

Background: The neuroanatomy of autism spectrum disorder (ASD) shows highly heterogenous developmental trajectories across individuals 1,2. Likewise, the behavioural characteristics of ASD are changing across the lifespan 1, with puberty representing a challenging stage of life for individuals with ASD 1. However, there is limited knowledge on longitudinal relationships between brain and behaviour, as well as their genetic underpinnings.

Objectives: The aim of this study was to compare longitudinal trajectories of cortical thickness (CT) in adolescents with ASD to those in typically developing controls (TD), and to examine their association with intra-individual variation in restrictive and repetitive behaviours.
Background:
Autism Spectrum Disorder is a condition characterized by impairments in social communication and interaction (SCI), and restrictive and repetitive behaviors (RRB)\(^1\). Autism has been associated with differences in neuroanatomy, such as cortical thickness (CT) and Surface Area (SA)\(^\text{2,3}\), and differential gene expression\(^4\). However, the categorical conceptualization of autism used in most studies fails to represent its high clinical heterogeneity as well as autism symptoms in subclinical and neurotypical populations. Additionally, the SCI and RRB symptom domains are likely to be associated with alterations in different brain regions\(^5\), and potentially linked to distinct putative underlying mechanisms\(^6\).

Objectives:
This study’s aim was therefore to 1) investigate the differential associations of dimensional symptom severity in SCI and RRB with alterations in CT and SA, and to 2) establish their putative genomic underpinnings 3) across a combined autism and neurotypical sample.

Methods:
572 participants, aged 6-30 (332 with autism, 27.71% female; 240 typically developing (TD), 39.17% female) underwent structural MRI-scanning at 7 different sites\(^7\) using 3T head-scanners. CT and SA were extracted from T1-weighted volumetric images using FreeSurfer.
SCI and RRB were operationalized using a short-form of the Social Responsiveness Scale (SRS-16), and the Restricted and Repetitive Behaviour Scale (RBS-R). The association between symptom severity and neuroanatomy was investigated by regression of a general linear model with SRS-16 or RBS-R, sex, age, IQ, Site and Mean_CT or Total_SA as model terms. A gene expression decoding analysis was performed within Neurosynth and Neurovault, utilizing gene expression data from the Allen Human Brain Atlas to assess the spatial correlation between our neuroimaging t-map and the patterns of expression for each of 20,787 protein coding genes. The resulting gene list was tested for enrichment of genes known to be associated with autism on the genetic and transcriptomic level.

Results:

Following random-field-theory-based cluster-correction (p<.05, two-tailed), increased symptom severity in SCI was associated with decreased occipital CT, decreased frontal SA and increased SA in central and fusiform gyri. Increased RRB symptom severity was associated with decreased CT in paracentral and posterior cingulate, decreased frontal SA and increased SA in posterior cingulate and fusiform gyrus (see Fig.1). For the t-map of neuroanatomical associations with RRB, we observed a significant enrichment of CTX.M16.down that is downregulated in autism, a gene set previously related to neuronal firing rates. The SCI t-map showed high expression of CTX.M19.up that is upregulated in autism and previously identified to have an altered developmental trajectory in autism.

Conclusions:

The associated neuroanatomy, as well as their genomic underpinnings, seem to be different for SCI and RRB domain, suggesting distinct neuroanatomical and genomic markers for the two core autism symptom domains. Our findings might thus contribute to establishing neuroanatomical and genomic biomarkers for distinct autism symptom domains. Differentially considering dimensional measures of autism core symptoms therefore constitutes another step towards precision medicine in autism.

Cognition: Attention, Learning, Memory

Panel Discussion — COGNITION: ATTENTION, LEARNING, MEMORY

208 - The Behavioral and Neurobiological Basis of Impaired Memory in ASD: The Heterogeneous Patterns and Interventions

Panel Chair: Lang Chen, 500 El Camino Real, Santa Clara University, Santa Clara, CA

Discussant: Vinod Menon, Stanford University, Stanford, CA

Recent studies revealed profound memory dysfunctions in individuals with ASD across social and non-social domains beyond their characteristic socio-communicative dysfunctions. Given the critical role of memory in developing cognitive and social skills, we need to understand the behavioral and neurobiological basis of memory dysfunctions in ASD and the effectiveness of relevant interventions. In this panel, we will present novel research findings on (i) heterogenous pattern separation memory and aberrant hippocampal circuits in children with ASD (from Dr. Chen at Santa Clara University with with Dr. Menon at Stanford University), (ii) animal models of the hippocampus and its relation to social memory (from Dr. Gould at Princeton University), and (iii) two intervention studies to remediate memory dysfunctions in ASD (from Dr. Wantzen at Université Bourgogne Franche-Comté and Dr. Delage at Université de Genève). These studies pointed to the hippocampus as a critical neurobiological basis for the memory dysfunction for both social and non-social stimuli in ASD, and cognitive interventions could potentially improve their memory, social and language skills. This panel provides findings from diverse approaches (behavioral, cognitive, neuroimaging, and animal research) and links the neuroscientific findings to interventions for ASD, which will clearly be of broad interest to the INSAR attendants.

208.001 (Panel Discussion) The Role of the CA2 Region in Social Memory in Developing Shank3B Knockout Mice: Potential Relevance to Autism Spectrum Disorder

E. Gould and E. J. Diethorn, Princeton Neuroscience Institute, Princeton, NJ

Background: Numerous studies have found that the CA2 region has unique molecular characteristics, including high expression of perineuronal nets (PNNs), specialized extracellular matrix structures known to regulate plasticity. The CA2 has also been shown to play an important role in social recognition memory, an important ability across mammalian species. Studies suggest that some people with Autism Spectrum Disorder (ASD) have difficulty recognizing familiar faces and voices. The etiology of ASD appears to be multifactorial, with the disorder arising through a complex interaction between genes and the environment. Genome wide association studies have identified...
multiple genes linked to ASD, including SHANK3, whose mutation can cause Phelan-McDermid syndrome (PDS) and FMR1, whose mutation can cause Fragile X syndrome (FXS). Both PDS and FXS can present with symptoms of ASD. Mouse models have been generated by transgenic ‘knock out’ of these genes, and both Shank3B and Fmr1 KO mice exhibit behavioral phenotypes that are relevant to ASD, such as excessive repetitive behavior and deficits in social interactions.

**Objectives:** Since ASD is a neurodevelopmental disorder, we sought to determine whether developmental trajectories of CA2-dependent social discrimination abilities are affected in Shank3B and Fmr1 KO mice and, if so, to probe the neural underpinnings of this dysfunction. We also sought to determine whether interventions in developing Shank3B KO mice are capable of restoring this function.

**Methods:** Wildtype (WT), Shank3B KO and Fmr1 KO mice of both sexes were used for these studies. Mice were tested on social discrimination tests during development and in adulthood. Brains were examined for potential differences in PNNs using labeling with the plant lectin Wisteria Floribunda Agglutinin and Aggrecan, and for potential differences in CA2 excitatory innervation using labeling for vesicular glutamate transporter vGLUT2. Manipulations of PNNs in the CA2 were conducted with the degradative enzyme chondroitinase ABC (chABC) in developing Shank3B KO mice to determine whether atypical PNNs contribute to social memory impairment.

**Results:** We found that WT mice can discriminate between novel and familiar mice around postnatal day 14 (P14), demonstrating a preference for novel peers, while both Shank3B and Fmr1 KO mice lack the ability to socially discriminate at this time, although Fmr1 KO mice eventually attain this function in adulthood. At P14, Shank3B KO mice have elevated CA2 PNNs relative to WTs, while Fmr1 KO mice have diminished CA2 PNNs. Atypical PNNs may alter CA2 afferents, with vGLUT2 intensity elevated in both models compared to WTs. In Shank3B KO mice, reducing CA2 PNNs restored social discrimination function and emerging novelty preference during development (Figure 1).

**Conclusions:** Our findings suggest that social discrimination abilities arise early in WT mice, but not in Shank3B KO and Fmr1 KO mice. Diminishing CA2 PNNs down to healthy levels in developing Shank3B KO mice improves social discrimination and allows for emerging social novelty preference, indicating points of intervention for enhancing social memory in this mouse model. The extent to which these findings pertain to humans with ASD remains unknown.

---

**208.002 (Panel Discussion) Atypical and Heterogeneous Pattern Separation Memory Abilities and Aberrant Hippocampal Circuits in Children with ASD**

*L. Chen*, J. Liu and V. Menon*, (1)500 El Camino Real, Santa Clara University, Santa Clara, CA, (2)Neuroscience Program, Santa Clara University, Santa Clara, CA, (3)Stanford University, Stanford, CA

**Background:** Pattern separation memory, a critical ability to form distinct memories from similar occurrences, is strongly associated with the function of hippocampus. Researchers have suggested that atypical pattern separation memory was associated with various clinical disorders including Autism spectrum disorders (ASD). Although recent studies have revealed a broad episodic memory impairment in individuals with ASD compared to their typically-developing (TD) peers, little is known about their pattern separation memory and the potential abnormality in hippocampal circuits in affected individuals, especially in children with ASD.

**Objectives:** Using a well-established behavioral paradigm for studying pattern separation memory, we aimed to show that children with ASD had atypical and heterogeneous pattern separation memory abilities compared to their TD peers. In addition, we aimed to reveal the dysfunctions in hippocampal circuits that were associated with their memory deficits in ASD.

**Methods:** Sixty-nine children with ASD (10F; M\text{age}=10.08, SD\text{age}=1.25) and 57 well-matched TDs (9F; M\text{age}=10.04, SD\text{age}=1.21) were tested on a pattern separation task (BPS-O), in which children were first shown images of everyday objects, and then performed a surprise memory test to identify “Old”, “Similar”, or “New” items from a new series of images (1/3 being repeated Target items, 1/3 being perceptually similar but not identical Lure items, and 1/3 being complete new Foil items). We first compared the accuracy between ASD and TD in the BPS-O task, and then derived a metric, i.e., $1-p$\text{(Old) for Target, Lure of varying similarity, and Foil items, to characterize subgroups of distinct profiles of pattern separation memory in ASD with a data-driven clustering approach. A subset of these children (25 in ASD and 29 in TD; well-matched on gender, age and IQ) also completed a resting-state fMRI scan, and we examined the functional connectivity of bilateral hippocampus seeds (+/-24, -14, -20) as well as its relationship to memory deficits across individual with ASD.

**Results:** We showed an overall impairment in pattern separation memory for nonsocial contents in children with ASD compared to their TD peers (Figure 1A). More interestingly, with a data-driven clustering analysis, we revealed three distinct profiles of atypical pattern separation memory performance in ASD (Figure 1B). Moreover, we observed hyper-connectivity of bilateral hippocampus with fusiform gyrus, thalamus, cerebellum, medial prefrontal cortex, and anterior cingulate cortex in ASD compared to TD, and the aberrant hippocampal connectivity was predictive to the memory abilities across individuals with ASD (Figure 2).

**Conclusions:** Our study demonstrated novel evidence on impaired pattern separation memory in children with ASD in the nonsocial knowledge domain, and there existed distinct subgroups with different profiles of atypical pattern separation memory. Findings from the resting-state functional connectivity also suggested that children with ASD had excessive brain connectivity of bilateral hippocampus,
converging on an observation that dysfunctions in hippocampus may underlie the memory impairment in children with ASD. This work highlighted the importance of focusing on the memory functions in ASD for future interventions, particularly aiming to remediate the atypical hippocampal circuits.

**208.003 (Panel Discussion) A Pilot Cognitive Intervention Program in ASD: Autobiographical Memory As a Tool for Improving Social Interaction**

**P. Wantzen** and B. Guillery-Girard, (1)LEAD-Université Bourgogne, Caen, France, (2)LEAD, CNRS UMR 5022, Université Bourgogne Franche-Comté, Dijon, France, (3)Normandie Univ, UNICAEN, PSL Research University, EPHE, INSERM, U1077, CHU de Caen, Neuropsychologie et Imagerie de la Mémoire Humaine, 14000 Caen, France, Caen, France

**Background:** Autobiographical memory (AM) is closely linked to self-identity and as a fundamental tool in social functioning. The AM is impaired in Autism spectrum Disorders (ASD), with reduced retrieval, specificity, and elaboration. Atypical AM makes it harder for individuals to initiate, develop, and maintain social interactions. Reduced social relations do not allow the acquisition of sufficient knowledge about oneself and disrupt the self-related information consolidation in memory. This fragmented consolidation will, in turn, impact the adaptation to new situations. For these reasons, AM may be a relevant tool for rehabilitation programs in ASD.

**Objectives:** We developed a cognitive intervention focusing on social interactions through AM. This program aimed to improve conversational skills and social interactions in adolescents with ASD. The originality of the present study lies in using the strengthening of AM as an adapted ecological communication tool to improve social inclusion and social identity.

**Methods:** We designed a cognitive intervention program consisting of individual and group sessions aimed to improve AM. The experimental intervention consisted of 8 weekly 90-min sessions. ASD participants underwent pre- (T1) and post-assessments (T2) of AM, and a general cognitive evaluation. The 30-min individual sessions were conducted with a therapeutic education approach and included personalized follow-up. During the sessions, participants focused on their specific difficulties. Group sessions were designed to improve participants' narrative and conversational skills, by encouraging them to share personal memories and knowledge, thus creating common social interaction bonds. We conducted a pilot study among three adolescents with high-functioning ASD, aged 12, 16, and 17 years (two males). Three other participants with ASD, not included in the rehabilitation program, were randomly selected for a comparison follow-up at T1 and T2. We compared each ASD participant's scores with scores of 13 age- and intelligence-matched controls and calculated z-scores.

**Results:** The first results seem to point to a beneficial effect of the workshops on the social relationships of adolescents with ASD. We showed at T2 increased extra-family narrative references and more markers of social integration. This result may reflect a social openness, beyond the family framework, with memory retrieval including more people. Qualitative observations showed that social interactions were facilitated during the intervention: adolescents spontaneously asked each other and increasingly took the initiative in interactions. For the three ASD participants who did not follow our intervention, we showed limited changes after one year concerning the narratives on the social spheres.

**Conclusions:** Although these results are preliminary, they are also encouraging. Our study of autobiographical narratives yielded interesting findings about how AM can be targeted in rehabilitation programs as a vector of social interaction. This approach allowed participants to gain a better understanding of their personal identity and relations with others through the sharing of memories. Consequently, the interventions helped them develop and reinforce their social identity and integration.

**208.004 (Panel Discussion) Impact of Working Memory Training on Syntax and Processing Speed in Children with ASD**

**H. Delage** and S. Durrleman, (1)Department of Psycholinguistics and Speech-Language Therapy, Université de Genève, Genève, Switzerland, (2)Department of Linguistics, Université de Genève, Geneva, Switzerland, (3)Department of Medicine, University of Fribourg, Fribourg, Switzerland

**Background:** In addition to persistent deficits in communication and social interaction, children with Autism Spectrum Disorders (ASD) have been reported to present weaknesses in complex syntax (e.g., Tuller et al., 2017) and working memory (WM) (e.g., Habib et al., 2019). Some empirical evidence suggests that these two deficits are closely related (Schuh & Eigsti, 2012; Durrleman & Delage, 2016). In previous work, we have studied the effects of WM training on the syntactic abilities of 32 children aged 6-12 with another condition affecting both of these domains: Developmental Language Disorder (DLD). We administered training via a novel iPad program, Magic Memory, which targets simple and complex spans. Participants benefited from this training to significantly improve on both WM and expressive syntax, which was not the case of age-matched children with DLD who received an alternative, global scholastic training (Author et al., 2019, 2021).

**Objectives:** Pursuing our investigation of the effects of WM training on syntax, this work extended the methods of the DLD WM training study to a population of children with ASD, using our Magic Memory training program. We predicted a significant increase in working memory scores following training as well as a significant improvement in complex syntax. This study also included attentional measures, in light of the observation that WM is closely linked to the attentional system (e.g., Veer et al., 2017).
and children with ASD are known to experience difficulties in executive functions. Given that intensive training might have a specific impact on attention, we also predicted an improved performance in attentional measures after training. Finally, participants completed a long-term follow-up three months after training. We predicted that potential effects on WM, syntax and attention would be maintained after such a delay.

Methods: Thirty French-speaking children with ASD aged 5 to 11 were trained on WM via Magic Memory. Baseline (T1) abilities were established via pre-tests one week prior to the first training session, comprising two 45-minute sessions to assess memory, attentional skills and syntactic abilities (using elicited production, repetition and comprehension of complex sentences). Participants then completed the 8-week intensive training regimen of three 30-minute sessions per week for a total of 12 hours. Tests were completed again one week after training (T2) with exactly the same structures but different items, matched in frequency, length and complexity, to avoid practice effects. Post-tests (T3) were administered three months after T2, to assess the long-term stability of effects.

Results: Results showed a direct effect of the training with significant improvement on untrained WM tasks, as well as transfer effects with better abilities in processing speed and expressive/receptive syntax. Moreover, long-term transfer effects were similarly positive, with improvements maintained on all measures showing T1 to T2 gains, whether in the areas of syntax or attentional skills.

Conclusions: These exciting findings provide impetus for further studies of working memory interventions. Thereafter, the training materials should be made available to children with WM or syntactic impairments, regardless of the proximal source of those impairments (e.g., DLD or ASD).

ORAL SESSION — COGNITION: ATTENTION, LEARNING, MEMORY

319 - Perception of Social & Non-Social Information

Moderator: Sebastian Gaigg, City, University of London, London, UNITED KINGDOM

319.001 (Oral) Autistic Group Differences in Social Attention AreMagnified By Real-World Perceptual Load and Linguistic Features

A. J. Haskins1, J. Menich2, T. L. Botch3, B. D. Garcia4, A. L. Burrows5 and C. Robertson1, (1)Dartmouth College, Hanover, NH, (2)Massachusetts Institute of Technology, Cambridge, MA, (3)Psychological and Brain Sciences, Dartmouth, Hanover, NH

Background: Autistic adults report experiencing difficulty with both social interaction and sensory processing in everyday life, but little is known about the causal relationship between these disparate functional domains. In the present study, we sought to understand how a core characteristic of the autistic phenotype—reduced social attention—is impacted by the complex multisensory signals and linguistic cues present in real-world environments.

Objectives:

1. Test the hypothesis that reductions in social attention associated with autism would be magnified by increasing real-world perceptual load (e.g., motion, multisensory cues).
2. Characterize the relationship between social attentional dynamics and autistic traits within individual participants.
3. Examine the temporal relationship between social attention and semantic meaning imparted by evolving linguistic cues from agents in the environment.

Methods: Adult participants (N = 40; 19 autistic) viewed a diverse set of 360° real-world scenes via a head-mounted virtual reality display in three experimental conditions. Across these conditions (static, dynamic, multisensory), we systematically varied perceptual load while holding constant the social and semantic information present in each scene. On each trial, participants’ gaze was measured via in-headset eyetracking. To quantify participants’ attention, we generated a continuous model of social information for each scene by combining rich, contextually informed judgments from a set of online human raters with a novel computational language modeling approach.

Results: First, we demonstrate that reduced social attention is not a static signature of the autistic phenotype. Though all participants increasingly allocated their attention toward social information with increasing perceptual load, we observed a significant interaction between group and condition (F(2,1680) = 3.82, p = 0.022), such that each increase across conditions was smaller for group of autistic, relative to non-autistic, participants. Crucially, this pattern was specific to the social domain: we did not observe differential impacts of perceptual load on attention directed toward nonsocial semantic (i.e., object, place) information or low-level fixation behavior (i.e., overall fixation frequency or duration). Second, we found that within participants, the susceptibility of social attention to perceptual load (i.e., the difference in attention between high- and low-load conditions) was significantly correlated with self-reported autistic traits, as measured by the Autism Spectrum Quotient (r = −0.53, p < 0.001). Finally, in a follow-up exploratory analysis, we explored how visual attention evolves over time in coordination with the semantic meaning imparted by real-world linguistic cues. We find a reduction in social attention for autistic relative to non-autistic participants that specifically precedes words of high social relevance (p = 0.006).
Conclusions: Here we provide a direct link between social and sensory processing in autism. Our results suggest that autistic group differences in social attention are not a static phenotypic signature, but instead are modulated by increasing perceptual load of real-world environments. Moreover, we provide evidence that group differences in social attention are temporally linked to semantic meaning embedded within an evolving stream of linguistic cues from social agents in the environment. All in all, our results provide a nuanced characterization of attentional divergence in autism as a cumulative, multimodal, and integrative process.

319.002 (Oral) Multimodal Parent Behaviors during Joint Attention Result in Less Attentional Boost in ASD
(1)Psychological and Brain Sciences, Indiana University - Bloomington, Bloomington, IN, (2)Division of Developmental and Behavioral Pediatrics, Cincinnati Children's Hospital Medical Center, Cincinnati, OH, (3)Cincinnati Children's Hospital Medical Center, Cincinnati, OH, (4)Psychiatry, Cincinnati Children's Hospital Medical Center, Cincinnati, OH, (5)Cognitive Science Program, University of Texas at Austin, Bloomington, IN, (6)Psychological and Brain Sciences, Indiana University, Bloomington, IN

Background: Joint attention (JA), broadly defined as two individuals looking to the same object at the same time, is characterized by a higher frequency of multimodal behaviors in typically developing (TD) children during toy play, particularly more touch of the object (Yu & Smith, 2016). TD children extend the duration of their attention to toys when they are in JA with a parent (Yu & Smith, 2016), especially when the parent is talking about or holding the toy (Yurkovic-Harding et al., 2022). Our recent work has shown that children with autism spectrum disorder (ASD) are able to achieve JA at similar rates and through similar pathways as TD children during toy play (Yurkovic-Harding et al., 2022), but it remains unknown how multimodal parent and child behaviors may modulate JA during naturalistic toy play in ASD.

Objectives: We first sought to use a data-driven approach to identify and characterize distinct subtypes of multimodal behaviors during JA looks. We then aimed to understand if children with ASD and TD children differed in their ability to use these behaviors to engage in JA and to extend their own attention.

Methods: Parents and their 24-48mo children (ASD=17; TD=15) played with toys while wearing head-mounted eye-trackers (Figure 1a). We identified child looks with 0.5s of JA or more and calculated each look’s overlap with child touch and parent look, look to child face, touch, and naming (Figure 1b). An unsupervised clustering approach was used to identify distinct subtypes of multimodality during child JA looks. Data were analyzed using generalized linear mixed effects models.

Results: Looks were classified into one of three clusters (Figure 2a): “Sparse” looks (few behaviors), “Parent” looks (more parent look, touch, talk), and “Child” looks (more child touch). There was a significant interaction of group and cluster on looks per minute (Figure 2b) – children with ASD used the “Parent” cluster less than TD children (F(1,30)=5.27, p=0.03). There was also a significant interaction of group and cluster on duration (F(2,761)=2396.51, p<0.01; Figure 2c). – TD children had a significant boost in look duration from the “Sparse” to the “Parent” cluster (t(214)=2.03, p=0.04), while children with ASD did not (t(147)=0.48, p=0.63). Additionally, “Parent” looks from children with ASD were shorter than those from TD children (F(1,243)=5.15, p=0.02). For both groups, looks in the “Child” cluster were the longest (all p<0.01). Of note, looks with JA were significantly longer than looks without JA for both groups (F(1,2155)=278.34, p<0.01).

Conclusions: Children with ASD were sensitivity to JA, as evidenced by longer look durations overall. However, children with ASD engaged less frequently and for shorter durations when the parent was “directing” the action (i.e., looking to, touching, and talking about a toy). The similar durations of “Parent” and “Sparse” looks suggests that children with ASD are less able to use parent behaviors to extend their own attention (i.e., attentional boost). Instead, children with ASD more frequently followed their own self-generated cues (i.e., hand-eye coordination) and were able to extend their attention through this multimodal behavioral pattern.

319.003 (Oral) Change Blindness and Autistic Traits - a Twin Study.
(1)Center for Neurodevelopmental Disorders at Karolinska Institutet (KIND), Department of Women’s and Children’s Health, Karolinska Institutet, Stockholm, Sweden, (2)Curtin Autism Research Group, Curtin School of Allied Health, Curtin University, Perth, Australia, (3)Center for Psychiatry Research, Region Stockholm, Stockholm, Sweden, (4)Swedish Collegium for Advanced Study (SCAS), Uppsala, Sweden

Background: Atypical sensory perception is common in individuals with autism spectrum condition (ASC). In particular, autistic traits have been associated with a stronger prevalence to process local over global sensory information, which can be advantageous for perceptual processing tasks that require high attention to detail (e.g., Mottron et al., 2013). Thus, in this study we analyzed how autistic traits influence performance in two different versions of the Change Blindness task where participants are asked to find small alterations in pairs of otherwise identical visual scenes. We modeled these associations in twins, both across the entire cohort and within twin pairs where they are implicitly controlled for familial factors.

Objectives: To further our understanding on perceptual characteristics linked to autistic traits.
Methods: Thirty-six twin pairs (N=72) participated in the experiment so far (mean age ± std =24.4±4.3) from which 9 pairs were discordant or concordant for ASC diagnosis (one or both twins fulfilling diagnostic criteria). In the Change Blindness task, visual scenes where one object was removed from one image were presented (Figure 2). In the original version of the task ("flicker"), the two images were presented one after the other (240ms) in cycles with a blank image in between (80ms). In the "side-by-side" version, both images were presented side by side. Participants had a maximum of 30 s to identify the missing/present item. Participants were eye-tracked while completing the task. Autistic traits were quantified by means of the Autism-Spectrum Quotient (AQ). Data was analyzed with linear-mixed models and a conditional regression to compare twins within pairs.

Results: Across the entire sample, autistic traits were associated with faster response times in the side-by-side condition ($\chi^2=5.53, df=1, p=.019$) where, on average, response times decreased by 47ms for every point increase in AQ (95%CI [−93; −6]) (Figure 1). At the same time, there were no differences in accuracy (i.e., proportion of correct trials) ($\chi^2=.09, df=1, p=.761$) and, therefore, faster responses could not be attributed to a speed-accuracy trade-off. In contrast, there was no significant relationship between autistic traits and performance in the flicker condition (all $p$s >.35). Conditional linear regression revealed that the twins with higher autistic traits showed a trend towards faster responses compared to their twins ($b=-.042, df=30, z=-1.93, p=.053$) with no drop in accuracy ($b=-.003, df=30, z=1.38, p=.017$). In contrast, autistic traits were associated with slower responses in the flicker task within-twin pairs ($b=.059, df=30, z=2.653, p=.008$) but no drop in accuracy ($b=-.002, df=30, z=-1.508, p=.132$).

Conclusions: Higher autistic traits were associated with better (faster) performance in the side-by-side condition – where individuals could inspect the images freely – suggesting a potentially more efficient search strategy in those with elevated autistic traits. Within twin pairs, where a large number of factors is implicitly controlled (family background, age, etc), we found worse/slower performance in association with autistic traits in the flicker condition. Hence, autistic traits can predict better or worse visual search performance depending on the characteristics of the task at hand and the level of control over familial factors.

319.004 (Oral) A Bayesian Modeling Investigation of Perceptual and Meta-Cognitive Decision Making in Autism

L. Fazioli, B. S. Hadad, R. Denison and A. Yashar, (1)Department of Special Education, University of Haifa, Haifa, Israel, (2)Special Education, University of Haifa, Haifa, Israel, (3)Department of Psychological & Brain Sciences, Boston University, Boston, MA

Background:

Recently there has been a growing interest in sensory processing in Autism Spectrum Disorder (ASD) as a core phenotype. Sensory symptoms serve as an independent diagnostic criterion, show a persistent relationship to clinical measurement of higher-level social behavior, and are evident early in development. Perceptual decision-making is a key process at the interface of perception and cognition. Thus, investigation of perceptual decision-making may shed light on the core mechanisms of ASD and their role in altering both simple and complex behaviors. However, little is known about perceptual decision-making in ASD.

Objectives:

Here, using a Bayesian inference framework, we systematically investigated the factors affecting perceptual and metacognitive decisions in ASD. Specifically, we tested the effects of expectation (prior), sensory evidence (likelihood), and reward (cost-function) information on decision criteria in orientation categorization task (perception) and decision confidence judgment (i.e., meta-cognition).

Methods:

The experiments include participants diagnosed with ASD (n = 59) and typically developed (NT) participants (n = 83). Observers simultaneously reported the orientation category of Gabor stimulus and their decision confidence using the keyboard (Fig 1). In the two studies manipulating the prior and the reward, the stimulus orientation was drawn from two Gaussian distributions with means $\mu_A = -4^\circ$ and $\mu_B = 4^\circ$, and standard deviations $\sigma_A = \sigma_B = 5^\circ$, which induced an overlap between the two distributions. To manipulate prior, we varied the base-rate probability of each category. To manipulate the cost function, we varied the reward between categories. To manipulate the likelihood, we varied the stimulus contrast in every experiment. Finally, in a third study, we used an embedded paradigm to examine the criteria shift based on likelihood. We drew the two Gaussian distributions with the same mean $\mu_A = 0^\circ$ and two standard deviations $\sigma_A = 3^\circ$ and $\sigma_B = 12^\circ$. This design requires distinguishing a more specific from a more general perceptual category, which typically leads to criteria shift as contrasts increases.

Results:

Both groups shifted decision criteria to favor the category with a higher base rate or reward, particularly when contrast (sensory evidence) was low (Fig 2A). An optimal observer analysis revealed that both ASD and NT were suboptimal to the same extent (Fig 2B). Finally, the ASD group showed typical abilities in metacognitively assessing their performances. The recruitment of participants for the likelihood
manipulation study is ongoing. Preliminary results show that ASD participants have similar abilities to integrate the likelihood information to adapt their decision criteria.

Conclusions:

Contrary to recent views, individuals with ASD integrate prior expectation with sensory evidence similarly to NT individuals. Moreover, both groups integrate prior and reward information with stimulus likelihood in a suboptimal manner, which is inconsistent with the Bayesian theory. In the context of a visual task, the metacognitive abilities also appear to be preserved. Our study suggests that reduced prior integration or decision suboptimality cannot explain atypical perception in ASD.

411 - Cognition: Attention, Learning, Memory I

411.127 (Poster) A Scoping Review on Immersive VR Research in Neurodevelopmental Disorders
S. Paavola1, M. Laakso2 and S. Saalaste3, (1)Faculty of Medicine, Department of Psychology and Logopedics, University of Helsinki, Helsinki, Finland, (2)Helsinki University Hospital, New Children’s Hospital, Child Neurology, Helsinki, Finland, (3)Faculty of Medicine, Department of Psychology and Logopedics, University of Helsinki, Helsinki, Finland

Background: Use of immersive virtual reality (IVR) in the assessment and intervention of neurodevelopmental disorders (NDDs) is growing fast. We will offer here a general view on the results of this research. According to ICD-11, NDDs are behavioral and cognitive disorders that arise during the developmental period (WHO, 2018). They may involve atypical development of intellectual, social, and linguistic skills (ICD-11), and lead to diagnoses such as disorders of intellectual development, developmental speech and language disorders, autism spectrum disorder (ASD), developmental learning disorder, and attention deficit hyperactivity disorder (ADHD). IVR allows the recreation of controlled real-life situations with high fidelity, sense of presence in 3D virtual environment, and measurement in real time. IVR is most commonly achieved with head mounted displays (HMDs) and cave automatic virtual environments, CAVEs.

Objectives: The aim was to analyze research on IVR assessment and intervention in NDDs to examine what interventions affect functioning in everyday life, and whether human guidance, besides IVR, is essential in the generalization process. Furthermore, we assessed the quality of the research.

Methods: The methods were reported according to PRISMA scoping review guidelines. The data search was performed in June 2021 in Scopus, Ovid PsycINFO and Web of Science. The search terms of NDDs were based on ICD-11. We included studies with children and adolescents; NDDs and IVR intervention or assessment; subjects, methods, and results reported and full text available, in English, from 2010 to June 2021. In March 2022 we used also Iris.ai (AI-powered search tool) and Google Scholar to search for relevant articles published after 2020.

Results: Database search resulted in 1102 papers of which we included 34 articles. IVR was mostly used in connection with ASD for assessment of and intervention in social skills (Figure 1.), and in ADHD for assessment of executive performance. Diagnostic measures varied or were not available, and the level of evidence was generally observational/descriptive (Joanna Briggs Institute Levels of Evidence, Figure 2.). Furthermore, few studies reported on feasibility and user experience and even fewer on human guidance and the generalization of intervention to everyday life. Our results suggest that human guidance during and after immersive VR may be crucial for generalization of skills. More research on IVR in other NDDs is needed, e.g., there were no search results on IVR and developmental language disorder (DLD).

Conclusions: IVR intervention can capture behavioral change, acting as an objective measurement tool, and should be broadened to target more NDDs. IVR makes it possible to practice complex social skills in a controlled situation close to daily life. Generalization of the IVR interventions was analyzed only in a few studies, with small groups of participants and variable designs, which limits the conclusions. Active human trainers and ecologically valid tasks in IVR involve the child in interaction and may help to customize the intervention for the individual. Participatory guidance may in fact, act as a bridge from IVR to real life, supporting the gaining and generalization of new skills for social communication. In future studies, this should be examined in more detail.

411.128 (Poster) A Transdiagnostic Profile of Executive Function in Children with Neurodevelopmental Conditions: A Systematic Review and Multilevel Analysis.
A. Sadozai1, E. A. Demetriou2, C. Sun3, A. Lampit4, K. A. Boulton5 and A. J. Guastella5, (1)Faculty of Medicine and Health, University of Sydney, Sydney, NSW, Australia, (2)University of Sydney, Camperdown, NSW, Australia, (3)University of Melbourne, Melbourne, VIC, Australia, (4)Brain and Mind Centre, Children’s Hospital Westmead Clinical School, Faculty of Medicine and Health, University of Sydney, Sydney, NSW, Australia, (5)Brain and Mind Centre and Children’s Hospital Westmead, Sydney, NSW, Australia
Background:

Executive function (EF) impairments have been found in many child neurodevelopmental conditions (NDCs). There is limited research examining the potential of EF as a transdiagnostic feature of NDCs and whether EF domains can differentiate NDCs.

Objectives:

The primary objectives of this meta-analysis were to examine EF outcomes across NDCs, to examine moderators of this effect, and to test differentiating EF impairments between NDCs.

Methods:

A systematic review and meta-analysis of EF across paediatric neurodevelopmental conditions was conducted. In line with PRISMA guidelines, a systematic literature review was carried out in MEDLINE, EMBASE and PsychInfo using a selection of relevant terms and covered the period of January 1980 to April 2022. The review was registered with PROSPERO (CRD42020210785). Of 175 identified studies, 96 met selection criteria. Two independent reviewers conducted study screening and assessed against the inclusion criteria. This included all studies that measured EF using established tests in participants under 18 years of age and describing populations comparing two or more NDCs. Methodology followed the PRISMA guidelines. Data extraction and risk of bias assessment was conducted by two independent reviewers. Data was pooled using a random-effects model. Outcomes across seven EF domains included attention, fluency, set shifting, set switching, response inhibition, planning and working memory. Main outcomes included scores on performance and informant-based EF measures. Analyses was conducted using the metafor package in R.

Results: A moderate effect size of EF impairment across all NDCs was found (g=0.70), in comparison to control. Younger children showed larger effect sizes of impairment, as did informant measures of EF. Children with ADHD showed greater problems with attention and response inhibition, children with autism showed larger impairments in set-shifting, while children with LD showed evidence of greater impairments in set-switching.

Conclusions:

EF impairment is a transdiagnostic feature of NDCs that is likely underpinned by accompanying divergence in brain development. Findings support the prioritisation of transdiagnostic approaches to EF delay in NDCs using longitudinal and intervention studies to improve life outcomes for these children.

411.129 (Poster) Altered Perception of Faces in ASD: Perceptual Biases Reveal Weaker Internal Representation of the “Typical” Average Face

M. Hartston\textsuperscript{1}, G. Avidan\textsuperscript{2}, T. Bash Lulav\textsuperscript{3}, Y. Goldstein-Marcusohn\textsuperscript{4} and B. S. Hadad\textsuperscript{5}, (1)Special Needs, University of Haifa, Haifa, Israel, (2)Department of Psychology, Ben-Gurion University of the Negev, Beer Sheva, Israel; Beer Sheva, Israel, (3)Department of Psychology, Ben-Gurion University of the Negev, Beer Sheva, Israel; Beer Sheva, Israel, (4)University of Haifa, Haifa, Israel, (5)Special Education, University of Haifa, Haifa, Israel

Background:

Atypical perception has been widely reported in Autistic Spectrum Disorders (ASD), and deficits in face recognition skills, in particular, are argued to be associated with social impairments experienced by these individuals. We have recently shown that these face processing deficits arise from perceptual alterations rather than being solely memory based. Moreover, face representations in ASD show reduced inversion and other-race effects suggesting that their facial processing is less refined by long-term statistics. However, the role of experience-based effects in these deficits is still unknown.

Objectives:

Here, we systematically investigated the effect of different timescales of stimulus history on face discrimination in ASD: the effect of (a) accumulated stimulus history given throughout the experiment, and (b) short-term history of stimuli presented on recent trials. These exposure-based effects were compared between own- and other-race faces to examine possible interactions between the statistics given in the experiment and life-long exposure to faces.

Methods:

We used a regression to the mean (RTM) paradigm to quantitatively measure the integration of stimulus statistics within face processing. Typically developed (TD) and ASD individuals performed a two-interval forced choice discrimination task between two faces presented in
succession (Fig 1a). Faces were sampled from a normal distribution around the mean of a sample of 100 morph levels created from two faces (Fig 1b). One half the trials contained the same face, and half were different faces that varied in morph range (Fig 1d). To examine the acquisition of the stimulus history, we tested the contraction of perceptual judgments towards the mean of the distribution (Fig 1c). Different distributions were created for own- and other-race faces.

Results:

TD individuals displayed greater regression effects, such that representations of current faces were biased by prior ones, significantly more for other-race faces than for own-race faces. The dynamics of the perceptual bias investigated by trial-by-trial performance further indicated greater bias by long-term stimulus statistics for own-race faces than for other-race faces. Individuals with ASD displayed overall weaker face discrimination abilities; yet, of most interest, face representations were refined by stimulus statistics, and were equally biased for own- and other race faces. Biases by recent trials equally contributed to performance as long-term statistics, indicating weaker internal model of a “typical” averaged face, even for the more frequently encountered faces (own race). See Fig 2.

Conclusions:

Our findings suggest modulations in the mechanism by which stimulus history affects perceptual representations of faces in autism. The weaker face representations displayed by individuals with ASD were considerably refined by the accumulated stimulus history provided during the experiment. Moreover, contrary to TD, recent trials equally contributed to performance as long-term statistics, indicating weaker internal model of the averaged face, even for own-race faces. The findings provide evidence of reduced specialization of the autistic perceptual system to the more frequently encountered stimulation. This has implications for day-to-day interactions within ASD and encourages therapeutic consideration of how this face processing deficit can and should be treated.

411.130 (Poster) Atypical Processing of Periodicity and Formant Structure of Vowels in the Auditory Cortex of Children with ASD. K. A. Fadeeva, A. O. Prokofyev, D. E. Goiaeva, T. S. Obukhova, T. Ovsyannikova, T. A. Stroganova and E. V. Orekhova. (1) MEG-Center, Moscow University of Psychology and Education (MSUPE), Moscow, Russian Federation, (2) MEG-Center, University of Gothenburg, Moscow, RUSSIA

Background: Speech delay and/or atypical speech are common in children with autism spectrum disorders (ASD) and may, at least partly, stem from abnormal processing of the basic features of speech sounds. Vowels are the most important category of voiced sounds, as they play a crucial role in speech recognition. The identity of a vowel is determined by its formant structure (‘vowelness’), while periodicity (pitch) characterizes a speaker’s identity and helps to track conversation in a noisy environment. These basic characteristics of vowels are detected by the auditory cortex automatically at the early stages of the sound processing stream. It is unknown whether such automatic processing of vowel features is altered in ASD.

Objectives: Here we used magnetoencephalography (MEG) to investigate whether the processing of vowel formant structure and periodicity pitch is atypical in the auditory cortex of children with ASD.

Methods: We independently manipulated the periodicity and formant structure of vowels while measuring auditory cortex responses using MEG in 26 boys with ASD and 20 typically developing (TD) control boys. Groups were matched by age (7-12 years), but not by IQ (KABC-II MPI IQ in TD: 117±15; ASD: 83±17). Subjects watched a silent movie and listened passively to synthetic vowels (‘periodic vowels’) interspersed with spectrally complex sounds matched by loudness and temporal characteristics and characterized either by 83 Hz periodicity (‘periodic non-vowels’), or formant structure (‘non-periodic vowels’), or neither of these qualities (control sound). The duration of all sounds was 800 ms and ISI varied between 500 and 800 ms. Periodic and non-periodic sounds characterized by formant structure were perceived as vowels, while those without formant structure (both periodic and non-periodic ones) were perceived as noise. We localized the auditory cortex responses using individual MRI and distributed source modeling. To reveal the effects of periodicity, ‘vowelness’, or their combination on neural activity (differential responses), we subtracted the response evoked by the control stimuli from the response to respective test stimuli.

Results: All types of sounds evoked typical ‘child-specific’ transient auditory components (Pm100, Nm200), followed by a ‘negative’ sustained field (SF). In both ASD and TD groups, the presence of periodicity and/or formant structure enhanced the sustained negative source current in auditory cortical areas. This sustained differential response started earlier than 100 ms after stimulus onset and lasted for at least 300 ms (for ‘vowelness’) or longer (for periodicity). In children with ASD, the negative differential responses to ‘vowelness’ and periodicity in both hemispheres were atypically reduced in 100-200, 200-300 and 300-400 ms intervals. In the left hemisphere, higher amplitudes of differential responses to periodic and non-periodic vowels predicted higher IQ in children with ASD.

Conclusions: Processing of vowel periodicity and formant structure in the auditory cortex is impaired in children with ASD already at a preattentive level. This neurophysiological deficit may affect phonetic perception and speech tracking in noisy environments in children with ASD.
411.131 (Poster) Autism Symptom Severity, Adaptive Behavior, and Cognitive Functioning Associated with Inattention, Noncompliance, and Track Loss during Eye-Tracking: Results from the Autism Biomarkers Consortium for Clinical Trials (ABC-CT) **N. G. Herman**, J. W. Griffin', A. Napels', K. Chawarska', G. Dawson', R. A. Bernier', N. Kleinhans', S. Jeste', S. Faia', J. Dziura', S. J. Webb', C. Sugar', F. Shic' and J. McPartland'; (1)Yale Child Study Center, Yale University School of Medicine, New Haven, CT, (2)Child Study Center, Yale University, Child Study Center, New Haven, CT, (3)Child Study Center, Yale School of Medicine, New Haven, CT, (4)Department of Psychiatry and Behavioral Sciences, Duke University Medical Center, Durham, NC, (5)Psychiatry and Behavioral Sciences, University of Washington, Seattle, WA, (6)University of Washington, Seattle, WA, (7)Children's Hospital Los Angeles, Los Angeles, CA, (8)Boston Children's Hospital, Boston, MA, (9)Yale University, New Haven, CT, (10)University of California, Los Angeles, Los Angeles, CA, (11)Center for Child Health, Behavior and Development, Seattle Children's Research Institute, Seattle, WA, (12)Child Study Center, Yale Child Study Center, New Haven, CT

Background: Eye-tracking technology provides researchers with an objective measure of visual attention that can be used to study social attention in autism spectrum disorder (ASD). While eye-tracking is noninvasive and easily deployable in neurodevelopmental populations, inattention and noncompliance can reduce data quality and increase attrition. Studies routinely exclude individuals who display high rates of data loss (Gaigg et al., 2020; Chawarska et al., 2012), reducing the generalizability of findings to the broader autism population. There are limited studies, however, that examine inattention and noncompliance during eye-tracking as a variable of primary interest.

Objectives: The current study aimed to (1) evaluate whether the number of breaks taken during eye-tracking was dependent on diagnostic group (typically developing (TD) vs. ASD); and (2) evaluate the relationships among social function and the number and type of breaks taken during eye-tracking.

Methods: As part of the Autism Biomarkers Consortium for Clinical Trials (ABC-CT), 278 autistic children (23.4% female; M=8.54, SD=1.64 years) and 117 TD children (30.7% female; M=8.51, SD=1.62 years) completed a battery of five passive viewing eye-tracking tasks, the Autism Diagnostic Observation Schedule, Second Edition (ADOS-2), and the Differential Ability Scales (DAS-II); Adaptive social function was measured with the Vineland Adaptive Behavior Scales, Third Edition (VABS-3). During eye-tracking tasks, participants received experimenter-mediated breaks when the eye-track was lost (recalibration break), when a participant exhibited noncompliant behaviors (noncompliance break), or when a participant exhibited compliant behaviors but were not attending to the screen (inattention break). The number of each break type was recorded for each participant. To handle this count data with excessive zeros, we used a zero-inflated Poisson regression model to examine how autism symptom severity, adaptive behaviors, and neurocognitive measures predicted the number and type of breaks taken during eye-tracking.

Results: Compared to their TD peers, autistic participants received a greater average number of recalibration (ADOS=1.18; TD=0.72), noncompliance (ADOS=2.46; TD=0.98), and inattention breaks (ADOS=1.12; TD=0.50) during eye-tracking. Across participants, the number of breaks was associated with lower overall adaptive functioning (b=-0.72, se=.13, p<.001) and full-scale IQ scores (b=-0.02, se=.02, p<.001). Higher ADOS-2 scores were associated with a greater number of overall breaks (b=0.11, se=.02, p<.001).

Conclusions: The results suggest that adaptive functioning, IQ, and autism severity predict the number of breaks received during eye-tracking assays. These findings encourage the systematic use of breaks in eye-tracking protocols for autistic participants, especially in cases where the eye-tracking task may be sensitive to participant inattention or noncompliance. Future research should explore how the use of experimenter-mediated breaks during eye-tracking procedures can be used to decrease overall data loss in autism research.

411.132 (Poster) Biological Motion Perception in Autism Spectrum Disorder: Developing an Analytic Approach to Eye Tracking Data **L. N. Kirsch**, T. Smith', C. W. Brune', E. V. Ocampo', L. Hermle', E. F. Dillon', L. V. Soorya' and E. T. Crehan'; (1)Child Study and Human Development, Tufts University, Medford, MA, (2)Department of Psychiatry, AARTS Center, Rush University Medical Center, Chicago, IL, (3)Department of Psychiatry, Rush University Medical Center, Chicago, IL, (4)Center for Autism and Related Disorders, Autism Assessment, Research, Treatment, and Services (AARTS) Center at Rush, Baltimore, MD, (5)Eliot-Pearson Department of Child Study & Human Development, Tufts University, Medford, MA

Background: In order to improve accuracy and equitability of Autism Spectrum Disorder (ASD) assessment and diagnosis, eye tracking has been suggested as a clinical tool. An accessible, indirect measure of neural activity, gaze behavior captured by eye tracking paradigms can provide key insights into cognitive patterns. The biological motion paradigm in which participants view point-light movement made by living beings illustrates this potential. Typically developing individuals preferentially attend to biological motion in infancy while individuals with autism often do not. By examining gaze behavior in the viewing of biological and non-biological motion, clinicians may be able to identify patterns indicative of ASD, potentially even correlating with severity or clinical presentation.

Objectives: Eye tracking data require substantial analysis in order to extract meaning from tens of thousands of individual eye movements. There is currently no standardized course of analysis for this data. We sought to develop an analytic approach, systematically extracting meaningful patterns in gaze behavior that may be unique to an autistic population.

Methods: We developed an analysis of eye tracking data based on a comprehensive literature review of current practices in both eye tracking and neuroimaging research. Our methodological review led us to a comprehensive, four-part analysis involving number of
Background: People are exposed to information every day. Categorization and categorical perception (i.e., discrimination sensitivity across categories) are essential processes to organize this information efficiently. Individuals with Autism Spectrum Condition (ASC) are suggested to experience difficulties with categorization, which may fit with accounts of enhanced ability to discriminate and reduced ability to generalize in ASC. However, studies empirically investigating categorization, discrimination, and generalization in ASC have mainly focused on one process at a time, and typically using only behavioral or neural measures.

Objectives: We aim to pinpoint these perceptual processes in adults with and without ASC by presenting them with an artificial multidimensional stimulus space. This allows us to investigate to what extent they (1) naturally discriminate between different instances of the space, (2) can be trained to categorize instances of this space, (3) discriminate between these different instances after category training, and (4) generalize trained categorization to an extended version of the stimulus space and a new stimulus space. In addition, by using Fast Periodic Visual Stimulation during electroencephalography (FPVS-EEG) measures, we can add a direct, non-task related neural index to standard behavioral tasks.

Methods: The experiment was completed by 29 adults with ASC and 28 neurotypical (NT) individuals. First, we assessed baseline discrimination ability by using FPVS-EEG measures and a complementary behavioral discrimination task. Throughout the FPVS-EEG, we presented a series of base stimuli periodically interleaved with a parametrically modulated oddball stimulus. Second, participants were trained to categorize the stimuli into 2 groups. This training consisted of 3 blocks with increasing categorization difficulty. Third, participants again completed the neural and behavioral discrimination measures. Fourth, participants performed a categorization task involving an extension of the trained stimulus set and a new stimulus space with similar properties to investigate generalization.

Results: Before training, results of the NT participants immediately revealed a tuning of discrimination, unlike ASC participants who showed highly similar discrimination across the space (Fig. 1A). During training, both participants with and without ASC were able to complete the different categorization blocks. However, in the initial phase of training, ASC participants seemed more uncertain and less precise (Fig. 1B). After training, ASC participants showed a significant effect of discrimination sensitivity across the category boundary with an even narrower tuning than NT (Fig. 1A). Finally, generalization of category learning within the same stimulus space was similar for both groups. However, transfer of the category learning to the new stimulus space seemed again more uncertain and less precise for the ASC participants (Fig. 1C).

Conclusions: Our findings indicate that both individuals with and without ASC are able to categorize highly similar stimuli and to generalize this categorization after training. In the initial stages of training and in generalization to a different stimulus space, individuals with ASC seemed more uncertain and less precise. Finally, category learning significantly enhanced the sensitivity of categorical perception in participants with ASC compared to NT participants. This multi-level approach sheds light on the mechanisms that underlie information processing issues in ASC.

Results: Initial results show an overall lack of preferential attention to biological motion across participants. Interestingly, the time course analysis unveiled an additional pattern in the viewing of this paradigm: an initial preference for non-biological motion that subsides across the experiment, which appears as a preference for biological motion by the final third.

Conclusions: Developing this analysis laid a promising approach to integrating eye tracking into intervention research targeting early-social cognitive skills. Our results are in line with previous research differentiating individuals with and without ASD on a biological motion paradigm. Further, they showed the potential for obtaining quantitative, nuanced metrics of learning during a brief (5-min) evaluations. The time-course analysis has potential to provide more objective judgements during evaluations and provide a nuanced tool to measure change in clinical trials.
Objective. To evaluate established hypotheses related to learning-via-imitation in autism

Methods. Literature review identified several hypotheses related to the role of imitation in autism. The Simons Powering Autism Research for Knowledge (SPARK) database contains questionnaire data around a variety of features of autism for 10,000s of individuals with autism. Items from the SPARK data dictionary were investigator-selected to fit theoretically specified constructs (Imitation, Social Skills, Social Withdrawal, Motor Skills). Symbolism was computed as the joint variance space of Verbal Language, Non-Verbal Communication and Imitative Play constructs. Covariates included age, sex and simplex vs. multiplex family history. We selected cases from the SPARK database based on absence of missingness for all studied items. Directed causal graphs of the hypotheses were evaluated using Kendall’s tau, with an eye to falsifying theoretically entailed relationships. Direction of associations was assessed through tests of conditional independence.

Results. N=11,673 children with autism. Because Mostofsky & Ewen posed a single mechanism for the learning of social skills and motor skills, a correlation between the two skill domains was expected but not found in the data (r=0.003; p=0.62). Moreover, conditioning on Imitation actually increased the effect size of the Social-Motor correlation, providing additional evidence that imitation ability is not a common cause of social and motor skill. Examining Rogers & Pennington’s model, Social Withdrawal, Motor Skill and Symbolism correlated to a reasonable degree with each other (0.12<r<0.41). However, conditioning on Imitation did not substantially reduce the strength of the correlations (0.09<r<0.35; ps<0.05), suggesting that imitation ability is a negligible cause of the variation in these abilities. Finally, in testing Baron-Cohen’s account, we used Social Skill as a proxy of metarepresentation (as it is also hypothesized to be downstream of metarepresentation, though in an independent pathway to Symbolism/Imitation). The large degree (77%) to which Symbolism mediates the relationship between Social Skill and Imitation is consistent with Baron-Cohen’s model.

Conclusions. Our results were inconsistent with two theories positing imitation as a learning mechanism for clinically-relevant skills in autism. Baron-Cohen’s model positing imitation ability as downstream of symbolism was not falsified, though the current results are also consistent with other causal relationships between constructs.

Background: Imitation is an ability used by humans both to enhance reciprocity during social interaction and to learning a wide variety of skills. At least two hypotheses propose how imitation may support the learning of skills relevant to the autism phenotype. Mostofsky & Ewen (2011) proposed that autism-related differences in learning and expression of motor skills is due to the same, imitation-dependent mechanism as differences in the learning and expression of social skills. Rogers & Pennington (1991) theorized that imitation differences cause autism-related alterations of symbolic expression and motor function as well as social withdrawal. Alternatively, Baron-Cohen (1988) hypothesized that differences in imitative behaviors were a consequence of differences in symbolic processing, which were in turn a consequence of metarepresentational differences. To our knowledge, these various hypotheses have not been tested in direct competition using the same dataset.

Objectives: To evaluate established hypotheses related to learning-via-imitation in autism

Methods: Literature review identified several hypotheses related to the role of imitation in autism. The Simons Powering Autism Research for Knowledge (SPARK) database contains questionnaire data around a variety of features of autism for 10,000s of individuals with autism. Items from the SPARK data dictionary were investigator-selected to fit theoretically specified constructs (Imitation, Social Skills, Social Withdrawal, Motor Skills). Symbolism was computed as the joint variance space of Verbal Language, Non-Verbal Communication and Imitative Play constructs. Covariates included age, sex and simplex vs. multiplex family history. We selected cases from the SPARK database based on absence of missingness for all studied items. Directed causal graphs of the hypotheses were evaluated using Kendall’s tau, with an eye to falsifying theoretically entailed relationships. Direction of associations was assessed through tests of conditional independence.

Results: N=11,673 children with autism. Because Mostofsky & Ewen posed a single mechanism for the learning of social skills and motor skills, a correlation between the two skill domains was expected but not found in the data (r=0.003; p=0.62). Moreover, conditioning on Imitation actually increased the effect size of the Social-Motor correlation, providing additional evidence that imitation ability is not a common cause of social and motor skill. Examining Rogers & Pennington’s model, Social Withdrawal, Motor Skill and Symbolism correlated to a reasonable degree with each other (0.12<r<0.41). However, conditioning on Imitation did not substantially reduce the strength of the correlations (0.09<r<0.35; ps<0.05), suggesting that imitation ability is a negligible cause of the variation in these abilities. Finally, in testing Baron-Cohen’s account, we used Social Skill as a proxy of metarepresentation (as it is also hypothesized to be downstream of metarepresentation, though in an independent pathway to Symbolism/Imitation). The large degree (77%) to which Symbolism mediates the relationship between Social Skill and Imitation is consistent with Baron-Cohen’s model.

Conclusions: Our results were inconsistent with two theories positing imitation as a learning mechanism for clinically-relevant skills in autism. Baron-Cohen’s model positing imitation ability as downstream of symbolism was not falsified, though the current results are also consistent with other causal relationships between constructs.
Results:

The classroom observation total score demonstrated good preliminary evidence of construct validity, as it had good correlation with the Swanson, Kotkin, Agler, M-Fllyn, and Pelham Scale (SKAMP; Swanson, 1992), a validated teacher-report measure of classroom-observed ADHD and EF-related behaviors in which higher scores represent greater challenges ($r = .44, p < .001$).

Overall, autistic students demonstrated fairly similar EF strengths and weaknesses as children with ADHD. There were no significant differences between the groups on demonstrating reciprocity, following rules, transitioning appropriately, avoiding negativity/overwhelm, or participating in class. Autistic children were rated as significantly more likely to get “stuck” during the observation than were their ADHD peers ($p = .037$). In a multiple linear regression predicting child total EF score that controlled for student characteristics of IQ, age, and household income, diagnosis was not significant ($F = 0.91, p = .46$).

Observations of teachers indicated that the majority of teachers (> 75%) demonstrated good planning, clear instructions, and use of visuals. However, far fewer teachers (< 30%) utilized favorable praise to correction ratios, primed students for transitions, demonstrated flexibility, reminded students of rules, or used a behavioral reward system.

Conclusions:

Similar EF profiles between autistic students and those with ADHD indicate they may benefit from similar types of accommodations and supports. Low teacher scores on EF-supporting practices indicate that teachers may need more training on the importance of these skills for children with ASD or ADHD to support inclusion classrooms. Further study is needed to determine the nature of the relationship between teacher and student EF skills.

411.136 (Poster) Configuration Does Not Affect the Allocation of Visual Attention to Foreground and Background Information Differently for Persons with Autism and Neurotypical Persons on a Change Detection Study

Background: Among their unique styles of attending, individuals with autism spectrum (ASD) appear to prioritize the processing of local – detailed information rather than the overall global structure of visual information (Evers et al., 2018; Plaisted et al., 1998). This style is thought to be associated with greater efficiency when attending to certain stimuli in the visual field (Burack & Brodeur, 2020; Mottron & Burack, 2001; Mottron et al., 2006), and superior abilities in detecting change in complex dynamic environments (Karaminis et al., 2020; Rensink, 2002). Although the research on change detection in ASD is mixed, the discrepancies are largely attributed to the diversity of the stimuli in our environment and the specific components of perception, attention, and cognition involved on the task (Hochhauser et al., 2018; Maccari et al., 2014; Rensink et al., 2002).

Objectives: The current study was focused on the abilities of individuals with autism, as compared to neurotypical (NT) individuals, to detect changes occurring within a simple static visual display at the local versus global level in the foreground and background aspects of a visual scene. Consistent with models of enhanced local perception, we expected that the participants with ASD would be better at detecting changes for local rather than global displays and better at detecting changes in the background than foreground compared to NT individuals.

Methods: Thirty-two individuals (2 female) aged 12 to 33 years with formal diagnoses of autism and 32 with no diagnoses (2 female) participated in the current study. The groups were match on chronological age ($M_{age\_autism} = 20.2, SD = 6.1, M_{age\_NT} = 19.7, SD = 6.2$) and perceptual IQ ($IQ_{autism} = 106.7, SD = 11.2, IQ_{NT} = 109.0, SD = 9.7$). In the change detection task, coloured rectangles displayed vertically in the background and horizontally in the foreground were presented in an organized configuration to simulate global processing or unorganized configuration to simulate local processing. The participants were required to indicate with a button press whether a change had occurred. Four possible changes could occur: (1) foreground change in the organized configuration, (2) foreground change in the unorganized configuration, (3) background change with organized configuration, and (4) background change with unorganized configuration.

Results: A significant effect of change condition was observed ($F(1.18, 73.32) = 212.05, p < .001, \eta_p^2 = .77$) in which accuracy was highest for both the ASD and NT participants when detecting no change, next when detecting foreground change and least when detecting background change. No main effect was found between global and local stimuli ($F(1.62) = 1.20, p = .278, \eta_p^2 = .02$). A significant interaction ($F(1.90, 117.32) = 3.86, p = .026, \eta_p^2 = .06$) revealed that change detection of foreground features was more accurate when presented with an unorganized, rather than organized configuration, for both the ASD and the NT participants ($p = .04$).

Conclusions: The individuals with ASD performed comparably to NT individuals when detecting changes in static, simple visual displays devoid of social content, as both groups directed their attention to the foreground and detected changes more accurately for unorganized
than organized configurations. This finding provides further evidence of similar styles of attending between persons with ASD and TD persons.

411.137  (Poster) Delayed Development of Episodic Future Thinking in Adolescents with ASD: A Longitudinal Study
P. Wantzen, R. Touati, F. Eustache and B. Guillery-Girard, (1)LEAD-Université Bourgogne, Caen, France, (2)LEAD, CNRS UMR 5022, Université Bourgogne Franche-Comté, Dijon, France, (3)Normandie Univ, UNICAEN, PSL Research University, EPHE, INSERM, U1077, CHU de Caen, Neuropsychologie et Imagerie de la Mémoire Humaine, 14000 Caen, France, Caen, France

Background: Autism Spectrum Disorders (ASD) is characterized by cognitive difficulties, including autobiographical memory (AM) impairments. AM corresponds to the ability to remember past experiences and to imagine possible future experiences. In ASD, AM is impaired with reduced retrieval, specificity, and elaboration, particularly in childhood. However, to date, there is no data to understand this atypical development during adolescence.

Objectives: We set up the first longitudinal study to evaluate the evolution of AM in adolescents with ASD and the factors influencing AM. We investigated the properties of past and future autobiographical productions with an objective (structured interview; From Past to Futur Task) and subjective (self-administered questionnaire; Survey of Autobiographical Memory) measurement of the AM over two years.

Methods: Twenty-six adolescents (10 - 19 years): 13 adolescents with ASD (11 males) and 13 age- and intelligence-matched controls (11 males) were followed for two years, three times, one year apart (T0, T1, and T2). For the objective measure of AM, participants were asked to free recall two past and two future autobiographical events. The content ("what", "who", and "how") and the context ("where" and "when") were evaluated. For the subjective measure of AM, items assessed self-reported future projection, episodic autobiographical, semantic, and spatial memory. The autistic severity was also measured with the Autism Spectrum Quotient (AQ).

Results: Episodic details during the projection towards the future increased during adolescence in the TD group but not in the ASD group (Fig 1). The analysis of self-questionnaires showed a lower score concerning spatial memory for the ASD group compared to the TD group. The objective evaluation confirmed this difficulty in remembering the spatial and temporal context. Exploration of event details revealed a significant increase of elements related to the content for both groups but without any change for the contextual elements in the ASD group. Finally, we showed that AM evolution in ASD was influenced by age and autistic traits (social skills, switching, imagination, and attention to detail, measured by the AQ).

Conclusions: AM is affected in a heterogeneous way in ASD development, with the progressive development of past event recall abilities, linked to the severity of the symptoms. However, through adolescence, we highlighted persistent difficulties of projection into the future and spatial memory. Recall past experiences would require lower cognitive and executive resources than imagining possible future experiences, which would slow down its development. Based on our results, we propose that difficulties in spatial memory and imagination impact the construction of mental scenes and then could impair the self-projection as well as into the future, but also in spatial navigation and toward others (i.e., theory of mind). Finally, given the difficulties in reporting contextual details ("where" and "when"), we could hypothesize that the AM organization in ASD could be different from neurotypical. Not according to a personal "timeline” but rather according to personal themes or concepts, linked to a more preserved semantic memory.

411.138  (Poster) Developmental Trajectories of Visual Disengagement during Early and Middle Childhood in Autistic Children
J. M. Almeida Osório, B. Rodríguez-Herreros, N. Sokhn, S. Richetin, D. Romascoano, V. Junod, M. Jequier Gygax, R. Caldarà, A. Maillard and N. Chabane, (1)STSA, CHUV, Lausanne, (2)STSA, CHUV, Lausanne, QC, Switzerland, (3)Université de Fribourg, Fribourg, Switzerland, (4)STSA, CHUV, Lausanne, Switzerland

Background: The ability to disengage and look away from captivating stimuli is an essential component of attentional orienting, and undergoes dramatic developments during infancy. Deficits in orienting to social and non-social stimuli have been described as one of the earliest signs to emerge in very young children with Autism Spectrum Disorder (ASD). There is ample evidence that children take more time to disengage attention than adults, and that the attentional system becomes more efficient during childhood and adolescence. Yet, its precise developmental trajectory during early and middle childhood for both typically developing (TD) and autistic children remains to be defined.

Objectives: To characterize the spatiotemporal accuracy of visual disengagement in both ASD and TD populations, its developmental trajectory and its putative association with autistic symptomatology.

Methods: Eye-tracking is a powerful technique to measure attentional switching in young children. A total of 37 ASD and 69 TD children took part in the study, all between 2 and 9 years of age. The ‘gap-overlap’ task is a well-established paradigm to measure flexibility in attentional orienting from a central (CS) to a peripheral stimulus (PS) presented unpredictably. We analyzed the efficiency of disengaging from CS to orient to PS derived from saccadic reaction times, and compare it between groups and across ages. We also evaluated the spatial distribution of the saccade landing position for each group and condition.
Results: We found that the latency for visual disengagement was reduced with age in TD children, being shorter in middle compared to early childhood. However, no changes were observed across ages in ASD children. Furthermore, we confirmed that ASD children exhibit a greater variability in the landing accuracy of the saccade to the PS, compared to TD children.

Conclusions: Our results indicate a less accurate visual disengagement in ASD compared to TD children, as well as a differential developmental trajectory. These findings provide additional evidence that the attentional system becomes more efficient with age, but that this process is altered in ASD population. We believe that these deficits in early-developing attentional control might have a far-reaching impact on cognitive skills.

411.139 (Poster) Distinct Attentional, Perceptual, and Neural Phenotypes in Autism and First-Degree Relatives: Neurocognitive Insights from a Multi-Method, Family Study of Visual Perception and Attention

Methods:

Participants included 32 autistic individuals (ASD) and 56 parents of autistic individuals (ASD parent), and 30 and 43 respective age- or IQ-matched controls. Top-down social attention was assessed with a suite of dynamic analytical methods (e.g., growth curve analyses, perseverative/regressive refixations) applied to eye-tracking data captured during presentation of a social-emotional scene, characterizing where and how participants looked. Two interactive match-to-sample tasks using illusions were administered on an eye-tracker to examine bottom-up visual processing that potentially underlies top-down social attention. Local/global perceptual (e.g., first fixations, fixation location within illusion) and strategy-based (e.g., vacillating fixations, match/non-match fixations) gaze composite scores were generated. Finally, event-related potentials (i.e., time-locked EEG responses to illusion and non-illusion stimuli), including P1, N1, and N2 components, were extracted to assess neural correlates of local/global processing.

Results: Compared to controls, both ASD and ASD parent groups showed reduced social attention over the course of the task, with a linear decrease and a dynamic looking pattern (Fig 1A; i.e., shifting away earlier and later from looking at social information). Both groups also exhibited more refixations toward non-salient, background objects. Autistic individuals demonstrated a greater local versus global visual perceptual and strategic style (Fig 1B). Parent groups differed in strategy-based measures of eye tracking, but not perceptual-based indices (Fig 1B). Finally, atypical N1 amplitudes in the occipital-parietal region were found in autistic individuals, with observable opposite patterns of neural responses occurring in the N2 component in both the ASD and ASD parent groups (Fig.1C). Social attention, and local/global gaze and neural components were related to (sub)-clinical features of the ASD phenotype.

Conclusions: Results of this study provide compelling evidence of disruptions in global perception potentially impacting top-down social attention in autistic individuals and, more subtly, in their parents. Fine-grained eye-tracking variables examined are thought to effectively tap different aspects of underlying cognition, revealing key mechanistic insights into the roots of social functioning differences in autism. Findings of fundamental local/global visual processing differences identified behaviorally (gaze) and neurally point to underlying neurobiological differences shaped by autism-related genetic variation. Brain-behavior relationships with (sub)clinical features in autism and parents support the utility of social/non-social visual perception/attention as key neurocognitive phenotypes that may be fruitfully applied in future treatment and genetic studies.

411.140 (Poster) EARLY Numerical Skills and Mathematical Domains in Students with Autism Spectrum Disorders in Primary School.

Participants included 32 autistic individuals (ASD) and 56 parents of autistic individuals (ASD parent), and 30 and 43 respective age- or IQ-matched controls. Top-down social attention was assessed with a suite of dynamic analytical methods (e.g., growth curve analyses, perseverative/regressive refixations) applied to eye-tracking data captured during presentation of a social-emotional scene, characterizing where and how participants looked. Two interactive match-to-sample tasks using illusions were administered on an eye-tracker to examine bottom-up visual processing that potentially underlies top-down social attention. Local/global perceptual (e.g., first fixations, fixation location within illusion) and strategy-based (e.g., vacillating fixations, match/non-match fixations) gaze composite scores were generated. Finally, event-related potentials (i.e., time-locked EEG responses to illusion and non-illusion stimuli), including P1, N1, and N2 components, were extracted to assess neural correlates of local/global processing.

Results: Compared to controls, both ASD and ASD parent groups showed reduced social attention over the course of the task, with a linear decrease and a dynamic looking pattern (Fig 1A; i.e., shifting away earlier and later from looking at social information). Both groups also exhibited more refixations toward non-salient, background objects. Autistic individuals demonstrated a greater local versus global visual perceptual and strategic style (Fig 1B). Parent groups differed in strategy-based measures of eye tracking, but not perceptual-based indices (Fig 1B). Finally, atypical N1 amplitudes in the occipital-parietal region were found in autistic individuals, with observable opposite patterns of neural responses occurring in the N2 component in both the ASD and ASD parent groups (Fig.1C). Social attention, and local/global gaze and neural components were related to (sub)-clinical features of the ASD phenotype.

Conclusions: Results of this study provide compelling evidence of disruptions in global perception potentially impacting top-down social attention in autistic individuals and, more subtly, in their parents. Fine-grained eye-tracking variables examined are thought to effectively tap different aspects of underlying cognition, revealing key mechanistic insights into the roots of social functioning differences in autism. Findings of fundamental local/global visual processing differences identified behaviorally (gaze) and neurally point to underlying neurobiological differences shaped by autism-related genetic variation. Brain-behavior relationships with (sub)clinical features in autism and parents support the utility of social/non-social visual perception/attention as key neurocognitive phenotypes that may be fruitfully applied in future treatment and genetic studies.
Background: In recent years, there has been a growing interest in providing a quality educational response to the needs of children with ASD. Mathematics is one of the main subjects were children with ASD present difficulties, manifesting themselves in four domains: number sense, number facts, procedural calculation, or mathematical reasoning. However, studies on mathematics and ASD are scarce, and provided mixed results.

Objectives: To this end, we conducted a study to explore the effect of early symbolic and non-symbolic numerical competencies in children with ASD as predictors of mathematics domains in Primary Education compared to typically developing children.

Methods: Forty-two children (21 children with high-functioning ASD and 21 typically developing children) from Primary Education participated in the study (mean age ASD= 9.54, SD = 1.75; mean age TD = 9.49, SD = 1.84). Assessments were conducted in 50-minute sessions with each participant. Four early numerical competencies were tested: verbal subitizing, counting, magnitude comparison, and projection. Two domains of mathematics were used as outcome variables: procedural calculation, and word/language problems. Control tasks such as Word and pseudoword reading (PROLEC-R), Digits (WISC-IV), Corsi Cubes, Manual speed, and Executive control (Go-NoGo) were also included.

Results: Significant differences were found between children with ASD and TD only in the first years of Primary Education in subitizing ($p = 0.010$) and projection ($p = 0.032$) tasks. No differences were found in the last years of Primary Education. In the group of children with TD almost all mathematical skills were significant predictors for calculation, while for children with ASD significant predictors were only found in the counting (F (5.697), $p = .033$) and magnitude comparison (F (14.076), $p = .002$) tasks for the calculation domain. However, nonsymbolic magnitude comparison tasks (F (8,486), $p = .012$) were predictors of problem solving only in this group.

Conclusions: The results suggest similar numerical processing between children with and without ASD, although in those with ASD the correlations were higher in tasks whose processing is purely nonsymbolic, while in the TD group the correlation is higher in symbolic tasks. This seems to indicate that, although the results in the mathematical domains are similar, early numerical skills affect in different ways (such as subitizing for example) to both groups. However, these differences are significantly reduced with age, indicating that both groups had a similar development in the last years of Primary Education. Future research should increase the sample for each year of Primary Education and to use longitudinal studies, studying in greater detail why subitizing ability is better in children with high-functioning ASD, and why it disappears as children's age increases.

411.141 (Poster) Examining Visual Processing of Hierarchical Figures through Behavioral Measures and Pupillometry in Relation to Autistic Traits in Adults

C. Brittenham and J. B. Wagner, (1)Psychology, The Graduate Center of The City University of New York, New York, NY, (2)Department of Psychology, College of Staten Island, CUNY, Staten Island, NY

Background: Although studies of global (i.e., gist) and local (i.e., detail) processing in autism spectrum disorder (ASD) are often contradictory, they converge to show slowed global processing in ASD (see Van der Hallen, et al., 2015). One potential source of inconsistency may arise from low-level vision confounds when using traditional hierarchical figures (see Brown & Crewther, 2017). Additionally, behavioral measures alone may be too insensitive to detect differences (see Samson et al., 2012) and do not directly address underlying mechanisms.

Objectives: The current study aims to examine global/local processing in non-autistic adults with varying levels of autistic traits through measures of behavioral (i.e., reaction time) and pupillary responses, using highly controlled stimuli to begin considering attentional mechanisms as an underlying factor.

Methods: The final sample included 54 undergraduates ($M_{age} = 25.3$ years, $SD = 8.1$). Gaze and pupil diameter were recorded with an SR EyeLink 1000 Plus eye-tracker while participants completed global and local hierarchical figure tasks (adapted from Campana et al., 2016). Reaction time (RT) was recorded through button presses. Participants were told they would see homogeneously-oriented local lines defining a rectangular global shape within the stimulus. Participants completed alternating blocks of global and local orientation identification trials, and then filled out the Social Responsiveness Scale, Second Edition (SRS-2; Constantino & Gruber, 2012) to assess levels of autistic traits.

Results: Using a cutoff SRS-2 T-score of 59, participants were separated into groups low ($N=39$) and high ($N=15$) on autistic traits. Two-by-two mixed-model ANOVAs were used to examine effects of condition (global, local) and traits group (high, low) on RT and pupil diameter. In examining RT, there was a significant condition effect ($F(1,52)=23.49, p<.001$), with participants generally responding faster in the global than local condition, and a significant interaction between condition and group ($F(1, 52)=4.37, p=.042$), with the low-traits group significantly faster to report the global as compared to the local orientation ($p<.001$), but no difference between conditions for the high-traits group was found ($p=.111$; see Figure 1). Pupil analyses revealed a marginal condition effect, with greater pupil dilation in the...
global than local condition, $F(1, 49)=3.74, p=.059$. This was related to a marginally significant condition by group interaction, $F(1, 49)=3.34, p=.074$, with pairwise comparisons showing significantly more dilation in the global compared to the local condition for the high-traits group ($p=.034$), but no condition difference for the low-traits group ($p=.91$; see Figure 2).

Conclusions: We found that non-autistic adults with low levels of autistic traits were faster to identify global-level information as compared to local-level information, while adults with high levels did not differ in timing to identify global compared to local information. Further, high-traits adults also showed more pupil dilation in identifying global compared to local information, while low-traits adults showed no pupil response differences between conditions. These findings suggest potentially different strategies for global/local processing depending on features of the broad autism phenotype, possibly facilitated by visual attention differences. Future work will investigate how autistic traits might relate to differences in pupil response trajectories.

411.142 (Poster) Inhibition Challenges Relate to Maladaptive Sleep Outcomes in Autistic Preschoolers
A. M. Cremone-Caira and S. Faja; (1)Assumption University, Worcester, MA, (2)Boston Children’s Hospital, Boston, MA

Background: Autistic children are commonly reported to have impaired behavioral inhibition (Cremone-Caira et al., 2021). Sleep problems, namely bedtime resistance and sleep anxiety, are also prevalent among the autistic community (Hodge et al., 2014; Mazurek et al., 2015). Emerging evidence suggests that poor sleep negatively relates to the development of executive functions including inhibition (Turnbull et al., 2013). To date, however, relations between inhibition challenges and sleep difficulties have not been characterized in preschool-aged children with a diagnosis of autism spectrum disorder (ASD). As the preschool years are a critical period of cognitive development and sleep transitions, further research in this age group is needed.

Objectives: Our goal was to characterize relations between behavioral inhibition and sleep problems among preschool-aged children with ASD and age-matched neurotypical controls (NTC).

Methods: As part of a larger study charting the development of executive function in ASD preschoolers, data were collected from preschool-aged children with and without a diagnosis of ASD and their caregivers. Children completed a battery of age-appropriate assessments that measured behavioral inhibition. Specifically, behavioral inhibition was operationalized as a composite score calculated across the A-not-B, Grass Snow, and Tricky Box tasks. Standardized clinical assessments were used to confirm child diagnostic status (ADOS-2, ADI-R) as well as caregiver-report of sleep problems (Child Sleep Habits Questionnaire for Toddlers; CSHQ-T; Goodlin-Jones et al., 2008).

Results: Behavioral inhibition was more impaired in ASD preschoolers relative to NTC ($F(1,153) = 43.178, p < 0.001, \eta^2 = 0.220$). Likewise, bedtime resistance ($F(1,76) = 15.830, p < 0.001, \eta^2 = 0.172$) and sleep anxiety ($F(1,75) = 10.591, p = 0.002, \eta^2 = 0.124$) were both greater in the ASD compared to the NTC group. Behavioral inhibition was significantly, positively correlated with bedtime resistance in ASD preschoolers ($n = 46, r = 0.294, p = 0.048$) but not NTC ($n = 29, r = 0.061, p = 0.752$). Sleep anxiety was also marginally, positively correlated with inhibition in the ASD group ($n = 45, r = 0.281, p = 0.061$) but not in the NTC group ($n = 29, r = 0.049, p = 0.800$). Bedtime resistance and sleep anxiety were significantly, positively correlated in both groups ($rs > 0.681, ps < 0.001$).

Conclusions: Collectively, the results of these analyses replicate previous findings highlighting inhibition difficulties and sleep problems in young, autistic children. Notably, inhibition challenges were only related to sleep problems in our ASD group. Although correlational, this finding suggests that sleep problems may negatively affect domains of executive function among young children with a diagnosis of ASD. Alternatively, it is possible that inhibition challenges may impede sleep. For example, bedtime resistance may reflect an inability to inhibit distractors in the sleep environment or internal thoughts related to sleep anxiety. Future research is needed to empirically test these hypotheses related to causality as well as the directionality of the relations identified in our analyses. Together with the findings presented here, additional work may identify targets for intervention to improve executive functioning and/or sleep among autistic preschoolers.

411.143 (Poster) Learning Strong Vs. Weak Multi-Cue-Outcome Associations By Autistic and Non-Autistic Adults
J. H. Ong and F. Liu; (1)School of Psychology and Clinical Language Sciences, University of Reading, Reading, United Kingdom, (2)School of Psychology & Clinical Language Sciences, University of Reading, Reading, United Kingdom

Background: Bayesian and predictive coding models have recently been proposed to understand autism. While the specifics differ, the models generally predict differences in learning probabilistic cue-outcome associations (i.e., associations that are not deterministic) among autistic and non-autistic individuals. Empirical evidence for this, however, is mixed. Moreover, previous studies tend to use simple cues (e.g., learning to associate one of two coloured boxes to an outcome), which is unlike in real life where there may be many cues and the cues in tandem may be associated with the outcome.

Objectives: We compared autistic and non-autistic individuals on learning cue-outcome associations that require integration of multiple cues. The associations were either unambiguous (strongly predictive) or ambiguous (weakly predictive).
Methods: Autistic and non-autistic adults (n=52 in each) completed a multi-cue probabilistic learning task online, in which they were asked to predict whether each one of 16 unique art pieces received a high or low rating from an art critic. Each art piece was composed of a combination of four binary cues: background colour (orange/purple), orientation (left/right), dot colour (black/white), and number of dots (3/6), and was associated with a probability of receiving a high rating. Half of the art pieces had a probability within the range of 0.1-0.2 or 0.8-0.9 (“unambiguous”) whereas the other half had a probability in the range of 0.4-0.6 (“ambiguous”). On every trial, the probability was compared to a random number between 0-1 to determine if the art piece received a high rating; if the random number was lower than the associated probability, then a high rating was the ‘correct’ answer. Trial-by-trial feedback was provided after each response. The 16 unique art pieces were repeated 8 times, resulting in a total of 128 trials. We compared performance of unambiguous and ambiguous art pieces during the first half (“early”) and the second half (“late”) of the task.

Results: Using a binomial mixed effects model to examine accuracy in learning performance, we investigated whether the learning of unambiguous vs. ambiguous associations differed among autistic vs. non-autistic during early vs. late phase. Our model revealed a significant interaction such that for unambiguous (strongly predictive) associations, performance was similar among autistic and non-autistic participants during both early and late phases, whereas for ambiguous (weakly predictive) associations, performance was similar between the groups during the early phase, but non-autistic participants outperformed autistic participants in the late phase (see Figure 1).

Conclusions: Compared to non-autistic individuals, autistic individuals do not show differences in learning associations that require integrating multiple cues when the associative strength is relatively strong, but they do when the cue-outcome associations are weak. The findings thus support the suggestion that autistic individuals may have higher inflexible precision of prediction error, treating every unreliable feedback as meaningful when it should be ignored. Given that many real-life social situations are complex and thus governed by weak cue-outcome associations, this may partly explain the challenges autistic individuals face in such situations.

411.144 (Poster) Reading Ability of English Language Learners with Autism
C. Conner, J. Shero, R. Marks, J. Stewart, and E. J. Solari. (1)University of Virginia, Charlottesville, VA, (2)Florida State University, Tallahassee, FL, (3)School of Education, University of Virginia, Charlottesville, VA

Background: As the percentage of children diagnosed with autism continues to rise (CDC, 2020), so do the percentages of students with diverse language needs in the United States. Additionally, over 60% of reported diagnoses of autism are from ethnic minority families, families whose primary home language may not be English. While there are proven benefits associated with multiple language exposure, children with autism in multilingual families are often denied the opportunity to receive reading intervention in their native language.

Objectives: We examine the reading performance of elementary-age children with autism who are language learners through two research questions. RQ1) How do rates of English to Speakers of Other Languages (ESOL) participation differ between students with autism and typically developing (TD) students across grades 1, 3, and 7? RQ2) Are there differences in literacy skills for students with autism across English Learner (EL) groups?

Methods: To assess trends of ESOL enrollment between autism and TD groups, a regression was used to examine progression of EL/ESOL membership through grades 1, 3, and 7. An ANOVA examined the literacy skills of children with autism in grades 1 (n=6,680), 3 (n=6,231), and 7 (n=2,821). The regression includes autism diagnosis, EL status (ESOL program enrollment), and an interaction term for children who graduated from the ESOL program (former language learners).

Results: RQ1) Results from the regression support a significant difference in ESOL enrollment rates on the basis of autism status and grade level and an interaction between grade level and autism status. See the attached image for more information. RQ2) ANOVA models revealed that the impact of EL status decreased as ESOL programming progressed. Students with ASD who were identified as current ELs demonstrated greater differences to their non-EL peers in areas such as vocabulary and reading comprehension when compared to the differences between former EL (graduated from ESOL) and non-EL students. These differences in how former and current EL students compared to non-EL students becomes more pronounced at higher grade levels, as former EL and non-EL students perform similarly on measures of reading comprehension by grade 7, while significant differences remain between current EL and non-EL students.

Conclusions:

RQ1) We found that student with ASD progressed through the ESOL program at a faster rate than their TD peers. We explore possibilities for this finding, including that students with ASD could have been misidentified as ELs due to language difficulties in the early grades.

RQ2) Students with autism who are labeled current ELs perform at a lower rate than typically developing students in the EL program, suggesting that there is an added deficit of being enrolled in the EL program for students with autism that is not present for TD students. However, once students with autism exit or graduate from the EL program, that deficit is not present. However, at grade 1 students with autism who have exited the program are still underperforming their TD peers at a greater rate than students with autism and TD students who were never identified for the EL program.
Background: Most information on face-directed gaze in autism relies on participants viewing social stimuli on a computer screen. However, more recent work indicates that face-directed gaze on computer screens does not predict gaze during live interactions (Grossman et al. 2019, Foulsham, T., & Kingstone, 2017). Face-directed gaze during conversation also changes based context, such as whether the person whose gaze is being measured is listening or speaking (Ho et al. 2015). Since live gazing behavior has rarely been explored in autism, little is known about these socially important, contextually driven differences in their eye gaze.

Objectives: Identify conversational-context-dependent differences in face-directed gaze patterns of autistic and non-autistic adolescents during live interactions.

Methods: Adolescents (15 autistic, 11 neurotypical or NT) wore SMI eyetracking glasses during a conversation with two research assistants (RAs). Participant groups did not differ significantly on age, gender, verbal- non-verbal, full IQ, or Core Language scores. During the conversation, RA1 asked an on-topic, contextually appropriate question, while RA2 asked an off-topic, contextually inappropriate question. The on-topic question occurred when RA1 asked the participant whether they had seen a movie the RA had just mentioned. The off-topic question occurred when RA2 described a moment at the gym and asked the participant, “What is a time that you’ve had when it was hard to breathe?” We captured audio-video recordings of the interaction and participant gaze data. The position of the on-topic vs. off-topic RA (left or right) was alternated between participants to avoid lateralization effects. We calculated dwell time to the speaker’s face during each question as percent of overall dwell time to the participant’s full field of view.

Results: A two (diagnosis) by two (condition: on-topic vs. off-topic) repeated measures ANOVA identified a significant main effect for diagnosis ($F(1, 24) = 5.52, p < .03$, partial $\eta^2 = .19$, with the NT participants gazing at both speakers more than the autistic participants. There was also a significant main effect of condition ($F(1, 24) = 15.15, p < .001$, partial $\eta^2 = .39$), with both groups showing more gaze to the face of the on-topic than the off-topic speaker, and a significant interaction between diagnosis and condition ($F(1, 24) = 5.22, p = .03$, partial $\eta^2 = .18$), with NT participants increasing their gaze to the on-topic vs. off-topic speaker significantly more than autistic participants. Post-hoc comparisons show that NT participants have significantly more face-directed gaze during the on-topic than the off-topic question ($p = .001$), while the autistic participants show no significant difference in speaker-directed gaze between the two conditions. The NT group has significantly more face-directed gaze than the autism group during the on-topic ($p = .005$), but not the off-topic question.

Conclusions: Speaker-directed gaze patterns of autistic and neurotypical adolescents are comparable in one conversational context but diverge in another. Autistic adolescents gaze at speakers’ faces equally, regardless of the contextual appropriateness of their conversation partners' questions, while NT adolescents differentiate their visual exploration of the speakers’ face for on-topic compared to off-topic questions.
report interview, rating form, and checklist (and self-report when applicable), as well as direct tests of ABM in the form of free recall, memory cueing, and staged event procedures. The AMP was administered to a caregiver and her 11-year-old autistic son (in a single 2-hour session) to pilot/refine procedures for administration, scoring, and interpretation. A report was generated characterizing the child’s ABM including recommendations for intervention that would be suitable complements of his existing therapeutic goals and education plan.

Results: For this single case, testing using the AMP revealed 1) strength in ABM semantic memory and cued and recognition memory and 2) challenges in episodic memory (detail, specificity, spontaneity, temporal sequencing; see Table). Piloting also revealed challenges to assessment in a clinical setting that if addressed, should enhance the utility of the measure going forward.

Conclusions: The AMP appears to be sensitive for tapping a range of ABM domains and yielded a coherent portrait of ABM memory strengths and challenges. This profile was consistent with the literature on ABM in autism suggesting tentative evidence for construct validity. Initial pilot data support further development and evaluation of the AMP especially for clinical, educational, and applied purposes.

411.147  (Poster) Autistic and Non-Autistic Individuals Show Comparable Anticipation of Visual Targets: Results from the Autism Biomarkers Consortium for Clinical Trials (ABC-CT)  
D. Miro-Rivera, S. Cramer-Benjamin, A. Naples, K. Chawarskar, G. Dawson, R. A. Bernier, S. Jeste, J. Dziura, S. J. Wehr, C. Sugar, F. Shic and J. McPartland, (1)McPartland Lab - Yale Child Study Center, McPartland Lab - Yale Child Study Center, Yale School of Medicine, New Haven, CT, (2)McPartland Lab, New Haven, CT, (3)Child Study Center, Yale University, Child Study Center, New Haven, CT, (4)Child Study Center, Yale School of Medicine, New Haven, CT, (5)Department of Psychiatry and Behavioral Sciences, Duke University Medical Center, Durham, NC, (6)Psychiatry and Behavioral Sciences, University of Washington, Seattle, WA, (7)Children’s Hospital Los Angeles, Los Angeles, CA, (8)Yale University, New Haven, CT, (9)University of California, Los Angeles, Los Angeles, CA, (10)Center for Child Health, Behavior and Development, Seattle Children's Research Institute, Seattle, WA, (11)Child Study Center, Yale Child Study Center, New Haven, CT

Background: In human vision, anticipating the location of a visual stimulus allows an individual to generate an eye-movement towards the stimulus more rapidly, increasing the efficiency of perception. Saccade latency, the time it takes to initiate an eye-movement towards a stimulus after it appears, is a low-level index of anticipation that exhibits substantial interindividual variability and has been used as a marker of differences in visual-attentional processing in autistic individuals. However, previous research shows mixed evidence of anticipatory differences in autism in predominantly small samples. The current study evaluated implicit predictions about the dynamic perceptual environment in a large sample of autistic and non-autistic (NT) individuals.

Objectives: Consistent with prior research suggesting decreased anticipatory attention in autism, we predicted that autistic individuals, relative to NT individuals, would be slower to look to fixation targets presented in a fixed order across repeated blocks (i.e., have longer saccade latency) than non-autistic individuals. We also predicted an interaction between age and saccade latency, such that older participants would demonstrate more rapid saccades relative to younger participants.

Methods: We evaluated this hypothesis in data collected from 280 autistic and 119 NT children (ages 6-11) through the Autism Biomarkers Consortium for Clinical Trials (ABC-CT). As part of the ABC-CT eye-tracking battery calibration procedure, participants are presented with three identical fixation tasks in which five targets, in the corners and center of the screen, are presented in a fixed order. Target appearance is contingent on participant looking, such that when a participant fixates on a target for approximately 200ms, the experiment operator cues the next target. Latency, per block, was calculated both as the median of the saccade latency between targets and as the total time to look to all five targets. Increases in anticipation, or learning, were calculated as the slope of the best linear fit of median saccade latency across the children's rating. The AMP was administered to a caregiver and her 11-year-old autistic son (in a single 2-hour session) to pilot/refine procedures for administration, scoring, and interpretation. A report was generated characterizing the child's ABM including recommendations for intervention that would be suitable complements of his existing therapeutic goals and education plan.

Results: Across all participants, there was evidence for saccade latency to increase, rather than decrease, as a function of increasing target blocks (rho = .16, p < .001). There were no differences by diagnostic group in changes in latency across calibration blocks (p = .85). Moreover, there were no relationships between change in saccade anticipation and age or cognitive ability. Ongoing analyses are exploring the extent to which results are sensitive to variability in the interindividual quality of eye-tracking data and whether alternative saccade parsing may reveal meaningful relationships among prediction and clinical features of autism.

Conclusions: Counter to theories that posit differences in ASD and NT based on attentional disengagement and predictive deployment of attention, there were no differences identified between diagnostic groups in the current study. While results revealed substantial individual variability in low-level attentional differences (within and across groups), these differences were not related to the individual’s diagnostic status or cognitive ability. These results align with previous research hypothesizing that differences in saccade latency to social information reflect prioritization of social information rather than low-level differences in visual attention.
**429.001 (Poster)** Links between Attention to Faces of People Speaking and Language in Toddlers with and without Autism

E. V. Edgar*, A. Vernetti†, F. Shic*, S. Macari and K. Chawarska*, (1)Child Study Center, Yale University School of Medicine, New Haven, CT, (2)Child Study Center, Yale Child Study Center, Yale School of Medicine, New Haven, CT, (3)Center for Child Health, Behavior and Development, Seattle Children’s Research Institute, Seattle, WA, (4)Child Study Center, Yale School of Medicine, New Haven, CT

Background: Toddlers with ASD (Garrido, et al., 2017) and other developmental disorders (DD) (Law et al., 2004) often exhibit language delays. Although toddlers with ASD spend less time attending to faces of speakers than typically developing (TD) controls, toddlers with other DD attend to faces of speakers at levels comparable to TD controls (Chawarska, et al., 2012; Shic, et al., 2020). Considering that faces of people speaking provide a great amount of intersensory audiovisual information (co-occurring facial gestures, articulations with vocal, prosodic information) which facilitates language development in TD children (Chawarska et al., 2022; Edgar et al., 2022), we examine contribution of attention to face during speech to language in toddlers with and without ASD.

Objectives: Across five domains of math ability, we explored the relative proportions of very high and low-achieving autistic youth compared to the expected rates in the general population. Second, we asked if the relative contributions of fluid reasoning [FR], expressive language (CELF-5), and EF skills (BRIEF2).

Methods: Thirty-one autistic youth (aged 5–16 years old) completed several tests to measure math ability (KeyMath-3), FR (Raven’s Progressive Matrices), expressive language (CELF-5), and EF skills (BRIEF2).

Results: A Chi-squared test (p < .001) revealed a significantly higher proportion of autistic youth who were low achieving or high achieving (6.45% through 25.81%) in our sample compared to the expected rates in the general population across all math domains. The strongest predictor of math ability across domains was FR, accounting for between 24% and 55% of the model variance. In data analysis

**429.002 (Poster)** Mathematical Ability of Autistic Youth: What Best Explains the Heterogeneity?

L. Hoveling-Hofmann†, K. Howard†, V. R. Smith†, M. Cutumisu†, M. J. Searle† and H. M. Brown†, (1)Educational Psychology, University of Alberta, Edmonton, AB, Canada, (2)University of Alberta, Edmonton, AB, Canada, (3)Queen’s University, Kingston, ON, Canada

Background: Autistic individuals are often stereotyped as gifted mathematicians, and as a result, autistic traits and behaviours are generally believed to lead to superior math ability. Society’s collective understanding of autism is based on media representations, which often foster unrealistic expectations of their skills by families and teachers, leading to additional barriers for autistic students (Draaisma, 2009). This understanding is concerning, given that autistic students are more likely to have a math learning disability [LD] compared to math giftedness (Oswald et al., 2016). Studies have found several variables that influence the math achievement of autistic students. Many autistic students struggle in the upper grades when math relies more heavily upon abstract reasoning and executive functioning [EF] (i.e., working memory skills; Barnett & Cleary, 2019), both of which are relevant for math success.

Objectives: Across five domains of math ability, we explored the relative proportions of very high and low-achieving autistic youth compared to the expected rates in the general population. Second, we asked if the relative contributions of fluid reasoning [FR], expressive language, and EF differed across math domains (e.g., geometry versus algebra).

Methods: Thirty-one autistic youth (aged 5–16 years old) completed several tests to measure math ability (KeyMath-3), FR (Raven’s Progressive Matrices), expressive language (CELF-5), and EF skills (BRIEF2).

Results: A Chi-squared test (p < .001) revealed a significantly higher proportion of autistic youth who were low achieving or high achieving (6.45% through 25.81%) in our sample compared to the expected rates in the general population across all math domains. The strongest predictor of math ability across domains was FR, accounting for between 24% and 55% of the model variance. In data analysis
and measurement domains, expressive language was an additional unique predictor of math ability (accounting for between 55% and 58% of the model variance). Finally, behaviour ratings of EF were not a significant predictor of math ability.

Conclusions: Our findings challenge prevailing stereotypes of an autistic advantage in math and emphasize the need to understand the unique strengths and needs of autistic students. While FR and language are known to be significant predictors of math ability in non-autistic youth, this study explicitly investigated and confirmed that FR and, to a lesser extent, language skills are contributors to autistic students’ ability across math domains. Although EF was not a predictor of math ability, researchers have shown it appears to be an important predictor when students solve complex math problems (not included in our subtests) using specific EF skills. To address the limitations of the BRIEF2, future research should consider using direct measures and investigate the role of EF in math problem-solving.

The belief that autistics are highly talented mathematicians, engineers, and scientists fails to account for autistic youth with a math LD. This study highlights the importance of promoting more accurate representations of math ability distribution across autistic youth. By understanding which variables best predict math achievement, educators can develop new, concrete strategies to ensure autistic students receive the necessary resources and support to succeed in math.

429.003 (Poster) Measuring the Relationship between Multilingual Exposure and Executive Functioning in Preschool Age Children with Autism

A. Jones, N. Nadwodny, G. Schnur, E. Pereida and S. Faja, (1)Laboratories of Cognitive Neuroscience, Boston Children’s Hospital, Brookline, MA, (2)Psychology, University of Massachusetts Boston, Boston, MA, (3)Developmental Medicine, Boston Children’s Hospital, Boston, MA, (4)Boston Children’s Hospital, Boston, MA

Background: Multilingual exposure has been shown to benefit various cognitive and verbal skills in neurotypical youth, including executive functioning (EF) (Baldimtii et al., 2016; Barac et al., 2014). However, few studies have systematically examined the relationship between multilingual exposure and EF in autistic children (Hambly & Fombonne, 2011). Due to concerns about language and cognitive development, providers often advise families against raising autistic children bilingually (Drysdale et al., 2015). However, recent literature has found no significant differences in cognitive or verbal skills between autistic bilinguals and monolinguals through both parent-reports and behavioral measures (Ohashi et al., 2012, Larocci et al., 2017), suggesting bilingual exposure poses no harm to language and cognitive development for autistic children.

Objectives: To investigate differences in executive functioning between autistic preschoolers with multilingual versus monolingual exposure.

Methods: A subsample of autistic children (n = 111, 80% male), ages 2 and 4 years old (M_age=41 months, SD_age=12.29), were taken from a larger study (n = 272) evaluating the development of executive functioning in autistic and non-autistic preschoolers. Participants were split into two groups based on exposure to multiple languages at home (n = 41) or only to English (n = 70). Multilingual exposure was determined by parent report that at least one language other than English was used with the child at home, and this was corroborated by later endorsement on a survey. Children completed behavioral activities (e.g., Tricky Box, Hide and Seek, A not B, and Flip Book; Goia et al., 1996) developed to measure several domains of executive functioning: Inhibition, Delay, Shifting, and Working Memory. Composite scores for each domain were computed as z-scores representing participant performance relative to non-autistic participants in the study. One-way ANOVAs were employed to investigate differences between multilingually exposed and monolingually exposed autistic children on each EF domain.

Results: We first confirmed the language exposure groups did not differ in age, nonverbal cognitive ability, or variance for the executive function battery. Next, analyses with our current sample documented that there were no significant differences between multilingually and monolingually exposed participants for inhibition (F(1, 73) = 0.02, p = .89), delay (F(1, 83) = 2.36, p = .13), shifting (F(1, 89) = 0.21, p = .65), or working memory (F(1, 65) = 1.19, p = .39).

Conclusions: Although, preliminary analyses did not show significant findings in this sample, it does reflect patterns in the literature demonstrating multilingual exposure does not negatively impact developmental skills for autistic children. While our analyses did not result in differences between the two groups, it should be noted that some tasks in our study do not yet have adequate amounts of data to draw a conclusion and data collection is ongoing. Understanding how exposure to multiple languages is associated with developmental outcomes has implications for clinicians and educators as they provide language recommendations and interventions.

429.004 (Poster) No Evidence for Reduced Susceptibility to Visual Illusions in Autism, but Synesthesia - a Twin Study

Background: The Müller-Lyer and Ebbinghaus illusions are visual illusions where nearby or constituent visual information influences size estimates of an object. Susceptibility to visual illusions has been reported to be reduced in autism spectrum condition (ASC) and
synesthesia. In synesthesia, certain sensory triggers lead automatically to additional sensory experiences – for example grapheme-color synesthesia (GCS), where numbers or letters trigger experience of certain colors. The evidence for reduced susceptibility for visual illusions has been mixed in the case of ASC and autistic traits, and limited in the case of synesthesia.

Objectives: In this ongoing study we investigate the association between susceptibility to visual illusions and autistic traits, ASC diagnosis and synesthesia, using a well-controlled twin design.

Methods: We assessed 40 twin pairs (n=80, 63 female, 48 MZ, age: 20-38, M=24.8, SD=4.7), in three groups: twins discordant for ASC or for autistic traits, (n=18, where 10 fulfilled diagnostic criteria for ASC), twins discordant for synesthesia (n=40, where 17 had GCS), and controls (n=22).

Autistic traits were measured with the Autism-Spectrum Quotient (AQ). Grapheme-color synesthesia was assessed with an objective synesthesia test.

Susceptibility to visual illusions was assessed with two tasks. In the Müller-Lyer task participants adjusted a target line to a reference line with constituent lines pointing in opposite directions (Figure 1). In the Ebbinghaus task they matched the size of circle that was surrounded by larger circles to a reference circle surrounded by smaller circles. There were 20 trials for each condition.

Accuracy was calculated by the mean difference between the size of the reference and the adjustable target. A lower value indicated higher accuracy. Values over 1.5 IQRs above the 75th percentile were excluded from analysis of that combination.

Results: We ran linear regressions both across the cohort (adjusting standard errors for twin-relationships) and within twin pairs separately for each task, with accuracy as dependent and AQ total score as independent variable (see Table 1). We found a within-pair association between AQ scores and lower accuracy in the Ebbinghaus illusion condition (b=0.0008, z=2.25, p=0.02). This association persisted when adding ASC diagnosis and synesthesia as predictors (b=0.0009, z=2.91, p=0.003). Further, GCS was associated with a more accurate score within pairs (b=-0.0251, z=-2.29, p=0.02) and across the cohort, (b=-0.0302, z=-2.94, p=0.003). We found no significant relationship between AQ scores and performance across the entire cohort or within pairs for the Müller-Lyer task, and no significant association between performance and ASC diagnosis overall.

Conclusions: We found no evidence for reduced susceptibility for visual illusions in individuals with higher autistic traits or ASC diagnosis, neither across the sample nor in the more controlled twin design. For one illusion type, there was evidence for a small increase in difficulty in estimating size in twins with higher autistic traits, compared to their co-twin. For the same illusion, individuals with GCS were less susceptible to the illusion, both across the sample and within pairs. Results need to be confirmed in a larger cohort, with more individuals with ASC.

429.005 (Poster) Priors in Facial Expressions: Difficulty Updating to Changes in Negative Facial Expressions in Autism

S. Szpiro1,2, R. Twito1 and B. S. Hadad1,2; (1)Special Education, University of Haifa, Haifa, Israel, (2)Edmond J. Safra Brain Research Center for the Study of Learning Disabilities, University of Haifa, Haifa, Israel

Background:

Abnormalities in the use of prior information of basic perceptual stimuli have been observed in people with autism spectrum disorder (ASD), yet it remains unclear whether and how these abnormalities extend to complex stimuli and emotional stimuli in particular. Although people often change their mood and corresponding facial expressions, whether and how people, and especially people with ASD, perceive these ongoing changes in facial expressions remains unclear. The ability to adapt to changes in the emotional expressions of others is at the core of social communication skills and thus especially important for people with ASD.

Objectives: Here, we compared people with ASD and neurotypicals in their ability to acquire and then update a prior of negative facial expressions.

Methods:

Two groups of observers participated in the task, neurotypicals (n=26) and people diagnosed with autism (n=26). Observers performed a two-interval forced choice discrimination task between two facial expressions presented in succession. Facial expressions were of the same identity and ranged between angry and sad. Half the trials contained the same face (‘same’) and half were different faces that varied in morph range (‘different’). To examine the acquisition of the prior, we used the paradigm of “regression to the mean”, in which discrimination between faces is modified according to the mean statistics accumulated during the experiment. In the first segment of the experiment, participants were exposed to facial expressions sampled from a normal distribution around one average prior (sad or angry). In the second segment of the experiment, the average changed to a different prior (angry or sad accordingly).
Results: Mixed design repeated measures ANOVA was carried to examine how accuracy changed between groups and conditions. As expected, in the first segment of the experiments neurotypicals performed better at the task than ASD. Nevertheless, both groups acquired the first prior to the same extent, demonstrating the people with ASD acquire emotional priors. In contrast, in the second segment of the experiment, only the neurotypicals updated and acquired the second prior. We calculated the magnitude of the bias in each segment of the experiment and found that while for the ASD group there was a negative correlation (i.e., as the effect of the prior in the first segment was larger, the effect of the prior in the second segment was smaller), there was no correlation for the neurotypicals.

Conclusions: Our findings reveal that people with ASD are able to acquire emotional priors of facial expression yet exhibit a unique difficulty in updating this acquired prior to a new prior when the statistics of facial expression changes. These findings point to an inflexibility in processing emotional information and shed light on the social behavior of people with autism.

E. Stockigt, R. L. Young, N. Brewer and N. Weber, (1)Psychology, Flinders University, Adelaide, SA, Australia, (2)Flinders University, Adelaide, Australia, (3)Flinders University, Adelaide, SA, Australia, (4)Flinders University, Adelaide, SA, Australia

Background:

- Autistic individuals may be perceived as less credible than non-autistic individuals (e.g., Lim et al., 2022). This may be because some autistic behaviours resemble behaviours commonly thought to indicate deception (e.g., gaze aversion and body movements).
- It has been hypothesised that deception judgments arise when behaviour is unexpected (expectancy violation theory). In the criminal justice system, autistic behaviours may violate expectations associated with innocence and, hence, autistic individuals may be judged as lacking credibility.

Objectives:

To investigate whether:

- Autistic individuals are perceived as less credible, and more likely guilty.
- Autistic individuals violate behavioural expectations more than non-autistic individuals
- Behavioural expectancy violations predict ratings of credibility and guilt.

Methods:

- Participants (N = 336) read a hypothetical crime scenario and were asked to give examples of verbal and non-verbal behaviours expected from persons accused of the crime. Responses revealed 11 verbal, and 11 non-verbal behaviours most mentioned as being expected in an innocent individual. These included many behaviours that may be abnormal in autistic individuals (e.g., eye contact, body movements, speech abnormalities).
- Autistic (N = 26) and non-autistic (N = 29) adults were interviewed about involvement in this hypothetical crime.
- Participants (N = 430) watched these interviews and provided ratings of credibility and likely guilt. They then provided ratings of the extent to which each individual had violated their expectations of engagement in verbal and non-verbal behaviours for an innocent individual.

Results:

- Expectancy violations were related to perceptions of credibility and guilt for nearly all verbal and non-verbal behaviours. Effect sizes ranged from small (d = .18, to large d = .61)
- Autistic individuals were perceived as less credible (d = .21)
- However, autistic individuals did not violate behavioural expectations more than the non-autistic group.

Conclusions:

- While there was no group differences in ratings of behavioural expectancy violations between autistic and non-autistic individuals, autistic characteristics did negatively impacted perceptions of credibility. Results suggest this is because these behaviours violate observers expectations.
• It remains unclear what drives differences in perceptions of credibility in this sample, where there were no group differences in expression of autistic characteristics.

429.007 (Poster) Relationships between Parenting Style, Child Language Ability, and Child Executive Control
S. Sundar, S. Salinas* and S. Faja*, (1)Labs of Cognitive Neuroscience, Boston Children’s Hospital, Brookline, MA, (2)Boston Children’s Hospital, Boston, MA

Background:

Social factors such as parent interaction style can significantly impact long-term brain structure and function (Huttenlocher, 2002). Specifically, prior research indicates that favorable (i.e., autonomy-supportive) and unfavorable (i.e., controlling) parent-child relationships can impact the development of executive functioning (EF) (Bernier et al., 2012). Autonomy-supportive parenting entails “the encouragement of children’s opinions, choices, decisions, and problem solving,” (Matte-Gagne & Bernier, 2011) by scaffolding or by providing age-appropriate problem solving strategies that can be employed later on when the child must work independently (Bernier, 2010). EF deficits in children diagnosed with autism spectrum disorder (ASD) have been studied extensively due to their relation to social and communication development (Ozonoff, 1991; Winsler, 2007). However, it is unknown whether parenting styles differ for autistic and neurotypical children and whether parenting strategies contribute to EF levels among young autistic children.

Objectives:

The objectives of this study were to examine whether parents of autistic children use different parenting strategies compared to parents of neurotypical children, and whether parenting strategies relate to child characteristics such as age, language ability, and EF.

Methods:

To date, parenting behavior has been coded for 16 autistic and 8 neurotypical toddlers and preschoolers aged 28-58 months (2 girls). Autistic children were diagnosed using the Autism Diagnostic Observation Schedule–Second Edition (ADOS-2) and the Autism Diagnostic Interview–Revised (ADI-R). Children and their parents engaged in an 8-minute interaction in the lab where they were asked to complete a construction task with Duplo blocks and make a puzzle together while being video-recorded. Parenting style was coded using procedures and schemes adapted from Grolnick (2002). Verbal and nonverbal parenting strategies were coded separately with eight potential scores ranging from controlling (1-4) to autonomy-supportive (5-8). EF was examined via a composite measure of behavioral control tasks that required waiting for desired objects.

Results:

Verbal parenting strategies differed by diagnostic group, t(22) = -2.88, p = .009, with parents of neurotypical children using more autonomy-supportive strategies. Nonverbal parenting strategies did not differ by diagnostic group (p = .23). Across diagnostic groups and controlling for age, verbal developmental level related to verbal parenting strategies, r(21) = .64, p = .001, but not nonverbal parenting strategies (p = .40). Finally, we examined whether parenting strategy predicted the ability to delay gratification using a linear regression. Although verbal parenting strategies predicted the ability to delay gratification (β = .47, p = .02), this relation was no longer significant (p = .42) when verbal developmental level (p = .01) was added to the full model.

Conclusions:

Our preliminary results suggest that parenting style may differ for autistic children, particularly regarding the type of verbal strategies used. For young children, parents may adapt their verbal strategies according to their child’s developmental level – using more directive strategies for children with less language. The level of verbal strategies used also corresponded with the ability to exert self-control while waiting for rewards, although child language level may account for both verbal parenting style and the development of behavioral control.

429.008 (Poster) Reported Engagement in Relation to Games Created By Autistic Youth in a Game Design Workshop

Background:

Students learn more when engaged (Boekarts, 2016). Research has shown alignment (Falkmer et al.,2012) and differences (Losh et al., 2022) between teacher- and student-reported engagement in educational opportunities. Misalignment may be particularly pronounced...
between teachers and autistic students, given that autistic people are often misinterpreted (Milton, 2012). Engagement can be a difficult but very important thing to assess in online educational contexts (Dewan et al., 2019). While researchers have studied how technology affects student engagement, no research has examined if technology products (e.g., video games) created by students may indicate engagement.

Objectives:

1. Assess whether student-reported engagement and teachers' ratings of student engagement will positively correlate with the diversity of game elements visible to the player in games produced by autistic students.
2. Assess whether student-reported engagement is more strongly associated with the diversity of game elements than teachers' reports of the students' engagement.

Methods:

20 autistic adolescents participated in a game design workshop where they were taught to create video games using a program called Flowlab. Three students did not provide links to their games to interviewers, so analyses focus on those who provided games. Games were inductively coded for front-end-type elements (the presence or absence of elements seen in Table 1). During pre- and post-assessments, students completed a survey that assessed computational thinking, self determination, and video game design self-efficacy and game-based assessments of cognitive skills (Cambridge Brain Sciences; Hampshire et al., 2012). Picture-based surveys measuring students' self-reported engagement and teachers' perceptions of student engagement were administered after specific workshop activities (see Figure 1). Individual differences and student and teacher engagement ratings were compared to summed front-end-type elements in the students' games.

Results:

Table 1 shows how often specific front-end-type elements appeared in students' games.

Summed front-end-type elements were largely unrelated to students' engagement ratings of workshop activities. However, engagement with two activities was associated with games with more front-end-type elements: a whole group activity where students created a game by taking the perspective of the player, \( r(12) = .69, p = .007 \), and that same activity delivered in small groups of 3-4 students, \( r(14) = .60, p = .014 \).

Teachers' ratings of students' engagement with the aforementioned activities did not correlate with students' engagement ratings (\( ps > .294 \)). Computational thinking, self-determination, and video game self-efficacy were also unrelated to front-end-type elements (\( ps > .270 \)).

Conclusions:

Front-end-type elements in autistic students’ games were positively correlated with students’ engagement during game design activities that encouraged students to take the perspective of the player. This suggests that engagement with activities that help students imagine players’ perspectives may encourage them to produce more engaging games. Findings align with evidence that perspective-taking activities may promote creativity (Chou & Tversky, 2020). Next, we will examine games produced by students in another workshop, and expand upon our focus on front-end types to include both front-end tokens and back-end coding used to create games in relation to student engagement. Findings thus far highlight autistic students’ creative projects as windows into their engagement with informal educational opportunities.

429.009 (Poster) Savant Abilities and Autism: A Scoping Review

A. Nordahl-Hansen; V. S. Slang and E. Gabarron; (1)Østfold University College, Halden, Norway, (2)Department of Education, ICT and Learning, Østfold University College, Halden, Norway

Background: The links between savantism and autism has a long history. The prevalence of savantism in autistic populations are occurring at a disproportionally higher rate compared to any other groups. Driven by media and possible other sources have perhaps led to the perception in the public that most autistic individuals have savant skills of some sort. However, studies indicate a prevalence within the autistic population somewhere around 10-30% (Rimland, 1978; Howlin et al., 2009) depending on how savantism is defined (Bölte & Poustka, 2004).

Objectives: In this review we give an insight into peer-reviewed publications on types of savant abilities, and the historical progress over the years in autism research.

Methods: We searched the database Scopus in October 2022 using no limitations in terms of language or publication period. Using a general database as Scopus gives a good insight into the overall trends of research in different areas. The following search string was used:
autism OR asd OR autistic OR Asperger OR pervasive developmental disorder OR pervasive development disorder OR pdd OR pdd-nos AND savant* OR exceptional skills OR genius OR prodigious. Publication included in this review had to have a focal point on savantism and autism, be peer-reviewed, and contain empirical data, both qualitative and quantitative. Reviews, editorials, and commentaries were also included.

Results: The search resulted in 289 references and after screening a total of 166 studies were included in the subsequent analysis. The earliest study on autism and savantism with empirical data detected in Scopus was from 1972. Most frequently the studies did not specify the type of savant ability the participants had (89 studies). The top frequent abilities specifically reported were musical-, memory-, artistic- and mathematical –abilities (see table 1 for full list of abilities). The historical trend indicates an increase of studies up until 2010 and a marked downward trend from 2011 to 2022 (Figure 1).

Conclusions: The relation between Savantism and autism is a topic of interest not just due to its mythical appeal but also as it is not yet entirely understood. In this review of the various types of abilities and trends within autism and savantism research we found some abilities are more researched than others, but the highest occurring number of studies was on savantism where ability type was not specified. Considering a massive increase in publications in general, and publications within the autism field the past couple of decades it is somewhat surprising that the trend of published research on savantism in autism indicate a decline in the past 12 years. As underlying causal factors and links between autism and savantism remain unclear we encourage researchers to continue investigate this topic area and in particular to collaborate with autistic individuals to better understand the phenomenon (Happé, 2018).

429.010 (Poster) Self-Related Processing and Mentalizing in Adolescents with Autism

L. Amodeo1, A. D. Nijhof2, D. M. Williams3 and J. R. Wiersema4, (1)Department of Experimental Clinical and Health Psychology, Faculty of Psychology and Educational Sciences - Ghent University, Ghent, Belgium, (2)Research group EXPLORA, Ghent University, Ghent, Belgium, (3)Department of Experimental Clinical and Health Psychology, Ghent University, Ghent, Belgium, (4)School of Psychology, University of Kent, Canterbury, United Kingdom

Background: The human tendency to preferentially process self-related material – i.e. the self-bias – and the ability to represent mental states – i.e. mentalizing – are essential for social functioning. Earlier research found both the self-bias and mentalizing to be altered in individuals with autism, who experience persistent social difficulties. Some studies, investigating either early- or late-stage self-processing, indicated autism-related reductions of preferential responses to self-related content. Others observed a decreased ability to attribute mental states to oneself, as well as to others (i.e. self- or other-mentalizing), in autism. However, findings regarding the self-bias and self-mentalizing, are mixed and inconclusive. To date, different aspects of self-related processing and mentalizing – potentially tapping into shared, overlapping cognitive mechanisms – have been investigated separately from one another. More research directly comparing these aspects within the same sample is thus warranted.

Objectives: Our study aims to elucidate which features of self-related processing and mentalizing differ between adolescents with and without autism.

Methods: Thirty adolescents with autism (age: $M = 14.37, SD = 1.85$; 20 males, 9 females, 1 genderfluid) and 26 age- and IQ-matched controls (age: $M = 14.73, SD = 2.05$; 13 males, 13 females) performed a visual search task (early-stage self-processing), a trait adjectives task (late-stage self-processing), a feeling-of-knowing task (self-mentalizing) and the Frith-Happé animations task (other-mentalizing). Parents also completed two questionnaires (i.e. SRS, SCQ) assessing the adolescent’s degree of autistic symptomatology.

Results: Groups did not differ on the two measures of self-bias and the magnitude of the self-bias effects was equivalent in both groups (all $t$s $\leq 0.61$, $ps \geq .542$, $ds \leq 0.16$). Also, no group difference was found for self-mentalizing ($t = 0.22, p = .828, d = 0.06$), while other-mentalizing was reduced in adolescents with autism ($t = 2.29, p = .026, d = 0.61$).

Conclusions: Taken together, our results do not provide support for altered self-processing in adolescents with autism, as neither self-bias effects nor self-mentalizing were reduced in the autism group, despite the group manifesting the expected diminution of other-mentalizing. This suggests that previous findings of altered self-processing (at least, these aspects of self-processing) in autism may not be reliable. The apparent dissociation between self- and other-processing observed in the current study presents a challenge to theories that postulate a common mechanism underpinning these abilities. Moreover, the results have relevant implications for optimizing support, which will be discussed.

429.011 (Poster) Smartphone-Based Eye Tracking for Longitudinal Studies of Autism

N. Y. Kim1, Q. Wu2, J. Turner1, L. K. Paul3 and R. Adolphs4, (1)California Institute of Technology, Pasadena, CA, (2)Psychological and Brain Sciences, Indiana University, Bloomington, IN

Background: In-lab eye tracking studies have demonstrated atypical gaze patterns in adults with autism, but most of them are based on small samples and data from a single session. In order to develop eye tracking as a quantifiable tool for autism screening and diagnosis, we
need a better understanding of between- and within-individual variability. However, conventional eye tracking methods require specialized and often expensive equipment, placing constraints on large-scale data collection. How could gaze data be acquired from a larger population recruited from diverse communities, or over extended longitudinal sampling?

Objectives: We addressed this challenge with a new smartphone-based eye tracking method that allows participants to provide data from the comfort of their home (Valliappan et al., Nature Communications 2020). Our aims were twofold: to validate smartphone-based eye tracking by direct comparison with in-lab acquisition; and to quantify within-subject consistency of gaze patterns over time and explore psychological factors that might contribute to session-by-session variability.

Methods: Adult participants (ASD n=14; mean age = 29.8; 2 females; typically developed controls (CTL) n=20, mean age = 32.2; 3 females) watched YouTube videos and static images (from the OSIE database; Wang et al., Neuron 2015) while gaze was monitored. ASD participants had a DSM-5 diagnosis and met criteria on the ADOS; all participants had IQ in the normal range and corrected-to-normal visual acuity. Gaze data were first acquired in the lab, where participants performed the video and image free-viewing task on a smartphone (Google Pixel 3a XL) and on a monitor with a standard Tobii 600Hz desktop eye tracker. For the longitudinal component, participants performed 10 weekly smartphone sessions at home and provided weekly self-reports regarding mood, anxiety, and perceived stress level.

Results: Smartphone gaze data were acquired at 30 Hz with 0.5 to 1° of gaze error, and Tobii gaze data at 600 Hz with 0.25 to 1° of gaze error. Analyses of smartphone gaze data showed that individuals with ASD looked less at faces (Cohen’s d = 0.96) and people (Cohen’s d = 0.74) featured in the stimuli compared to CTLs, replicating the findings that are reliably reported in the literature. Gaze time proportions to social features were reliable within each individual across the two methods (smartphone in-lab Tobii; gaze time to faces: \( r_s=0.39, p<0.01 \); gaze time to people: \( r_s=0.46, p<0.01 \)) and across the weekly at-home sessions (smartphone in-lab and at-home sessions; faces: \( r_s=0.63, p<0.004 \); people: \( r_s=0.49, p<0.03 \)), both in the ASD and CTL groups, consistent with other reports (Keles et al., Molecular Autism 2022). Preliminary analysis suggested that session-by-session variability in gaze patterns in ASD is associated with self-reported stress (\( F(1,46) = 5.7, p<0.02 \)).

Conclusions: We demonstrate the power of at-home eye tracking using smartphones to collect high-quality, reliable gaze data. The approach can be used in participants with autism and can be used to collect in-depth longitudinal data, as well as data in larger samples and in underserved populations that may be difficult to test in the lab.

429.012 (Poster) Teachers’ Perceptions of Executive Functioning and Challenging Behaviors in a Sample of Students with and without Autism.

**A. Dimachkie Nunnally**, J. Vega Garcia, J. C. Bullen, C. Alexander, C. Parks, N. S. Tseng, P. Mundy and N. Sparapani, (1)UC Davis MIND Institute, M.I.N.D. Institute, UC Davis, Sacramento, CA, (2)UC Davis, Davis, CA, (3)School of Education, University of California, Davis, Davis, CA, (4)University of California, Davis, Davis, CA, (5)Teacher Education, University of California, Davis, CA, (6)University of California at Davis, Davis, CA, (7)UC Davis MIND Institute, University of California, Davis, Sacramento, CA

Background: Autistic students commonly experience challenges in executive functioning (EF) (Tschida & Yerys, 2022), which can result in behaviors that are perceived to be oppositional or defiant by their teachers (Maddox et al., 2018). Teachers’ abilities to accurately identify children’s challenging behaviors from behavioral manifestations of EF challenges would allow teachers to better support their students’ EF development.

Objectives: This study aims to examine group difference in teacher-reported EF and challenging behaviors between students with and without autism.

Methods: We present preliminary results using data from a larger sample, which was collected during an ongoing longitudinal study (R324A210288). Participants include 30 students between Pre-K and 5th grade, 15 of whom have Individualized Education Programs (IEPs). The sample is comprised of 8 autistic students, 7 students with non-autistic (Other) IEPs and 15 neurotypical (NT) students. Participants in this study had a mean age of 7.39 years (SD = 1.25) and 7 females and 13 males. All participants had IQ in the normal range and corrected-to-normal visual acuity. Descriptive statistics for EF scores and challenging behaviors scores are presented in Table 1. Kruskal-Wallis H-tests were used to evaluate group differences in EF abilities and challenging behaviors, with a Bonferroni adjustment for multiple comparisons. Results revealed significant differences in EF abilities, such that students in the NT group (Mean Rank = 12.10) had significantly less impaired EF abilities than students in the Autistic group (Mean Rank = 30.39; \( p<0.001 \)) and the Other group (Mean Rank = 12.10; \( p=0.11 \)). Similarly, students in the NT group (Mean Rank = 9.73) had significantly fewer challenging behavior scores than students in the Autistic group (Mean Rank = 21.93; \( p=0.007 \)) and the Other- group (Mean Rank = 20.69; \( p=0.013 \)). No significant difference was detected between Autistic and Other groups. Finally, EF and challenging behaviors were significantly correlated in all three groups, such that strongest association was seen in the Other group (\( r=0.962; p<0.001 \)), followed by the Autistic group (\( r=0.850; p=0.008 \)) and the NT group (\( r=0.750; p<0.001 \)).
The magnitude of the association was found to be significantly different between the Other group and NT group \((z = -1.24; \ p = .042)\), with no other significant differences detected.

**Conclusions:** This study contributes to the nascent literature examining EF abilities within schools. Findings reveal that students in the Autistic group and the Other group had EF abilities that indicate mild/possibly clinical impairment, and students in the Other group exhibited levels of challenging behaviors that placed them at-risk for clinical problem behaviors. Challenging behavior was strongly and significantly correlated with EF abilities for all groups. Providing teachers training to discriminate between EF challenges and challenging behaviors would allow teachers to better support students’ EF development.

**429.013 (Poster) Temporal and Time-Frequency Signatures of Auditory Change Detection in Autism Spectrum Conditions**

**P. Liu, Anhui Medical University, School of Mental Health and Psychological Sciences, Hefei, China; Sun Yat-Sen University, Department of Psychology, Guangzhou, China**

Background: In the ever-changing environment, we are constantly confronted with mixture of sounds. Change detection, the ability to detect and quickly respond to potentially relevant information, has been proved to be of significance for survival. Atypical sensory profile has been an important clinical description in individuals with autism spectrum conditions (ASC), but the neural basis underlying auditory change detection remains inconclusive.

Objectives: Our study was aimed to elucidate how autistic individuals react to two stages of auditory change detection: pre-attentive stage and attentive-dependent stage. To do this, we used a hierarchical change detection paradigm (Bekinschtein et al., 2008) to specifically evaluate the electrophysiological responses associated with two types of deviants’ detection (local and global) and how different frequency bands modulate these processes by analyzing event-related potentials (ERPs), time-frequency representations (TFRs).

Methods: A total of 21 typical developing individuals (10 females) and 20 autistic individuals (14 females) participated in this study. Continuous EEG was acquired while participants perceiving sound sequences consisting of 5 tones spaced 100 ms apart. Within each sound sequence, the first 4 tones were identical, whereas the fifth tone was either identical (local standard) or different (local deviant). On top of the within-trial level, rare sound sequences occasionally delivered to a serial of frequent sound sequences (global standard) led to a longer-term stimulus deviance (global deviant). This design enables 2 types of examinations, namely local effect (local level of change detection) and global effect (global level of change detection), which correspond respectively to the difference of neural responses between local deviant and local standard and between global deviant and global standard.

Results: We found that, compared to TD individuals, MMN response, indexing the pre-attentive process during local deviants detection, was decreased in individuals with ASC, which was accompanied by decreased power in both in the delta and theta frequency bands. In addition, the P3b amplitude, serving as a marker of attention-dependent process during global deviants detection, was reduced in individuals with ASC. This process was accompanied by significant reductions both in the delta and theta frequency range in ASC group, as well as a reduced power suppression in the beta frequency range, compared to TD group. There were no significant differences between the two groups in terms of the alpha reactivity.

Conclusions: Our results reported the profile of hierarchical auditory change detection in ASC and have the potential to enhance our understanding of brain functions in this population.

**429.014 (Poster) The Effects of Age on Temporal Reward Discounting in Autistic Children and Adolescents**

**H. Van de Vyver, E. Demurie and H. Roeyers, (1)Department of Experimental-Clinical and Health Psychology, Ghent University, Ghent, Belgium, (2)Department of Experimental-Clinical and Health Psychology, Ghent University, Ghent, BELGIUM**

Background: Temporal reward discounting (TRD) refers to the phenomenon in which the subjective value of a reward declines when the reward is delayed (Green & Myerson, 2004). As a consequence, the individual will more likely choose for a sooner smaller reward, instead of a later larger reward (Scheres et al., 2007). The majority of TRD studies in children indicates no significant differences between autistic children and neurotypical children (e.g., Karalunas et al., 2018), whereas some studies find a steeper TRD-slope in autistic adolescents and adults (e.g., Carlisi et al., 2017; Warnell et al., 2019).

Objectives:

This study investigated the steepness of the TRD-slope and the development with age in autistic children and adolescents, compared to neurotypical children and children with attention deficit hyperactivity disorder (ADHD).
Methods:

Participants were 298 children and adolescents aged between 8 and 16 years with autism (N = 73), ADHD (N = 84) and neurotypical development (N = 141). In 2 computer tasks they had to make a choice between an immediate reward and a delayed reward with a higher value. The reward was money (task 1) or an alternative reward (material, food, a social reward or an activity; task 2).

Results:

Linear regression with age, group, and their interaction as predictors for the TRD-slope of monetary rewards revealed significant main effects of age (F(1,284) = 6.18, p = .013) and group (F(2,284) = 3.44, p = .034). More specifically, a less steep TRD-slope was found with increasing age. Autistic and neurotypical children showed a significantly less steep TRD-slope than children with ADHD. No significant difference was found between autistic and neurotypical children. The interaction of age and group was marginally significant (F(2,284) = 2.70, p = .069). Only within the group of autistic participants no significant age effect was found. A second linear regression was conducted for the TRD-slope of alternative rewards with the same predictors, inclusive reward type. A main effect of reward type was found (F(3,210) = 3.81, p = .011), with a less steep TRD-slope for materials compared to other rewards. Also, a main effect of age (F(1,210) = 7.87, p = .005) and group (F(2,210) = 3.57, p = .03) was found, and the interaction term was marginally significant (F(2,210) = 3.00, p = .05). Just like in the first task, TRD-slopes were less steep with increasing age, but only in the neurotypical group. No significant effects of age were found in the autistic children and children with ADHD. However, with increasing age, group differences emerged between autistic and neurotypical children.

Conclusions:

Like most studies, no differences in TRD were found between autistic and neurotypical children, while children with ADHD showed a steeper TRD-slope. Also, no age effects were found within the group of autistic children, whereas the steepness of the TRD-slope in neurotypical children and children with ADHD mostly decreases with age. This might be in line with research in autistic adolescents and adults, where steeper TRD-slopes were found, and may indicate an increasing appreciation of rewards with age.

429.015 (Poster) The Experience of Superior Perceptual Capacity in Neurodivergent Adults

Background:

Studies have found strong evidence for superior perceptual capacity - the ability to process more information at any one time - in autistic people without intellectual disability. It is crucial to investigate the experiences of participants directly by building on these simplified, lab-based experiments. In addition, to evaluate superior perceptual capacity as a marker of autism, it is paramount to understand whether it pertains specifically to autism, or is a general consequence of neurodivergence. Currently, most autism research is carried out in comparison with the majority population, yet this cannot assess the uniqueness of a particular trait. This study compared experiences with those who have Attention Deficit Hyperactivity Disorder (ADHD). Here we move beyond normalcy and take a qualitative cross-syndrome approach to understand whether superior capacity is a specific component that underpins autism.

Objectives:

We aimed to gather rich qualitative data to (1) understand the experiences of perceptual capacity in autistic people, people with ADHD, and the majority, and (2) compare experiences across diagnostic labels.

Methods:

This project upholds participatory ideals and an open research approach. A long-form online text survey asking about perceptual experiences was co-designed by an autistic researcher from the team, working with a neurodivergent majority consultancy group. 362 adults were recruited from UK advocacy groups. Respondents were adults diagnosed or identified as autistic (n=100), ADHD (n=35), autistic with ADHD (n=110) or majority (n=117). Alongside the survey, participants completed the brief autism and ADHD scales to provide additional dimensional information respectively. Pre-registration and codebooks were published on the Open Science Framework for replication.
Thematic analysis was an apropos methodology for a 113,260 word dataset of novel text. The two coding researchers approached the text without knowledge of participants' diversity; only once themes had been developed were groupings revealed and further conceptualisation made. In their negotiation of salient themes the researchers brought their own experiences of neurodiversity, autism and ADHD.

Results:

Themes clustered around concepts of control and strategy, focus and distraction, and the perceptual reality of an ideal place. Control was discussed as more than simple avoidance of the personal cost of distraction, it was an inherent strand of being able to advocate for strategies that could either fill excess sensory capacity or modulate the sensory world. A “fine balance” was sought by participants to “smooth” and control the sensory world in which distraction and focus were experienced. This was evident in real world narratives of annoyance and frustration and in the soothing escape of being “happy and in flow” through thinking with a robust “association network”. Facets of ideal spaces to flourish were remarkably similar across all participants.

Conclusions:

These findings tentatively posit a restructuring of practice that ceeds control over environments through a host of potential tools and strategies that would be to the benefit of all. Furthermore, it suggests that the superior sensory capacity is a wider underlying symptomatic construct that suggests further linkages between autism and ADHD.

429.016 (Poster) The Link between Alexithymia, Sustained Attention, and Emotion Regulation in Children with Autism
A. P. Costa and G. Steffenen, (1)University of Luxembourg, Esch-sur-Alzette, Luxembourg, (2)Institute for Health and Behaviour, University of Luxembourg, Luxembourg

Background: It is known that attention can be used to regulate emotions (Derryberry & Rothbart, 1988). Furthermore, it has been shown that children with autism who have difficulties in emotional awareness (i.e. alexithymia) tend to focus more on negative or irrelevant information (Embrechts & van Nieuwenhuijzen, 2009). Thus, leading to the assumption that alexithymia may impair attentional deployment (Rieffe et al., 2011), which can lead to poorer emotion regulation. However, little research exists on the link between attentional capacity, alexithymia, and emotion regulation in autistic children.

Objectives: To analyse the link between alexithymia and the attention capacity of children with autism and their role in emotion regulation ability.

Methods: Thirty-seven autistic children (5 female) and 41 typically developing (TD) children (9 female) aged 3-13 years old participated in the study. Parents reported on their children’s alexithymia using an adapted version of the Alexithymia Questionnaire for Children (Rieffe et al., 2006). Children first took part in a sustained attention task in which they watched a 3-minute slide presentation of 15 pictures. Then, children were exposed to the “toy behind a barrier” frustration-eliciting situation. In the sustained attention task, the total amount of time looking at the presentation was coded (duration: maximum = 180 seconds) as well as the intensity of facial interest (interest: 0=not interested, 1=interested, 2=very interested). In the frustration-eliciting situation, children’s behaviors were coded into 12 categories and then grouped into three emotion regulation strategies: disruptive, passive, and active self-regulation.

Results: Regarding emotion regulation, autistic children displayed more disruptive \( F(1,76)=25.24, p<.001, n_2p=.25 \) and less passive strategies \( F(1,76)=11.35, p<.01, n_2p=.13 \), but similar levels of active self-regulation \( F(1,76)=2.03, p=.16, n_2p=.03 \) than TD children. Autistic children were reported by their parents as having significantly more alexithymia than TD children \( t(76)=4.98, p<.001 \) and showed poorer focused attention than TD children: their sustained attention was shorter \( t(43)=5.492, p<.001, d=1.33 \) and their interest lower \( t(70)=4.118, p<.001, d=0.96 \). Correlation analyses revealed that both indicators of attention were negatively correlated to the use of disruptive \( r=-.56, p<.001 \; \text{interest}: r=-.28, p<.05 \) and positively correlated to passive strategies \( r=.57, p<.001 \; \text{interest}: r=-.33, p<.01 \). However, no significant correlation was found between attention and active self-regulation, nor between attention and alexithymia. Further regression analyses were conducted to predict the use of the three emotion regulation strategies using a enter method (see Table 1). They revealed that the duration of sustained attention could predict the use of disruptive and passive strategies above and beyond autism diagnosis. However, alexithymia did not contribute to it. Further analyses exploring possible moderation roles of alexithymia also revealed no significant results.

Conclusions: Our results show a significant association between children’s capacity for sustained attention and their use of less disruptive and more passive emotion regulation strategies. However, contrary to what expected, alexithymia was not linked to attention and did not contribute to explain emotion regulation. The present results can offer new perspectives on how attention difficulties could contribute to better understand emotion dysregulation in children with autism.

429.017 (Poster) The SIB Study – Exploring the Links between Executive Function and Self-Injurious Behaviour in Autistic Children with a Co-Occurring Intellectual Disability
Background: Self-injurious behaviours (SIB), such as headbanging and skin picking are common in children with autism and a co-occurring intellectual disability. Previous research identifies an association between the presence of SIB and caregiver-reported impulsivity and overactivity in autistic samples (Richman at al., 2012) with higher levels of impulsivity reliably predicting the presence of SIB over both three years (Richards et al., 2012) and 10 years (Laverty et al., 2020). These findings suggest there may be stable and reliable behavioral mechanisms that play a key causal role in SIB; though until now have not been explored through direct methods. Traditional approaches of understanding SIB often assume an operant learning framework, whereby behaviors are maintained through an interaction between an individual and their environmental reinforcers (Emerson et al., 2012). Though this position is helpful, it neglects a key question; what are the underlying mechanisms beyond the learning account that may lead to the development of SIB? There may be underlying cognitive difference that at present remain unexplored in children who have autism and a co-occurring intellectual disability due to a paucity of developmentally appropriate robust assessments.

Objectives: The SIB study aimed to investigate the putative relationship between both direct and informant-based measures of executive function (EF) abilities and the presence and severity of SIB in autistic children with co-occurring ID.

Methods: A novel and developmentally appropriate EF battery was developed as part of a battery of assessments administered remotely to a sample of 159 children with autism and a co-occurring intellectual disability (mean age =10.40 [range= 4.02–15.49], 37 female, vineland adaptive age equivalent mean=2.85 [range = 1.26–11.3]). The SIB study was conducted completely remotely, with parents and caregivers delivering a battery of EF tasks in their own home to their child guided in real time through Bluetooth headphones.

Results: Preliminary analysis of the first 60 participants indicated SIB was moderately associated with a direct measure of updating and inhibition (r=-.28, p <.05), caregiver-rated impulsivity (r=.41, p =.001) and overactivity (r=.33, p <.05). Impulsivity and overactivity were significant unique predictors of SIB (p <.05), over and above general cognitive ability. In an age-and-ability matched subset, children who displayed SIB were rated as significantly more impulsive on average than those who did not (g=.78). On direct measures of EF, there was a significant small to moderate association between efficiency scores and SIB, and a small to moderate relationship between perseveration and SIB which also approached significance.

Conclusions: Preliminary findings from the SIB study replicate previous findings of a robust relationship between caregiver-rated impulsivity and SIB. The direction and magnitude of effects between direct measures of EF and SIB offer tentative support for a role of behavioral inhibition in the developmental course of SIB. These findings extend our current understanding of SIB, the operant model and inform proactive intervention strategies. Additionally, novel methodology’s highlight the feasibility of remote EF assessment in children with autism and a co-occurring intellectual disability, and under-represented group within the current evidence base of SIB and EF.

429.018 (Poster) Thermal Imaging for Internal State Detection
Y. Mohamed and A. Güneysu Özgür, (1)KTH, Stockholm, Sweden, (2)Robotics, Perception and Learning, KTH Royal Institute of Technology, Division of Robotics Perception and Learning, Stockholm, Sweden

Background:
As humans we struggle in identifying social queues, let alone complicated compound emotions like frustration, enjoyment and boredom (Internal states). Similarly, children with ASD would face a multiplied version of this issue when having normal interactions everyday in particular as they do have a harder time identifying these emotions (Bal E. et.al, 2010).

Understanding these emotions would allow us to have more harmonious interactions and more empathy towards the participants of the interaction. Therefore, multiple studies have been done to automatically detect those internal states using physiological signals like heart rate or EEGs. These signals however would need intrusive sensors that would feel uncomfortable for kids, in particular the kids that are sensitive to touch.

Therefore, other studies have used facial expressions and gaze to detect the internal states of children with ASD. But, children with ASD tend to show less facial expressions for limited duration, which makes the use of facial expression detection during an interaction in real-time challenging and inaccurate (Trevisan, D. A et.al, 2018).

With the recent wide use of thermal cameras, a study focus was established in this area, as multiple works have been recently published to detect emotions using thermal imaging in healthy adults (Mohamed Y. et.al, 2022) and detecting autism in children (Ganesh K. 2021).

Objectives:
In this work we propose to use thermal imaging combined with machine learning approach to detect internal emotional states in real-time and mitigate them using robots during gamified therapy sessions for personalization.

This process is composed of two parts: data collection and validation on healthy adults and testing on people with ASD.

Methods:

We collected both Thermal regions and facial expressions of 29 participants during 20 minutes of using a gamified robotic platform using palmsized tangible robots. The participants then play 10 rounds of the tangible PacMan inspired game while physically manipulating the robot and avoiding the autonomous ghost robot (Guneysu Ozgur et.al, 2018). The data collection composed of three conditions induced through game difficulty design: baseline, enjoyment, frustration and boredom. Each condition has different game configuration to provoke the emotion.

After each set of 10 rounds the participants would answer self reports of how frustrated, enjoying or bored they were.

Results:

After running an ANOVA, the self reported emotional states correlated to the emotion provoked (P < 0.001). Similarly, using the thermal data the averages of the thermal regions collected also was significantly different during each condition. Furthermore, A machine learning algorithm (LSTM) was developed and was able to detect each condition from thermal features with accuracy of 77% using both thermal and action units, compared to the use of just action units which has the accuracy of 69%.

Conclusions:

The use of thermal data can significantly improve emotion detection during gamified robot-mediated exercises, which is the first step to mitigating negative emotions through game difficulty adaptation. Evidently, the use of thermal data for healthy adults did increase the detection accuracy and it is hypothesised that this increase would be more evident on people with ASD.

429.019 (Poster) Trajectories of Attention Problems in Children with ASD

Background:

Attention-deficit/hyperactivity disorder (ADHD) frequently co-occurs with autism spectrum disorder (ASD). Cross-sectional studies show that children with co-occurring ASD and ADHD have poorer social skills than children with either condition alone. Two previous longitudinal studies found multiple trajectories of attention problems (AP) in autistic individuals followed from 2 to 6 years (Visser et al., 2017) and from 9 to 26 years (McCauley et al., 2020). In the latter study, high and decreasing AP (41% of sample) were associated with fewer positive adult outcomes (including social outcomes) compared to the low and decreasing AP trajectory (59%).

Objectives:

Describe trajectories of AP in autistic children from age 2–4 years to age 10.5–11 years and examine the association of trajectories with social skills outcome. We hypothesized that (1) we would find at least two trajectory groups, one with low AP over time and another with elevated AP; (2) higher autism symptom severity, lower child IQ, and higher socio-economic risk (SER) at baseline would be associated with higher or increasing AP; and (3) children with elevated AP (initial or later) would have lower social skills than children with less severe AP.

Methods:

Data from 394 children, assessed across eight time points from baseline (T1; $M_{age}= 3.35$ years, $SD= 0.78$; 84% boys; $M_{FSIQ}= 51.22$, $SD= 28.71$) to age 10.5–11 years (T8; $M_{age}= 10.75$ years, $SD= 0.23$), were drawn from the pan-Canadian Pathways in ASD cohort study. Trajectory groups based on Child Behavior Checklist (CBCL) Attention Problems (AP) scores were derived through group-based trajectory
modeling. Baseline covariates included autism symptom severity (Autism Diagnostic Observation Schedule calibrated severity score; ADOS CSS), child full-scale IQ (FSIQ; Merrill-Palmer-Revised Scales of Development or Wechsler Preschool and Primary Scale of Intelligence-III), and SER represented as an ordinal variable incorporating lone parent status, caregiver education and immigration status, and annual household income. The Vineland Adaptive Behavior Scale, Second Edition, Socialization standard score at T8 indexed social skills.

Results:

A five-group model with linear slopes had optimal fit and adequacy (Figure). Compared to children in the Low Stable group, the Moderate Increasing group had higher baseline ADOS CSS ($t = 3.04; p = .002$); the High Stable group had higher baseline SER ($t = 2.99; p = .003$). The High Stable group had significantly lower socialization scores at T8 than any other group and the Moderate Decreasing group had higher socialization scores than the Moderate Increasing group (Table)—group differences remained significant when controlling for ADOS CSS, FSIQ, and SER.

Conclusions:

Our findings support various AP trajectories from preschool years to age 10.5–11 in autistic children. This contrasts with fewer, decreasing trajectories identified at older ages (McCauley et al., 2020). Approximately 50% of children in the current cohort had either persistently high or moderate and increasing AP, a similar pattern as found by Visser et al. (2017). More severe baseline autism symptoms and higher SER were associated with high or increasing AP trajectories, which were in turn associated with poorer social skills outcome, supporting a negative effect of ADHD symptoms on social skills of children with ASD.

429.020 (Poster) Transition in Regular and Special Education in Autistic Children: A Longitudinal Study on Predictors and Policy Effects.

**G. E. van den Helder**, R. Plak, M. Meeter and S. Begeer, (1)Vrije Universiteit Amsterdam, Amsterdam, Netherlands, (2)Leiden University, Leiden, Netherlands, (3)Educational and Family Studies, Vrije Universiteit Amsterdam, Amsterdam, Netherlands, (4)Clinical Developmental Psychology, Amsterdam, Netherlands

**Background:**

Since 2014, inclusive education policy (IE policy) allows children with additional support needs, including children with autism, to attend regular education in the Netherlands. It is unclear whether this was effective or for which autistic children this policy impacted on school placement and rate school transitions. Individual child characteristic seems to be related to school placement and transitions of autistic children (Lord et al., 2022). The current study explored the impact of inclusive education on autistic children’s school placement and school transitions over time.

**Objectives:**

We explored the impact of the IE policy on autistic children’s school placement and transition by examining 1) the proportion of autistic children attending education in a special school changed over time; and 2) school transitions since in the introduction of the inclusive education policy; and 3) how individual child characteristics are related to their placement and transitions.

**Methods:**

The current study is a longitudinal cohort study using data collected through the Netherlands Autism Register (NAR). 1523 Adult parents or legal guardians of autistic children completed online surveys from 2013 to 2021. They provided information on demographics, their child’s autistic traits, strengths and difficulties in behavioral indicators, (e.g. emotional, behavioral, peer relation problems, inattention/hyperactivity) and type of education. Hierarchical logistic regression analyses were performed.

**Results:**

The likelihood of placement in a special school was higher for children with male gender, lower intelligence and co-occurring conditions. Surprisingly, year and inclusive policy did not predict school placement. The likelihood of placement in a special school increased with a higher score on strengths and difficulties in behavioral indicators. Both behavioral problems and peer relation problems were associated with placement in special schools ($p <.05$). The likelihood of a school transition from a regular school to a special school was higher for younger children with lower intelligence levels and for the first years since the introduction of the policy. For the transition from special to regular education, the findings on the child characteristics intelligence and age were the mirror image: transitions were more likely for older children with higher intelligence levels. Year was not a significant predictor for a transition from a special to regular school.
Conclusions:

To our surprise, the inclusive policy had no impact on the proportion of autistic children in regular and special schools. Individual child characteristics were associated with school placement, especially the behavioral indicators behavioral problems and peer relation problems. Especially, behavioral indicators that are perceived as disturbing by the environment seemed to be related to placement in special education. The inclusive policy had no impact on the school transitions of children with autism. Only in the first years after the introduction, there were more transitions to regular schools, but school transitions were limited. As expected, intelligence and age were associated with transition between types of education.

K. Marlow, C. Laverty, G. Agar, C. Wright, R. Devine, F. J. Symons, A. Bagshaw and C. Richards, (1)School of Psychology, University of Birmingham, Birmingham, United Kingdom, (2)University of Birmingham, Birmingham, United Kingdom, (3)Aston University, Birmingham, United Kingdom, (4)University of Minnesota, Minneapolis, MN

Background: Self-restraint refers to purposeful restriction of own body parts and occurs alongside seemingly ‘involuntary’ self-injurious behaviour (Dizmang & Cheatham, 1970). A recent meta-analysis revealed 39% of individuals with autism, intellectual disability and/or rare genetic syndromes self-restrain, most commonly by ‘holding or squeezing objects’ or ‘holding onto others or others’ clothing’ (both 32%; Marlow et al., 2022). Self-restraint is understood through paradigms of negative reinforcement through the escape of self-injury (Luiselli, 1993), however this theoretical approach challenges prevailing models of operant learning: the presence of self-initiated restraint suggests self-injury may not be a purely learned behaviour that is constrained by environmental or sensory contingencies. Models of impaired inhibitory control suggest that for a subgroup of individuals self-restraint may emerge as an attempt to regain control over uncontrollable, function-less, non-adaptive SIB. Supporting evidence from Richards and colleagues (2017) identified the presence of SIB and impulsivity predicted the presence of self-restraint two-fold in a sample of autistic individuals. However, despite empirical support self-restraint remains an under-researched and poorly understood behaviour.

Objectives: This study explored the putative role of impulsivity in the paradoxical association between self-restraint and self-injurious behaviour.

Methods: Caregivers of 159 children with autism and a co-occurring intellectual disability (mean age = 10.40 [range = 4.02 – 15.49], 37 female, Vineland Adaptive Behavior age equivalent mean = 2.85 [range = 1.26 – 11.3]) completed a battery of questionnaires exploring self-restraint, self-injurious behaviour and executive function. Child adaptive functioning was assessed using The Vineland Adaptive Behavior Scale – Third Edition (Sparrow et al., 2016). A novel battery of play-based assessments measuring impulsivity and other executive functions were administered remotely via video conferencing software.

Results: The prevalence of self-restraint in the first 152 participants within this sample was 95% (n = 145). 111 participants (73%) showed both self-restraint and self-injury, while 35 children (23%) self-restrained in the absence of self-injury. Five individuals (3%) self-injured without self-restraint, while one participant did not self-injure nor self-restrain. The most prevalent self-restraint behaviours were ‘wraps a blanket, sheet or other material around self’ (70%), ‘asks for others to hold their arms’ (64%) or ‘hands’ (59%). The least prevalent behaviours were ‘holds hands together behind their neck’ (14%), ‘wraps their hands/arms together with pieces of long material’ (14%) and ‘wraps a long piece of material either of both arms’ (8%). Self-restraint scores and SIB severity scores were statistically significantly associated, r = .17, p < 0.05. Preliminary analysis of the first 60 children to complete the remote play-based assessments revealed a small association between self-restraint and inhibition, r = -.18.

Conclusions: Preliminary findings revealed most of the sample of autistic children with intellectual disability showed some form of self-restraint. According to caregiver report, most individuals showed both self-restraint and self-injurious behaviour, with analyses replicating previous findings of a statistically significant association. A small negative correlation was identified between self-restraint and a play-based direct assessment of inhibition, indicating that impairments in behavioural inhibition might underpin the presence of self-restraint.

429.022  (Poster) Understanding the Relationship between the Interdependence of Attentional Networks and the Locus Coeruleus – Norepinephrine (LC-NE) System and ASD and ADHD Traits: A Pupilometry and ERP Study

Y. Kim, A. W. Saunders, N. P. Fujii, R. N. Rozniarek, K. Cortes, A. F. Hamilton, S. E. Schieber, D. Schneider and B. Keehn, (1)Speech, Language, and Hearing Sciences, Purdue University, West Lafayette, IN, (2)Purdue University, West Lafayette, IN, (3)Department of Psychological Sciences, Purdue University, West Lafayette, IN

Background:

Attention has been divided into alerting, orienting, and cognitive control. The alerting network is responsible for maintaining a state of increased sensitivity to incoming stimuli, whereas cognitive control is critical for filtering irrelevant information. Previous research has highlighted the interdependence between these two networks, with individuals with ASD showing atypically increased alerting-cognitive
control interactions. However, the neural mechanism(s) associated with attentional network interdependence in ASD remains unknown. Prior finding has shown that individuals with ASD demonstrate atypical the locus coeruleus – norepinephrine (LC-NE) system, the neuromodulator associated with the alerting network. Yet, it is unclear whether differences in LC-NE activity contribute to greater attention network interactions.

Objectives: Current study examined 1) whether the higher network interdependence is associated with ASD and ADHD traits, and 2) the association between tonic and phasic LC-NE activity and alerting-cognitive control interdependence and ASD traits in cohort of neurotypical individuals with high- and low-autism traits.

Methods: Participants included 80 college students with the highest (n=40) and lowest (n=40) quartiles of Autism Quotient. The study included two experiments: 1) a cued-flanker paradigm to measure alerting (RT, cue-induced pupil-dilation response [cue-PDR]) and cognitive control (RT, N2, P3 ERP amplitude, target-induced PDR [target-PDR]), and 2) a resting task to measure pupil diameter as a measure of tonic LC activity. For cued-flanker paradigm, isoluminant stimuli (cue, arrows) were presented on a gray background. Participants were instructed respond to the direction of center arrow. For resting task, participants were asked to look at a black central crosshair, which was displayed on a gray background. Pupil diameter was monitored using an EyeLink 1000 Plus remote eye-tracking system and EEG was recorded using 128-channel high-density Geodesic electrode array. ASD and ADHD traits were measured using the Broad Autism Phenotype Questionnaire (BAPQ) and Conners ADHD Adult Rating Scales (CAARS).

Results: For cued flanker, network interactions were present for both RT and N2 amplitude (p<.05), which supports the interdependence of alerting and cognitive control attention in both behavioral and electrophysiological measures. The interaction was not significant for target-PDR or P3 amplitude.

The RT alerting-cognitive control interaction score was positively related to BAPQ and CAARS scores (p<.05), which indicates the greater interdependence is linked to increased ASD and ADHD traits.

Contrary to our hypotheses, both tonic (resting pupil diameter) and phasic (cue-PDR) LC measures were not related to RT alerting-cognitive control interaction scores. However, increased tonic (larger resting pupil size) and decreased phasic (cue-PDR) activities were associated with increased BAQ (p<0.05), which suggests atypical LC-NE activity is associated with increased ASD symptoms.

Conclusions: As hypothesized, our findings show that a greater interdependence between alerting and cognitive control attentional networks was related to higher ASD and ADHD traits. Consistent to prior results, increased ASD traits were associated with elevated tonic and decreased phasic activation of the LC-NE system. However, interindividual differences in tonic and phasic activity were not associated with variations in attention network interdependence. These findings expand our understanding interplay between attentional processes and suggests that they may be linked to ASD and ADHD symptoms.

429.023 (Poster) Use of Contextual Information Varies with ASD and ADHD Traits: Transdiagnostic Insights from a Novel Computational Model and Task Paradigm.

W. W. Pettine1, S. Jacob2, A. D. Redish3 and J. D. Murray1, (1)Yale University, New Haven, CT, (2)Department of Psychiatry, University of Minnesota - Twin Cities, Minneapolis, MN, (3)University of Minnesota, Minneapolis, MN

Background:

Rigid patterns of behavior exhibited in autism spectrum disorders often manifests as difficulty in generalizing and adapting previous knowledge to a novel context (Plaisted 2001). Heterogeneity along the autism spectrum suggests there are multiple potential drivers of behavioral rigidity. Furthermore, these drivers may also relate to ASD’s high comorbidity with attention-deficit hyperactivity disorder (ADHD) (Antshel et al. 2016). However, we lack a rigorous understanding of cognitive generalization in autism, how that manifests heterogeneously across the spectrum and how it relates to transdiagnostic overlap with conditions such as ADHD. In part this gap arises from our incomplete understanding of how humans in general (both with and without ASD / ADHD) categorize and generalize stimuli and situations.

Objectives:

To investigate heterogeneous learning, attention and generalization behaviors in subjects with ASD-related traits, particularly in the context of a new computational model of human categorization processes (Pettine et al. 2021). Initial data is in the general population. Additional data is being collected with members of the adult ASD community.

Methods:
We paired commonly used trait questionnaires with newly-developed reinforcement learning tasks to investigate the use of attention during latent-state learning (Pettine et al. 2021). These tasks investigate how context information drives learning and generalization, based on a new computational model of the cognitive processes driving subject behavior (see Figure 1). Subjects (N=104) were recruited through an online research platform (Prolific) to perform online tasks. We used the trait questionnaires to categorize subjects according to the presence or absence of ADHD and ASD traits (See Figure 1), and analyzed the continuum of scores along trait questionnaire subscales. We then examined the generalization patterns in the new tasks using confusion matrices, the overall proportion of errors during generalization, and whether subjects used holistic internal state representations versus discriminative features for categorization. Parameters in the model enabled us to characterize how context information shaped error patterns during generalization (see Figure 2).

Results:

Increasing hyperactivity-impulsivity scores were associated with increased overall task performance, while increases in the inattentiveness score were unrelated to overall performance (Figure 2B). Using trait thresholds, we found a load effect for ASD and ADHD (Figure 2A, C). Each clinical trait was independently associated with a specific form of attention that over-learned the discriminative rule. Those high in both ASD and ADHD traits showed an additional effect where they attended differently to the features of states learned in initial contexts, based on the sequence of learning. Both phenomena can be described by alterations in context learning in the model (Figure 2D).

Conclusions:

These results provide insight into the heterogeneous manifestation of altered learning, attention, and generalization in subjects with ASD traits. We are currently collecting and comparing the data with autistic adults and will present additional findings.

429.024 (Poster) Use of the Weekly Calendar Planning Activity to Assess Executive Functioning in Autistic Adolescents

A. Duncan1,2, E. Hamik, A. Zoromski and L. Tamm1, (1)Division of Behavioral Medicine and Clinical Psychology, Cincinnati Children’s Hospital Medical Center, Cincinnati, OH, (2)College of Medicine, University of Cincinnati, Cincinnati, OH

Background: Youth with autism spectrum disorders (ASD) are known to have challenges with executive functioning in the areas of organization, prioritization, time management, and planning as rated by caregivers and teacher. However, there are few ecologically valid measures to objectively assess their skills in these domains. The Weekly Calendar Planning Activity (WCPA) is a complex, cognitively demanding performance-based measure that involves entering 18 appointments into a weekly schedule while adhering to rules and avoiding conflicts. Successful completion requires planning, flexibility, inhibition, and prospective memory. Thus, the WCPA holds promise as an objective measure of executive functioning deficits in autistic youth; however, to date, no studies have examined the performance of adolescents with ASD on the WCPA.

Objectives: To characterize the performance of autistic adolescents on the WCPA, and to explore whether WCPA accuracy is associated with behavior ratings of executive functioning.

Methods: Participants included 36 autistic youth (ages 11 to 14 years, M=12, SD=96; 88.9% male; 75% White) without an intellectual disability (IQ>80; M=104.5, SD=14.9). ASD status was confirmed via the ADOS-2 (n=34) or score ≥15 on the Social Communication Questionnaire (n=2). Participants completed the WCPA and caregivers completed the Behavior Rating Inventory of Executive Function, Second Edition (BRIEF-2). The WCPA involves scheduling a list of appointments into a weekly calendar while following rules, avoiding conflicts, monitoring time, and inhibiting distractions. Descriptive statistics were used to characterize WCPA performance, and correlations between WCPA appointment accuracy and BRIEF-2 subscales were computed.

Results: Teens with ASD performed poorly on the WCPA. Many struggled to even enter a single appointment, and of those who entered an appointment, their accuracy was <5 out of 18 on average (Table 1). In fact, the majority of teens performed at the <5th percentile for number of appointments entered, accuracy, and strategy use, and at ≤10th percentile for rule following. Notably teens lacked insight into their poor performance; i.e., difference between actual appointments entered accurately and what the teen thought that they entered accurately was 5.34 (SD=5.7). In terms of errors, the majority had ≥3 missing appointment errors (Table 2). Many teens (n=18) made >2 location errors. Few made repetition, incomplete, self-recognition, or time errors. The majority of the sample followed 3 or more of the 5 rules (n=29) and used 2 or more strategies (n=22). Number of accurate appointments was not significantly associated with any caregiver-reported BRIEF-2 subscales (all p’s <.14).

Conclusions: Overall the WCPA was quite cognitively demanding for youth with ASD, with many failing to successfully schedule any appointments. Most autistic teens made errors including difficulty placing appointments or neglecting to put an appointment on the calendar. These results have implications for utilizing evidence-based strategies to teach autistic teens how to manage their own time and plan and prioritize homework assignments, extracurricular activities, etc. Further, it appears that the WCPA may be measuring aspects of executive functioning not captured by the BRIEF-2 caregiver-report, which suggests it may be a complementary, real world assessment of
Background: Individuals on the autism spectrum sometimes exhibit difficulties with understanding narratives. Narrative comprehension requires, among other cognitive processes, the generation of inferences to understand story elements that are not explicitly stated. Although difficulties with inferencing are documented among autistic individuals when using linguistic stimuli, it remains unclear whether similar difficulties would occur for non-linguistic stories. Here, we investigated this issue in adults using visual narratives, (i.e., comic strips) without dialogue or captions.

Objectives: To use visual narrative sequences to test inference-making abilities in individuals across the autism spectrum.

Methods: Autistic and non-autistic individuals participated in two studies of inference generation. In the Deletion Recognition Paradigm (DRP), we measured participants’ (N=101) accuracy at identifying where a panel had been removed from a comic strip. In the Self-Paced Viewing Paradigm (SVP), we measured participants’ (N=48) reaction times (RTs) to view each panel in 6-panel comic sequences that were intact (“normal” condition), 5-panel sequences where the “Peak” panel (i.e., that reflecting the height of the action) was missing (“inference” condition), and 6-panel sequences where the Peak was replaced by an incongruous panel (“violation” condition). Participants also answered comprehension questions after 40% of trials. For both experiments, participants completed the Autism Quotient (AQ) questionnaire, to determine levels of autistic traits, and the Visual Language Fluency Index (VLFI) to assess experience with visual narratives. We used linear regressions to examine the relationship between AQ and VLFI scores on accuracy and RTs in each task.

Results: For the DRP, increasing visual language fluency (i.e., experience with visual narratives) was associated with higher accuracy at identifying when an early panel in a sequence had been removed, but only for individuals with lower levels of autistic traits (“low AQ” group); for those with higher levels of autistic traits (“high AQ” group), visual language fluency did not modulate accuracy. For the SVP, VLFI scores were positively associated with accuracy on comprehension questions in the violation condition for the low AQ group, but negatively associated in the high AQ group. Across both tasks, scores on the Imagination subscale of the AQ, which measures participants’ inclinations for fantasy pretending and character perspective-taking, were negatively associated with inference-making abilities (accuracy in identifying a missing panel in the DRP; comprehension question accuracy in the SVP); as scores were increasing on the subscale (i.e., imaginative thinking abilities were decreasing) reduced levels of accuracy were found.

Conclusions: For individuals across the autism spectrum, the relationship between visual narrative experience and inferencing abilities was dependent on the level of autistic traits: higher VLFI scores were associated with better accuracy on both tasks, but only for those with lower AQ scores. Across both experiments, the ability to use imaginative thinking was specifically associated with inferencing abilities, such that participants reporting more difficulties with imagination showed lower accuracy on our inferencing tasks. These studies confirm that inferencing may also be different in visual narratives for autistic individuals, and reveal important individual differences to consider when examining inferencing abilities in adults across the spectrum.

Background: Superior visual search (i.e., an odd stimulus is to be found among others) has been reported quite consistently in autism, which might be an expression of enhanced attention to detail in this group. Superior disembedding (i.e., finding a target embedded in a complex background) has been reported less consistently. Synesthesia, a sensory phenomenon where individuals perceive additional sensations in response to certain trigger stimuli, is also associated with superior performance in visual tasks requiring detail focus, while only a handful of studies exist.

Objectives: Here we assessed visual search and a task mimicking real-life disembedding, using invariants built on the same target but with variations in size and rotation. Associations with attention to detail traits, autism diagnosis, synesthesia and familial influences were explored using a twin design.

Methods: The sample consisted of adult twins (total n=58), distributed among the following groups: a) twin pairs where one or both twins fulfilled DSM-5 criteria for autism (n=16, 10 with autism diagnoses), b) twin pairs where one was identified to have grapheme-color synesthesia with an objective test (n=28, 14 pairs discordant for grapheme-color synesthesia) and c) neurotypical twin pairs (n=14).
Participants completed computerized tasks identifying invariants in visual search and disembedding. In each task, an image with 12 targets was presented for a maximum of 30 seconds, and the participants were instructed to identify targets by mouse-clicks as fast as possible. Accuracy was defined as total number of identified targets per image. Autistic traits were assessed using the Attention to Detail subscale of the Autism Quotient (12 items).

We used one-way ANOVA to compare the three groups of twin pairs and linear regression analyses to assess task performance as a function of attention to detail traits, autism diagnosis and grapheme-color synesthesia, both across the entire sample and within twin pairs.

Results: The three twin groups (a-c) differed in visual search (F(55)=5.9, p<.005) but not in disembedding performance (p=.81). Post-hoc t-tests revealed that twin pairs where one or both had autism found on average 1.5 fewer targets compared to the two other groups (p-values<.005). Across the entire sample, attention to detail traits were associated with better visual search (b=.17, SE=.05, p<.001), but not disembedding performance, and having an autism diagnosis was associated with lower visual search performance (b=1.50, SE=.41, p<.0005). The positive association between attention to detail and visual search was significant also within twin pairs, where familial factors are implicitly controlled for (b=.39, SE=.16, p<.05). No significant associations were observed for synesthesia, neither across the sample nor within pairs.

Conclusions: In line with our expectations, higher attention to detail traits appear to be an advantage in visual search. However, in contrast to our expectation, autistic individuals found fewer targets in the visual search task, and neither autism or autistic traits, nor synesthesia were associated with superior disembedding of targets with varying sizes and rotations.

S. A. Kim and C. Kasari, (1)School of Education and Information Studies, University of California Los Angeles, Los angeles, CA, (2)University of California Los Angeles, Los Angeles, CA

Background: Working memory (WM), an important component of executive functioning, involves maintaining and updating incoming information, then revising them by replacing old information with newer, more relevant information. Working memory is associated with positive classroom engagement, academic readiness, early mathematical and literacy skills, language acquisition, and Theory of Mind. While WM is an area of difficulty for many autistic children, it is highly malleable throughout childhood with various student-level and environmental factors playing important roles in their development.

Objectives: The current study aims to identify student- and environmental-level factors that are associated with autistic children’s working memory performance upon school entry, and factors that contribute to their longitudinal growth throughout their elementary school years.

Methods: This study used the Early Childhood Longitudinal Studies-Kindergarten Class of 2011 (ECLS-K: 2011). A piecewise conditional latent growth models were constructed to identify predictors for autistic children’s WM performance upon entering kindergarten and their relative growth throughout their elementary school years. Approximately 310 students were identified as having autism and were included in the analysis. The following covariates entered the model for controlling purposes: Sex Assigned at Birth, Race, ADHD status, and LD (Learning Disabilities) status. The following covariates entered the model as time-invariant covariates to test the predicting power on the parameter estimates: Socioeconomic Status (SES), Special Education Services for Autism, Student-Teacher Relationship (STR), and Approaches to Learning (ATL).

Results: Results indicate that SES and students’ ATL positively predicted autistic children’s WM performance upon school entry. Students’ ATL positively predicted their rate of growth during the first three years, and negatively predicted their rate of growth during the last three years of elementary school. Student-teacher relationship positively predicted their rate of growth during the last three years of their elementary school years. Further, autistic students who started at a lower standing in working memory upon school entry were more likely to receive special education services during their elementary school years.

Conclusions: Broadly, findings suggest that student demographic characteristics, learning behaviors and school or home environment collectively play an important role in autistic children’s WM development, and these are especially malleable during their elementary school years.
These findings highlight the importance of identifying ways to teach young autistic children from low SES backgrounds learning-related behaviors from a very young age through early intervention programs (e.g., Part C of IDEA, Head Start). Additionally, one important target for these early intervention programs must be enriching their home environments that can remediate the SES-based disparities in young autistic children’s WM trajectories. Further, educators must examine ways that evidence-based WM interventions can be broadly utilized through the public school system. Lastly, school districts’ effort to implement school-wide programs that are designed to foster positive student-teacher relationship is indicated to foster autistic students’ WM development.

429.028 (Poster) Autistic Children’s Visual Sensitivity to Face Movement

Q. Wang, X. Li’, X. Gong’, T. Yin, T. K. Lam’ and L. Yi’, (1) Peking University, Beijing, China, (2) Peking University Sixth Hospital, National Clinical Research Center for Mental Disorders, Beijing, China, (3) Peking University Sixth Hospital, Peking University Sixth Hospital, National Clinical Research Center for Mental Disorders, Beijing, China, (4) Beijing Normal University, Beijing, China, (5) School of Psychological and Cognitive Sciences and Beijing Key Laboratory of Behavior and Mental Health, Peking University, Beijing, China

Background: Privileged attention to biological motion (e.g., face movement) is assumed to be a prerequisite for identifying others’ affective and mental states. Therefore, there is a pressing need for studies of large sample sizes and variable age ranges to delineate the mechanism underlying visual insensitivity to biological motion in autism spectrum disorder (ASD). Earlier work using dynamic stimuli with high communicative intent found that autistic people were less likely to look at the face, eyes, or mouth when actors spoke or engaged with participants. It is unclear what drives autistic people’s limited attention to a speaker or engagement with a person’s eyes or mouth. One possibility may lie in the insensitivity to social saliency in ASD, given their diminished activation of social brain areas involved in processing human voices, gaze, emotion, and intention. Alternatively, limited attention to moving eyes and mouth in ASD might be determined by their insensitivity to basic face movements.

Objectives: We focused on the basic movement of the eyes or mouth in guiding attention. We minimized the social effect of the face movement by not using faces with gaze shifting to an object or an articulating mouth as stimuli. Instead, the stimuli face blinked continuously or moved the mouth silently. By comparing the attention to the eyes or mouth of the dynamic face to the same static face, we can conclude whether autistic people are visually sensitive to basic face movement.

Methods: In a large sample (145 autistic and 132 non-autistic participants) ranging from preschoolers to teenagers (3 to 17 years old), we assessed whether autistic participants showed reduced visual attention to basic movement of the eyes or mouth using a free-viewing eye-tracking task.

Results: Figure 1 shows the results. We found that, like non-autistic participants, autistic participants increased eye-looking time when viewing the blinking eyes and increased mouth-looking time when viewing the mouth-moving face. Furthermore, these effects were stable across age, suggesting the presence of a developmentally stable attentional capture by basic face movements in both groups. We also found that autistic participants were less sensitive to basic face movement than non-autistic participants.

Conclusions: Our results suggest that autistic children and adolescents could modulate their visual attention to the basic face movements, but their modulation effect is weaker than non-autistic participants. However, we only tested the basic face movement effect on gaze behavior. Future studies should test the social saliency effect to further understand the mechanism underlying visual attention to face movement in autistic people.

J. W. Griffin’, G. Dawson’, B. Keehn’, S. J. Webb’ and J. McPartland’, (1) Yale Child Study Center, Yale University School of Medicine, New Haven, CT, (2) Department of Psychiatry and Behavioral Sciences, Duke University Medical Center, Durham, NC, (3) Speech, Language, and Hearing Sciences, Purdue University, West Lafayette, IN, (4) Psychiatry and Behavioral Sciences, University of Washington, Seattle, WA, (5) Child Study Center, Yale Child Study Center, New Haven, CT

Background: Visual face recognition - the ability to encode, discriminate, and recognize the faces of others - is fundamentally supported by eye movements and is a common source of difficulty for autistic individuals. Generally, this difficulty is attributed to reduced attention allocation to faces or specific facial features, but few studies have systematically evaluated dynamic patterns of visual attention (i.e., scan paths) during encoding versus recognition stages of face recognition.

Objectives: We aimed to apply a computational modeling approach to determine whether (1) autistic individuals’ eye movement patterns, across encoding and recognition stages, differed from neurotypical peers during a face recognition task.

Methods: Autistic (n=17) and neurotypical (n=15) participants aged 12-17 (M=14.5, SD=1.4) were eye-tracked during a recognition task that consisted of encoding (passive viewing) and recognition (discriminating) phases for faces, inverted faces, monkey faces, and abstract three-dimensional shapes (greebles). To understand how visual processing strategies (i.e., eye movement patterns) directly support encoding and recognition of faces in autism, we applied a novel probabilistic modeling approach to incorporate the spatial (fixation location) and temporal (sequence of fixations) components of eye movements. Participants’ eye movement data were summarized with a hidden Markov model (HMM). To discover common patterns among participants, we used clustering to derive representative HMMs that consisted of data-driven regions of interest (ROIs) and transitional probabilities within and between ROIs.
Results: Overall, autistic participants showed worse recognition performance than neurotypical peers; however, these results were largely driven by differences in inverted face recognition performance. We discovered two distinct eye movement patterns across all participants. A focused strategy was characterized by high probability (>85%) of initial fixations to a small face region, followed by a low probability (<25%) of subsequent fixations to a larger face ROI. An exploratory pattern was characterized by lower probability to a small face ROI (<85%) followed by a larger transitional probability to the larger face ROI (>25%). When evaluating eye movement patterns across encoding and recognition phases, we found that autistic individuals did not alter their eye movement patterns as much as neurotypical participants, who adopted a more focused pattern during encoding and a more exploratory pattern during recognition.

Conclusions: Autistic participants do not alter their visual processing strategy across encoding and recognition phases, which may be an indicator of less efficient face recognition and contribute to face processing difficulties.

**Combined Topics**

**POSTER SESSION — COMBINED TOPICS**

**407 - Combined Topics I**

**407.401 (Poster)** Perceived Stress and Satisfaction before, during and after an Autism Diagnosis, for Autistic Adults and Parents of Autistic Children and Young People in the UK.

*M. Brosnan*, A. Russell and E. Smith; (1)Centre for Applied Autism Research, University of Bath, Bath, United Kingdom, (2)Psychology/Centre for Applied Autism Research, University of Bath, Bath, UNITED KINGDOM, (3)University of Bath, Bath, United Kingdom

Background:

The Autism Act (2011) was the first condition-specific legislation in the UK stipulating statutory health services provide autism assessment for children and young people (CYP) and adults. A 10-year review of the impact of the act (APPGA, 2021) highlighted high levels of stress and a perceived lack of support by the autistic and broader autism communities. There is currently a lack of understanding of how the diagnostic process itself contributes to perceived stress and what is wanted by key stakeholder communities in terms of support around the autism diagnostic pathway.

Objectives:

1) To identify stakeholder experience of the autism assessment pathway, before, during and after diagnosis, comparing CYP and adult services; and 2) to identify what stakeholders want from the diagnostic process.

Methods:

An online survey was completed by 246 autistic adults and 181 parents of autistic children in the UK. The survey asked about perceived levels of stress, and satisfaction with help and support during three time periods: 1) from initial referral to starting the assessment; 2) during the assessment and 3) the first year after the assessment. Participants also rated the outcomes of diagnostic assessment that were most helpful to them.

Results:

Paired samples t-tests highlighted a significant decrease in stress and a significant increase in satisfaction between time periods 1 and 2, for both CYP and adult services separately (all p<.001). However, there was a significant increase in stress and decrease in satisfaction between periods 2 and 3, for both CYP and adult services (all p<.003) separately - the exception was the increase in adult stress did not reach significance (p=.3).

A MANCOVA for each time period investigated the impact of group (CYP or adult) and gender (male, female, Non-binary) on perceived stress and satisfaction, with ‘years since diagnosis’ as a covariate. There was a significant effect of group on stress in the first time period (p=.021). Parents of those who had accessed CYP services were significantly more stressed than adults accessing services prior to assessment. There was also a significant group by gender interaction for stress during the assessment period (p<.001). Highest levels of stress during the assessment were reported by parents of males accessing CYP services and female adults accessing services. Both parents of non-binary CYP and non-binary adults accessing services also reported higher levels of stress. All other differences were non-significant (p>.05).
The most beneficial aspect of receiving an autism diagnosis was reasonably consistent across the groups of respondents, see Table 1.

Conclusions:

Conclusions

The time periods before and after autism assessment are perceived as stressful by the majority of people and lacking in support. Some groups of stakeholders, i.e. parents of male CYP, female adults and individuals of non-binary gender identity perceive the greatest stress during the assessment process. Few respondents reported benefits in terms of access to health services following diagnostic assessment. Pathways to diagnostic assessment and support outside statutory healthcare services may be less stressful, more helpful and better meet the needs of many of those seeking an autism diagnosis.

407.402 (Poster) Females’ Perceptions of Relative Strengths and Weaknesses of Autistic Males in an Online Dating Context. M. Brosnan and J. Gavin, (1)Centre for Applied Autism Research, University of Bath, Bath, United Kingdom, (2)University of Bath, Bath, United Kingdom

Background:

Research consistently identifies that those with highly stigmatising views towards autism evaluate individuals on the autism spectrum negatively with a reduced willingness for interaction. Within the context of online dating, recent research has also found that low levels of stigmatisation towards autism have a relatively positive effect – specifically, an increased desire-to-date. This suggests the presence of relatively positive views about autism in an online dating context.

Objectives:

To identify both the perceived challenges and benefits of dating/marrying an autistic male and the likelihood of these challenges/benefits being relative weaknesses or strengths in an autistic male.

Methods:

Participants were different for each of 3 studies, but were always females aged 18-25, residing in the UK, who would date a male. Each study involved participants responding to an online dating profile. All participants indicated they were aware of having had contact with an autistic person.

Study 1: 188 participants responded to two open questions asking what they believed to be (1) the challenges, and (2) the benefits - of dating/marrying an autistic person, compared to a non-autistic person. The data were analysed using qualitative content analysis.

Study 2: 208 (new) participants rated their perception of whether the themes identified in Study 1 were likely to be relative strengths or relative weaknesses of an autistic male. One sample t-tests identified which items were significantly different from the neutral mid-point.

Study 3: 216 (new) participants rated the likelihood that a male in an online dating profile had a relative strength or a relative weakness in the themes identified in Study 1 (as in Study 2). T-tests compared an explicit label of autism condition (n=107) with a no label of autism condition (n=109) – otherwise profiles were identical.

Results:

Eleven themes related to the challenges and benefits of dating/marrying an autistic male: 1) Trustworthiness, honesty; 2) Romance, intimacy; 3) Fidelity, faithfulness; 4) Socially interactive with friends; 5) Commitment, loyalty; 6) Equal partner in the relationship; 7) Intellectual abilities; 8) Easy going, flexible; 9) Passionate about interests; 10) Acceptability to family; and 11) Suitability to be a father. Of these, 8 were perceived to be relative autistic male strengths: 1, 3, 5, 6, 7, 9, 10, and 11, and 3 relative autistic male weaknesses: 2, 4, and 8. All 11 themes differed from the neutral mid-point of the scale (p<.001). The profile with the explicit autism label was perceived to be significantly more likely to have all three relative weaknesses (Romance, intimacy; Socially interactive with friends; Easy going, flexible) as well as one relative strength (Passionate about interests). (All p<.05).

Conclusions:
There are 11 themes that females perceived to be relevant when considering online dating with an autistic male. Three of these were perceived to be relative weaknesses in autistic males and may impact on stigmatisation towards autism. Eight were perceived to be relative strengths in autistic males. The addition of an explicit autism label in a profile accentuated all 3 relative weaknesses (and potentially stigmatisation towards autism), yet only accentuated one relative strength.

407.403  (Poster) Determinants of Social Inclusion of Children with Autism Who Exhibit Challenging Behaviors in Sunday School Classrooms

J. D. Lee1, S. McGuire2 and G. Kim3, (1)Department of Psychiatry and Behavioral Sciences, University of Washington, Seattle, WA, (2)Bowling Green State University, Bowling Green, OH, (3)University of Kansas, Lawrence, KS

Background: Autistic children or children with developmental disabilities or delays (DD) are more likely to exhibit behaviors that are perceived as challenging than typically developing peers. Unfortunately, these behaviors may result in limited access to daily activities and exclusion from social settings. Though inclusion in faith-based organizations (e.g., church) is a crucial measurement of an individual’s quality of life, families of children with autism can be excluded from these opportunities due to the children’s challenging behavior. Therefore, understanding the facilitators and barriers to promote the inclusion of children with autism who may engage in challenging behaviors is warranted.

Objectives: The purpose of this investigation is to gain a deeper understanding of the perceptions of caregivers of young autistic children (i.e., 2-8 years old) and children with other DD and Sunday school teachers who work with the same population of children on (a) what the facilitators and barriers are for including young children with autism and other DD who exhibit challenging behavior in Sunday school classrooms, and (b) what additional supports may be needed in Sunday school classes to promote inclusion.

Methods: Qualitative methods via a semi-structured virtual individual interviews were used to investigate the facilitators and barriers perceived by caregivers of young children with autism and DD who engage in challenging behavior and Sunday school teachers who have experience working with those children. The interview protocol consisted of three sections including (1) caregivers’ or professionals’ experiences of inclusion; (2) perceived barriers and facilitators to inclusion; (3) areas of needs to promote inclusion. The data of 13 participants (4 caregivers and 9 professionals) were included and preliminary analyzed using a thematic analysis.

Results: Preliminary findings indicate that caregivers of young children with autism and other DD report a need for more equitable access to Sunday school classes, additional knowledge and training to support children with disabilities for Sunday school teachers, and additional collaboration between caregivers and Sunday school teachers. Sunday school teachers also reported the need for additional training related to supporting children with disabilities in Sunday school classes and the need for building collaborative relationships with caregivers of children with disabilities. Sunday school teachers also felt the inequitable access to Sunday school classes was a result of pastoral and/or leadership decisions instead of decisions made by Sunday school teachers.

Conclusions: Based on preliminary findings, there are three areas of need. First, Sunday school teachers would benefit from training focused on supporting children with disabilities. Second, a collaborative system may be created in which caregivers and Sunday school teachers create plans of support for children with disabilities in Sunday school classes. Such plans can account for the needs of the child (e.g., sensory needs, behavior needs). Finally, and probably most importantly, changes may need to occur at pastoral or leadership levels to create climate change within church settings. If the climate changes within faith-based settings that promote the inclusion of individuals with disabilities the needs of caregivers and Sunday school leaders will be easier to facilitate.

407.404  (Poster) A Systematic Quality Appraisal of Cultural Adaptation of Caregiver-Implemented Interventions for Young Autistic Children

J. D. Lee1, H. Meadan2, M. Sands3, A. K. Terol4, M. Martin5 and C. D. Yoon6, (1)Department of Psychiatry and Behavioral Sciences, University of Washington, Seattle, WA, (2)University of Illinois, Champaign, IL, (3)University of Wisconsin at Oshkosh, Oshkosh, WI, (4)University of Illinois at uc, Champaign, IL, (5)University of Illinois Urbana-Champaign, Champaign, IL, (6)University of Illinois at Urbana-Champaign, Champaign, IL

Background: Many evidence-based practices (EBP) in autism aim to improve outcomes for both autistic children and their families. Caregiver-implemented intervention (CII) is an example of autism EBP for promoting developmental outcomes at both the caregiver and child levels in natural environments (Hume et al., 2021; Barton & Fettig, 2013). It can be especially relevant for marginalized families from diverse cultural and linguistic backgrounds who raise young autistic children due to the flexibility and wide range of targeted skills in CII (Steinbrenner et al., 2020). While literature suggests that cultural adaptation of interventions may be an effective way to ensure equitable implementation, it is still difficult to claim its efficacy among these populations without appraising the quality and rigor of cultural adaptation, and little is known about the process of adaptation in CII.

Objectives: The purpose of this study is to synthesize research evidence on culturally adapted CII and to systematically appraise the quality of cultural adaptation in these studies.
Methods: We conducted a systematic search of the literature that implemented culturally adapted CII with marginalized caregivers of young autistic children. Using three databases, we initially identified 475 articles, then we identified articles that fit our inclusion criteria and based on the PRISMA guideline. Two authors conducted full-text reviews of 30% of each other’s articles (n=5), resulting in 90% interrater reliability. A total of 16 studies met the inclusion criteria. We coded each article to extract information related to (a) participant demographics, (b) intervention providers, and (c) IV and DV. We systematically appraised the quality of cultural adaptation using the Cultural Adaptation Checklist (CAC; Lee et al., under review), a quality indicator tool with 32 items across seven dimensions based on the Ecological Validity Model (Bernal et al., 1995). A total of four authors coded the articles, and the average interrater reliability of eight articles was 75%, ranging from 41% to 91%.

Results: All studies reported some degree of cultural adaptation to an existing model of CII to increase contextual fit with their respective targeted population that comprised a total of 569 caregivers and 495 children. Researchers reported culturally adapting the interventions in more than 10 languages, including Spanish (23.9%), Hindi (18.8%), and Chinese (15.1%). Researchers also reported varying roles of the interventionists who provided the training and coaching to caregivers, including (a) community health workers, (b) parent mentors, and (c) researchers. Studies varied greatly in the quality of their cultural adaptation with an average percentage of 58% (SD=20.4, ranging 22%-94%) when measured by the CAC, which indicates that researchers addressed or reported an average of 18 out of 32 items of the CAC.

Conclusions: While cultural adaptation is a crucial process in promoting intervention delivery with underrepresented populations in autism research, the level and quality of cultural adaptation of CII are inconsistent and varied. Although this may have been affected by conventional practices of reporting research, which may not fully document or reflect the researchers’ efforts of cultural adaptation. Implications for research will be discussed in detail.

407.405 (Poster) Iterative Development of an Echo Autism Program to Improve Healthcare for Autistic Adults

M. O. Mazurek, N. C. Cheak-Zamora, I. Huerta, N. Dare, E. Sadikova, G. Stobbe, R. L. Loftin, M. Mirza-Agrawal, A. Hess, A. Westphal, D. Caudell, S. M. Shore, K. Sohl and B. A. Malow; (1)University of Virginia, Charlottesville, VA, (2)Health Sciences, University of Missouri, Columbia, MO, (3)University of Missouri, Columbia, MO, (4)Seattle Children’s Autism Center, Seattle, WA, (5)Department of Psychiatry and Behavioral Sciences, Feinberg School of Medicine, Northwestern University, Chicago, IL, (6)Agrawal Family Foundation, Miramar, FL, (7)Nationwide Childrens Hospital, Columbus, OH, (8)Child Study Center and Department of Psychiatry, Yale University, New Haven, CT, (9)Vanderbilt University, Nashville, TN, (10)Special Education, Adelphi University, Garden City, NY, (11)ECHO Autism Communities, Child Health, Columbia, MO, (12)Sleep Disorders Division, Department of Neurology, Vanderbilt University Medical Center, Nashville, TN

Background:

Autistic adults face high rates of co-occurring health and mental health conditions and are at increased risk for suicide and premature mortality. However, they experience significant barriers and poor access to healthcare services. One key driver of these barriers is a shortage of healthcare providers with expertise in caring for autistic patients. The Project Extension for Community Healthcare Outcomes (ECHO) framework represents an innovative solution for building capacity for best-practice healthcare for autistic adults. ECHO Autism is a technology-enabled collaborative learning model developed to train community-based providers through mentoring, case-based learning, and guided practice.

Objectives:

The objectives of this project were to develop and iteratively test a new ECHO Autism program for primary care providers (PCPs) focused specifically on adult healthcare.

Methods:

Qualitative and quantitative approaches were employed to develop and test the new program. To inform program development, the perspectives of autistic adults (n=20), caregivers (n=24), and healthcare providers (n=14) were gathered through qualitative interviews and focus groups. Data were analyzed using a phenomenological analysis approach, and results guided the selection of curricular topics and program format. A 6-month ECHO Autism program was then implemented and tested with two consecutive cohorts of PCPs (n=20, and n=17). Satisfaction surveys and qualitative interviews were administered post-ECHO to assess participants’ satisfaction, experiences, and suggestions for improvement.

Results:

The results of key stakeholder interviews revealed both distinct and overlapping themes regarding healthcare barriers and suggestions for healthcare improvement from autistic adults, caregivers, and providers (e.g., system and clinic-level factors; provider-level factors; accommodations; coordination and partnership; and training needs). These themes were used to directly inform the development of the
Conclusions:

Autistic adults, caregivers, and providers expressed similar challenges, barriers, and suggestions for improvement to the healthcare system for autistic adults. These qualitative findings pointed to a need for specific training for primary care providers in delivering patient-centered, comprehensive, and coordinated care that is responsive to the unique needs of autistic patients and their families. Directly incorporating these perspectives into the development and refinement of a new training program for PCPs ensured that the model was both clinically relevant and responsive to the needs of both patients and their healthcare providers. Future research is needed to directly test the effects of the ECHO Autism program on provider practice and patient-level outcomes.

407.406 (Poster) Autistic Adults’ Perceptions of Mental Health Therapy Strategies
M. O. Mazurek, J. E. Pappagianopoulos, S. M. Brunt, E. Sadikova, R. E. Nevill, M. Menezes and C. Harkins, (1)University of Virginia, Charlottesville, VA, (2)Clinical and School Psychology, School of Education and Human Development, University of Virginia, Charlottesville, VA, (3)Curry School of Education and Human Development, University of Virginia, Charlottesville, VA

Background:

Autistic adults are at high risk for co-occurring mental health problems and need access to effective and appropriate mental health treatment. Despite growing interest in this topic, research on mental health interventions for autistic adults remains sparse. The relative effectiveness or acceptability of specific mental health strategies among autistic adults has not been previously evaluated. This is an important avenue for investigation because these factors could directly inform personalized treatment and clinician decision-making.

Objectives:

The current study was conducted to gain a deeper understanding of autistic adults’ experiences and preferences regarding specific mental health strategies. A convergent mixed methods design was employed to enable a quantitative understanding of relative helpfulness of a range of mental health strategies, as well as deeper insights into aspects of therapeutic strategies that relate to their helpfulness or ease of use.

Methods:

The sample included 303 autistic adults (ages 21-77) recruited online through the Simons Foundation Powering Autism Research for Knowledge (SPARK) Research Match process. Participants completed a demographic survey, the AQ-Short, and questions about mental health experiences. Participants provided ratings for helpfulness (1=not at all helpful, to 5=very helpful) and ease of use (1=very difficult, to 5=very easy) and answered open-ended questions about each type of strategy they had used (“Please tell us more about how well these strategies worked for you”). Spearman-rank correlations examined associations between autism characteristics and strategy ratings. Open-ended responses were analyzed using a data-driven qualitative content analysis approach.

Results:

Most participants (88.8%) had participated in therapy before. Among this subsample (n=269), most had experience with cognitive strategies (74.7%), followed by deep breathing (53.5%), mindfulness (45.0%), guided imagery/visualization (30.9%), behavioral activation (27.9%), progressive muscle relaxation (PMR) (21.2%), and exposure (19.7%). Behavioral activation, mindfulness, and deep breathing strategies were rated most positively in terms of perceived helpfulness. Deep breathing and behavioral activation were rated as being the easiest to implement, while exposure and cognitive strategies were relatively more difficult. AQ Total Score was negatively correlated with perceived helpfulness of guided imagery (r=-.253, p=.021) and exposure (r=-.353, p=.009), and was negatively correlated with perceived ease of use of cognitive strategies (r=-.179, p=.011), guided imagery (r=-.282, p=.010), PMR (r=-.306, p=.022), and exposure (r=-.319, p=.020). Qualitative results revealed that almost all strategies were seen as helpful for reducing anxiety and improving mood (Theme 1). However, autistic adults reported that most strategies are difficult to generalize to their daily lives (Theme 2), and that they can be difficult to implement (Theme 3) due to both autistic characteristics and specific requirements of each approach. Several participants found some strategies, especially exposure, to be distressing or anxiety-provoking (Theme 4).

Conclusions:
Overall, the results highlight the importance of considering individual differences and preferences of autistic clients when selecting and implementing mental health strategies. Although many autistic adults found mental health strategies to be helpful, some strategies may be less preferred or helpful depending on the autistic adult’s communication and information processing needs. Strategy modifications and support for real-world implementation would be helpful for many autistic clients.

407.407 (Poster) Autism Identity Profile of Autistic Adolescents and Young Adults
L. Lamash and S. Meyer, (1)Occupational Therapy, University of Haifa, Haifa, ISRAEL, (2)Occupational Therapy, Ariel University, Ariel, Israel

Background:

In recent years, the identity-first language (i.e., autistic person) is considered an appropriate way of expression, strengthened by the autistic community, self-advocacy groups and scholars. Developing an identity is a central developmental stage from during adolescence into young adulthood. Frequently identity development processes are more intricate for autistic adolescents. While some tend to focus on their strengths resulting from their autism diagnosis, others perceive their autism as unfavorable and try to distance themselves from the autism label. The Illness Identity Questionnaire (IIQ) is a measure used to evaluate illness identity in chronic health conditions. It refers to the role and attitudes people develop about themselves related to their health condition and how it integrates into their identity and daily life. Understanding the identity perceptions among adolescents and young adults with ASD at the critical stage of identity development is imperative. In this pioneering study, we adapted the IIQ to autism to shine a spotlight on adolescents’ and young adults’ point of view about how their autism is integrates into their daily life.

Objectives:

To present the autism identity profiles of autistic adolescents and young adults, as illustrated by the IIQ.

Methods:

A total of 102 autistic adolescents and young adults (89% males; 11% females) aged 12 to 25 yrs (M = 18.03, SD = 2.76) completed the self-report IIQ in person. Participants were students in the public education system (57%) and in two transitioning to workforce programs (43%). The IIQ describes four illness identity components: acceptance, enrichment, rejection, and engulfment. Descriptive statistics were used to present demographic variables and identity profiles. Paired sample t-test were calculated to compare between the positive and negative identity components.

Results:

The total positive score of IIQ was significantly higher than the total negative score, t(101) = 6.47, p < .001, d = .43. In detail-the feelings of autism Acceptance were significantly higher than Rejection, t(101) = -5.46, p < .001, d = .54; Enrichment, t(101) = 10.65, p < .001, d = 1.05; and Enrichment, t(101) = 7.52, p < .001, d = .74 feelings. Finally, the Engagement feelings were significantly lower than Rejection, t(101) = 3.66, p < .001, d = .36; and Enrichment, t(101) = -5.21, p < .001, d = .72 feelings. Figure 1 presents the participants’ autism identity profile.

Conclusions:

Adolescents and young adults with ASD present a more positive than negative autism identity profile. However, feelings of rejection and engulfment still constitute a significant share of their entire perceived sense of identity. Previous literature shows that positive identity perception is highly significant for maintaining independence in adult life in the community. Therefore, it is important that parents, teachers, therapists, researchers, and stakeholders, identify and promote positive autism identity at this critical and fragile developmental stage.

407.408 (Poster) Assessing the Efficacy of a Remote Intervention Program to Promote Goal Achievement of Autistic Adolescents
E. Yaar, E. Gal, G. Bedell and L. Lamash, (1)Occupational Therapy, University of Haifa, Haifa, Israel, (2)Department of Occupational Therapy, University of Haifa, Haifa, Israel, (3)Occupational Therapy, Tufts university, Medford, MA, (4)Occupational Therapy, University of Haifa, Haifa, ISRAEL

Background: The adolescence period marking the transition from childhood to adulthood crucially shapes autistic adolescents’ developmental trajectories and provides a basis for independent adult living. Research indicates that developing skills to manage day-to-day life is one of the autistic community’s top research priorities and that autistic adolescents and their caregivers desire autonomy and social participation. Remote intervention characteristics (e.g., incorporating technology and involving natural environments) can
significantly increase adolescents’ motivation and engagement in interventions. Social Participation and Navigation (SPAN), a remote intervention program, combines in-person and web-based interactions to promote individual participation and autonomy goals among autistic adolescents in daily activities and environments.

Objectives: This study aimed to assess the SPAN remote intervention’s initial efficacy among autistic adolescents.

Methods: Twelve autistic adolescents (12–20 years) participated in this single-subject, multiple-baseline design study. They completed a 12-week process, including eight weekly remote sessions with clinicians, with three assessment phases: baseline (T1), pre-intervention (T2), and post-intervention (T3). They used the SPAN website to define measurable short-term goals, set achievement plans, implement the plans while focusing on strengths, and monitor goal achievement. Two self-reported measures assessed the SPAN’s efficacy: the Canadian Occupational Performance Measure for performance and performance satisfaction with the chosen goal and Social Participation and Navigation Self-Efficacy Scale (SPAN SES) for self-efficacy in setting and achieving personal goals. We used Friedman’s nonparametric tests for repeated measures and post-hoc Wilcoxon signed-rank tests to evaluate timeline differences.

Results: Friedman’s tests showed significantly improved goal performance, $\chi^2(2) = 10.61, p < .01$, and satisfaction with performance, $\chi^2(2) = 10.85, p < .01$. As expected, the Wilcoxon analysis revealed no significant differences in performance or satisfaction between T1 and T2. However, all participants reported higher performance ($Z = -2.92, p < .01$) and satisfaction ($Z = -2.86, p < .01$) levels following the intervention (between T2 and T3; Figure 1). In all SPAN SES measurements, the participants highly rated their self-efficacy ($M = 4.12–4.20$), with no significant differences between assessment times.

Conclusions: Preliminary evidence indicated that the SPAN program is an effective remote intervention for achieving autistic adolescents’ personal goals. Implementation studies with larger samples should be conducted.

407.409 (Poster) Exploring the Relation between Early Intervention Provider Characteristics and Provider Performance in Role Play Training Activities

Y. S. Stern¹, E. M. Harrington¹, B. R. Ingersoll¹, A. S. Carter, W. L. Stone¹ and A. Wainer⁶, (1)Psychiatry and Behavioral Sciences, Rush University Medical Center, Chicago, IL, (2)Psychology, Michigan State University Psychology Department, East Lansing, MI, (3)Psychology, Michigan State University, East Lansing, MI, (4)Department of Psychology, University of Massachusetts Boston, Boston, MA, (5)Psychology, University of Washington, Seattle, WA, (6)Department of Psychiatry, Rush University Medical Center, Chicago, IL

Background:

Although there is significant need for and interest in effective approaches to training community early intervention (EI) providers in EBIs for autism spectrum disorder (ASD), few studies have explored the association between pre-training provider characteristics (e.g., experiences, attitudes) and provider training outcomes. Understanding the role of provider characteristics on training outcomes is a critical step in designing effective models of training EI providers in specialized ASD interventions.

Objectives:

(1) To characterize pre-training characteristics (i.e., clinical practices, self-efficacy) of EI providers undergoing training in Caregiver-Implemented Reciprocal Imitation Teaching (CI-RIT), an evidence-based naturalistic developmental behavioral intervention; (2) To examine the relation between pre-training characteristics and provider fidelity during CI-RIT role plays, completed as the final stage of training.

Methods:

This study was conducted as part of an ongoing randomized controlled trial of the effectiveness of CI-RIT in Part C EI. Participants include 35 EI providers (Table 1) undergoing a three-stage CI-RIT training process: (1) self-directed online modules, (2) 12-hour synchronous virtual workshop, (3) two individual role plays, completed at least one week apart, in which providers conduct full-length CI-RIT sessions. An RIT Trainer rates role play session components, yielding fidelity scores for each role play. Before training, providers report on their clinical practices using the Provider Practices Survey (28-item questionnaire using 1-to-5 rating scale), focused on use of common intervention strategies (PPS-Child) and coaching techniques (PPS-Caregiver) with families of children with social communication delays. Providers report on their pre-role play confidence in delivering CI-RIT using a Self-Efficacy survey (SE; 7-item questionnaire using 1-to-7 rating scale). Pearson’s correlations were conducted to examine the relation between role play fidelities and (1) pre-training clinical practices (PPS scale sums), (2) pre-role play self-efficacy (SE sum). See Table 2 for a summary of measures.

Results:
Responses on the pre-training PPS indicated that on average, providers “often” used evidence-based intervention strategies with children with social communication delays, reflected in a mean response of 4.14 (SD = .49), and “sometimes” used evidence-based caregiver coaching strategies, reflected in a mean response of 3.47 (SD = .43). SE responses indicated that on average, providers felt “somewhat confident” (M = 5.78, SD = .57) in CI-RIT following the workshop but prior to the training role plays (Table 2). PPS-Child was not significantly correlated with fidelity on Role Play 1 (r = -.15) or Role Play 2 (r = -.10). PPS-Caregiver also was not significantly correlated with fidelity on Role Play 1 (r = -.16) or Role Play 2 (r = -.50). SE was significantly correlated with fidelity on Role Play 1 (r = 0.37, p = 0.04), though not Role Play 2 (r = .28).

Conclusions:

Providers’ typical clinical practices were not associated with CI-RIT fidelity. However, the significant positive correlation between SE and Role Play 1 fidelity, the first activity completed following the workshop, suggests that it is important to further explore provider attitudes (e.g., buy-in, confidence), especially at various stages of training, given the need for optimized approaches to training EI providers with diverse backgrounds and experiences, in specialized ASD interventions.

407.410 (Poster) Characterizing Parent-Reported Reasons for Missing Data and Attrition in an Autism Intervention Trial

A. Hirshman1, Y. S. Stern1, A. Wainer1, S. Licona2, and Z. E. Arnold3; (1)Department of Psychiatry, Rush University Medical Center, Chicago, IL, (2)UCSB Koegel Autism Center, Santa Barbara, CA, (3)The University of Alabama at Birmingham, Birmingham, AL

Background:

Clinical trials of caregiver-implemented naturalistic developmental behavioral interventions (NDBIs) for children with autism spectrum disorder (ASD) rarely provide detailed accounts of reasons for missing data and attrition. Published data often excludes participants who are unable to complete procedures, resulting in samples with limited generalizability, and perpetuating challenges of engagement and retention, especially for underrepresented families who may experience significant barriers to clinical trial participation. Although retrospective research on attrition in caregiver-implemented intervention studies has identified associated demographic (e.g., family income, distance to clinic) and psychosocial factors (e.g., parental depression), understanding participant-reported challenges related to clinical trial participation is key to designing study retention strategies for diverse families, and accordingly, more equitable early interventions.

Objectives:

(1) To characterize circumstances reported by participants and study staff as missed activities and attrition occurred in a clinical trial of Caregiver-Implemented Reciprocal Imitation Teaching (CI-RIT), an NDBI for young children with ASD; (2) To offer considerations for participant retention and trial feasibility.

Methods:

Participants included 61 children (78.33% male; Table 1) between 16 and 60 months old (M = 37.64 months, SD = 9.27 months) with suspected or diagnosed ASD and their parents (86% mothers), recruited from a metropolitan Midwestern region. Following remote and in-person baseline study tasks all families received access to a self-directed online program designed to teach RIT. Five weeks later, families were randomized to (1) continue the self-directed program, or (2) receive five weeks of weekly, hour-long telehealth RIT coaching sessions. Families completed remote and in-person outcome measures 10 weeks after baseline, as well as remote play videos at 20 and 30 weeks after baseline. Families were compensated up to $50 for completing all study tasks.

As participants progressed through the study, research staff recorded Note to Files (NTFs), documenting communication with participants in relation to missed study activities, protocol deviations (e.g., significant shifts in participation timelines), and active or passive withdrawals. Two staff members qualitatively coded each NTF to identify attrition and data-loss themes and resolved discrepancies through consensus discussion.

Results:

Nine distinct themes were identified across 120 NTFs (Table 2). The highest-occurring theme was family scheduling limitations (n = 45) (i.e., unable to complete study tasks within the designated timeline due to conflicting obligations). While some families provided non-specific explanations for scheduling difficulties, others offered explanations such as caregiver work schedules and child therapy schedules. Another frequently identified theme was familial emergent life events (ELEs; n = 10), or discrete episodes that the family characterized as stressors (e.g., births, deaths in the family, and employment changes). It is also notable that 37 NTFs documented lack of participant response to contact attempts from research staff, highlighting the challenge of retention in the context of participants’ reported conflicts.
Conclusions:

Methods of collecting and reporting caregiver-reported participation conflicts should be systematically incorporated into clinical trials of NDBIs given their potential to contextualize the generalizability of intervention study results, improve intervention design, and inform proactive engagement and retention strategies that are tailored to experiences of families of young children with ASD.

407.411 (Poster) Creation of a Statewide Care Navigation Model for Families of Young Children with Diagnosed or Suspected ASD
A. S. Weitlauf1, A. Lavanderos1, A. Miceli1, N. Harris1, E. Rogers1, M. West1, F. V. Alzhyri2 and Z. Warren3, (1)Vanderbilt Kennedy Center, Vanderbilt Kennedy Center, Nashville, TN, (2)Vanderbilt University Medical Center - TRIAD, Nashville, TN, (3)Vanderbilt University Medical Center, Nashville, TN, (4)Vanderbilt Kennedy Center, Vanderbilt University Medical Center, Nashville, TN, (5)Vanderbilt University Medical Center - Treatment and Research Institute for Autism Spectrum Disorder, Nashville, TN

Background:

Children diagnosed with autism or developmental delays face numerous barriers to accessing therapies and resources (Feinberg, 2021), especially families living in poverty or in rural, medically underserved areas. Family navigation can promote service access by increasing family knowledge and reducing barriers care. To better support families during the diagnostic period, we collaborated with key stakeholders and community partners to create the Tennessee Cares for ASD Navigation Network, a multi-tiered model of family navigation for caregivers of children with confirmed or suspected ASD.

Objectives:

We created a statewide family navigation model to connect families to therapies, community supports, and other resources during the diagnostic journey and evaluated programmatic structure, efficacy, and feasibility over the four-year grant period.

Methods:

As part of a federally funded multi-year grant, we created a family navigation model to serve families of children with ASD and developmental delays (mean age: 47.6 months, 71% male; Table 1). Community providers, stakeholder groups, and clinicians provided input into the structure of the navigation model. Families were referred by community providers such as PCPs, early interventionists, and community agencies. Navigators then contacted families to provide support and resources if needed. Information about each family was recorded in a REDCap database and navigators followed up with families as needed.

Results:

Since network inception, over 2,360 families have received family navigation services. Participating caregivers have been almost entirely female (93.8%) while participating children have been almost three quarters male (71.1%) (Table 1). Navigators follow a pre-defined and stakeholder informed referral structure to online learning opportunities, local advocacy groups, statewide support networks, Part B and Part C intervention and educational systems, and social or financial supports. The network served over 500 families in Year 1 and has grown by at least 25% in following years. Initially the care navigation team provided all families with three mandatory points of contact and three attempts to make each contact. To increase flexibility of our model, at the end of Year 2 we altered the contact structure to provide families with only one point of contact if needed, or multiple points of contact if requested by the family or a clinical provider (Figure 1). For consenting families, contact notes are shared back with referring medical providers.

Conclusions:

Our work demonstrates the feasibility of a stakeholder informed care navigation model that connects diverse families to regional supports. This model was informed by families and partnering groups and has evolved over its lifespan to provide increased flexibility based on family and provider need. This work highlights the importance of meeting with local families and stakeholders to develop a model of family navigation that works for the specific region, team, or community.

407.412 (Poster) Black Families’ Experiences of Autism Diagnosis: Preliminary Parent Feedback to Inform Culturally Competent Care
A. Miceli1, A. Vehorn1, T. Pinnock1, Y. Dada1, J. Hine1, Z. Warren1 and A. S. Weitlauf1, (1)Vanderbilt University Medical Center, Nashville, TN, (2)Meharry Medical College, Nashville, TN, (3)Vanderbilt University Medical Center - Treatment and Research Institute for Autism Spectrum Disorder, Nashville, TN, (4)Vanderbilt Kennedy Center, Vanderbilt Kennedy Center, Nashville, TN
Background: Black families face significant barriers in receiving a timely diagnosis of autism spectrum disorder (ASD). Lack of knowledge of autism, distrust of health systems, and racial bias on the part of healthcare professionals all contribute to diagnostic delays (Constantino et al., 2020). These diagnostic delays can result in delayed access to therapies and support services, furthering documented disparities in service access (Stahmer et al., 2019). We surveyed 400 caregivers of Black children with autism to understand their diagnostic experiences and they suggested improvements for clinicians and systems of care. This yielded a rich qualitative data set, from which we now describe family-reported barriers and facilitators to accessing diagnostic care.

Objectives: To describe barriers and facilitators to autism diagnostic care for Black children based upon parental responses to a national survey.

Methods: 400 families of children with autism (mean age: 71 months, 323 male) were recruited from the Simons Foundation SPARK cohort Research Match program. Individuals were eligible if they were data consented for SPARK, were the parent or guardian of a child with autism aged 8 years and under, and the parent and child self-identified as Black or African American (including multiracial families). The SPARK research team sent invitation emails in batches until our recruitment goal of 400 was reached. Respondents completed the survey with their eldest child with autism in mind.

Results: When asked about facilitators to accessing care, most caregivers (n = 281; 71.3%) said their pediatricians provided help during the diagnostic process and during diagnostic follow-up (n = 255; 64.6%) (Figure 1). About 10% of caregivers (n = 41) appreciated that their pediatrician mentioned autism as a specific concern, and over 40% of parents (n = 169) indicated that their pediatricians provided referrals for further evaluation and intervention. Caregivers also endorsed the importance of their state’s early intervention systems in accessing care and providing support (n = 29, 7.2%). Caregivers reported a variety of barriers to accessing care, including diagnostic delay (n = 21; 5.2%), incorrect diagnoses, and provider disagreement with parent concerns (n = 88; 22%). Fifty-seven caregivers (14.2%) reported that their pediatrician did not discuss autism while 31 caregivers (8%) indicated that their pediatrician did not assist with post-diagnostic care. At the systems level, 16 caregivers (4%) encountered barriers related to work/income, 14 (3.5%) related to their ability to access care in their communities, and 31 (7.7%) related to insurance coverage. Finally, approximately 10% of caregivers (n = 41) indicated that they did not pursue a diagnosis because they were not familiar with autism.

Conclusions: Survey responses provided insight into barriers and facilitators Black families experience when accessing autism-specific care for their children. The involvement of pediatricians was both a barrier and facilitator depending on provider behavior and level of engagement. Future work will continue to examine caregivers’ qualitative responses to identify further barriers, facilitators, and ways of improving access to care.

407.413 (Poster) Using Telehealth to Coach Caregivers of Young Autistic Children in South Africa: Intervention Adaptation, Implementation Outcomes, and Caregiver-Child Signals of Change

M. Viljoen, N. Serts, N. Shabalala, Z. Dawood, P. J. de Vries, L. Franz and M. Ndlovu. (1)Centre for Autism Research in Africa, Division of Child & Adolescent Psychiatry, University of Cape Town, Cape Town, South Africa, (2)Division of Communication Sciences and Disorders, University of Cape Town Faculty of Health Sciences, Cape Town, South Africa, (3)Department of Psychiatry and Behavioral Sciences, Duke University, Durham, NC

Background: Telehealth can meet some service needs of families in under-served, low-resource areas of South Africa. The digital divide can reinforce existing disparities. It is therefore critical to consider cost and feasibility when developing telehealth interventions. The COVID-19 pandemic interrupted an autism clinical trial at the University of Cape Town in South Africa, where Naturalistic Developmental Behavioural Intervention (NDBI)-informed caregiver coaching was being delivered by non-specialists. Researchers pivoted to telehealth.

Objectives: We describe adaptations made to the non-specialist coaching sessions to facilitate telehealth delivery and examine implementation outcomes (acceptability, feasibility, and appropriateness). We assess signals of change in autisticchildren and their caregivers following 12, 1-hour long sessions of telehealth NDBI-informed coaching delivered by non-specialists over smartphones.

Methods: The Framework for Reporting Adaptations and Modifications to Evidence-based Interventions (FRAME) and the Exploration, Preparation, Implementation, Sustainment (EPIS) framework were used to describe adaptations and factors that guided adaptation. A mixed methods approach was used to examine implementation outcomes. Quantitative and qualitative data were analyzed using directed content analysis and descriptive statistics respectively. A single-arm pre-post design was used to assess caregiver and child signals of change. Change over time will be displayed as tabular and graphical summaries. Outcomes included implementation fidelity, behaviors assessed using the Joint Activity Rating Inventory (JERI), and child adaptive behaviour measured on the Vineland Adaptive Behaviour Scales (VABS-3). Quantitative analyses were conducted using SPSS statistics. Implementation data were collected from 9 caregiver-child dyads, 5 non-specialists, and 3 intervention supervisors.

Results: Eleven adaptations were made to the intervention content, delivery context, training and evaluation, and implementation strategies. Adaptations were informed by outer contextual factors (government mandated COVID policies, national internet infrastructure, participant characteristics, and inter-organizational network factors), inner contextual factors (supportive organizational characteristics, leadership, and
Background: Autism spectrum disorder (ASD) is a neurodevelopmental disease and its pathogenesis may be attributed to gene-environment interactions. The development and maintenance of the blood-brain barrier (BBB), the first line of defense in environmental threats, is regulated by a cross talk of WNT and Sonic Hedgehog (SHH) signaling. There are no definitive mechanisms explaining how environmental triggers can lead to ASD although compromised BBB, brain inflammation, immunity, and oxidative stress are involved. The accumulating evidence indicates an association of either exposure to toxic metals including cadmium (Cd) or obesity with ASD or other neurodevelopmental disorders (NDDs) in humans. We hypothesize that environmental factors interrupt the cross talk between WNT and SHH signaling to promote abnormal neurovascular signaling and autism like behaviors.

Objectives: To determine whether whole-life low-dose Cd exposure and post-weaning diet-induced obesity have a synergic effect on brain impairments and WNT/β-Catenin signaling.

Methods: 9-week-old parental C57BL/6J mice were administrated with drinking water containing either 0 or 5 ppm Cd for one week prior to breeding. After weaning, the offspring were continuously exposed to Cd and were fed either a normal diet (ND, 13% kcal from fat) or a high-fat diet (HFD, 60% kcal from fat) until sacrifice at 24 post-weaning weeks. The Cd accumulation and pathological changes in DNA oxidation, glial response, inflammation, blood-brain barrier (BBB) integrity, and core components of the β-catenin destruction complex were analyzed by ICP-MS, immunofluorescence, and quantitative PCR. Mouse behaviors were measured by usual standard assays. All data were presented as mean ± SD and analyzed by two-way ANOVA with diet-by-strain interaction. Significance was set at p<0.05.

Results: Cd exposure but not post-weaning HFD feeding significantly increased its accumulation in cortexes, hippocampi, and cerebella of the offspring brains with whole-life low-dose Cd exposure. Cd exposure or HFD can induce increased oxidative DNA damage in cortex and hippocampus but not in cerebellum. Moreover, HFD dramatically enhances Cd-induced the DNA damage, especially in the pyramidal cells of CA1-3. Compared to the control offspring, both HFD- and Cd-exposed mice demonstrate activation of microglia and astrocytes. More severe glial activation was observed in Cd-exposed mice than that in HFD-fed mice, which is exaggerated by HFD. Cd exposure only can increase the transcriptions of TNFα and IL-10. The BBB is damaged only in Cd-exposed offspring but aggravated by HFD. Mice fed Cd but not HFD exhibited deficits in social novelty and increased grooming but not social preference deficits. Mice fed Cd and/or HFD traveled a less total distance in the open field assay compared to vehicle fed a normal diet. While mRNA of WNT/β-Catenin pathways was not markedly changed, a Cd dose dependent increase in active β-catenin and phosphorylated (Serine 9) GSK3β was observed.
Conclusions: Whole-life low-dose Cd exposure or post-weaning HFD can cause oxidative stress and glial activation in offspring plus disrupts the BBB integrity. Post-weaning HFD exacerbates Cd-induced brain impairments. Cd dosing impacts the canonical WNT/β-Catenin signaling which is linked barrierogenesis. Further experiments will determine the relationships of these observations to autism-like behavior in Cd exposed offspring.

419.402 (Poster) A CAD System for Classifying Autism Spectrum Disorder Using Diffusion Tensor MRI
Y. Elnakieb, M. T. Ali, A. Gibrell, A. Shalaby, A. Elnakieb, R. Keynton, G. Barnes and A. S. El-Baz, (1)Bioengineering, University of Louisville, Louisville, KY, (2)Mansoura University, Mansoura, Egypt, (3)Bioengineering, University of North Carolina Charlotte, Charlotte, NC, (4)Neurology and Pediatric Research Institute, University of Louisville School of Medicine-UL Autism Center, Louisville, KY. (5)University of Louisville, Louisville, KY

Background: The term autism spectrum disorder (ASD), or autism, refers to a group of conditions in which social skills, repetitive behaviors, speech, and nonverbal communication are challenged. Conventional diagnoses are time-consuming and tedious because they require repeated interviews and evaluations of the autistic subject, on the other hand, neuroimaging techniques provide a quicker and more objective method of diagnosis. Despite numerous investigations identifying different aspects of brain dysfunction, it was still difficult to identify consistent similarities between different brain abnormalities, whether in shape, functionality, or connectivity.

Objectives: In this work, diffusion tensor MRI imaging data (DTI) of the brain is used to infer connectivity anomalies in an autistic brain. Based on brain imaging data, white-matter connectivity is analyzed, and a CAD framework is used to classify autistic subjects, and identify which features are most significant. Our objective was to test our framework on 225 subjects using a large data set obtained from the ABIDE-II database, from 5 different sites.

Methods: Anonymized MRI scans were obtained for 225 subjects (125 autistics and 100 typically developed, ages 5-46.6 years) from ABIDE-II database. The framework mainly consists of three stages: first, a preprocessing step to reduce artifacts and eliminate non-brain tissues, including skull stripping and eddy current correction. In the second stage, feature extraction, WM integrity is examined by extracting most prominent features representing WM connectivity from DTI. Six different features (fractional anisotropy, axial and radial diffusivities, mean diffusivity, and skewness) are calculated based on the 3 eigenvalues $\lambda_1$, $\lambda_2$, and $\lambda_3$ on each voxel, and atlas-based segmentation technique is used to allocate features for each area, on John-Hopkins white matter atlas. After that, interactions of WM features between different areas in the brain, demonstrating correlations between WM areas’ features were used, and feature selection among those correlations are made using recursive feature elimination with cross-validation. Finally, a set of 5-fold cross validated classifiers were employed to get the final diagnosis.

Results: To ensure system robustness, 5-fold cross validated classifiers were. To obtain the subject global diagnosis decision, multi-stage system is used. First, feature selection using RFE-CV with different kernels, then $n$ selected features are fed to next set of classifiers. LSVM kernel provided best global distinction being autistic given these features, providing global decisions, which achieved a cross-validated diagnostic accuracy of 99%. The top brain area pairs contributing to the decision is also highlighted by the algorithm.

Conclusions: This promising work provides not only fast and high early-stage diagnostic accuracy, but also allows identifying the localized abnormalities for each individual subject, characterized by the areas of highest rank, which may aid in understanding the autistic subject behavior and help the clinician to deliver a tailored personalized treatment. More medical interpretation to map the impacted regions to the corresponding expected behaviors is needed to validate the personalized maps. Using diffusion tensor imaging data, these promising results emphasize the ability of neuroimaging-based techniques to detect abnormal brain connectivity and provide an accurate diagnosis.

419.403 (Poster) Behavioral-Driven ASD Diagnosis Using Structure MRI
M. T. Ali, A. Gibrell, A. Shalaby, A. Soliman, A. Mahmoud, M. Ghazal, G. Barnes and A. S. El-Baz, (1)Bioengineering, University of Louisville, Louisville, KY, (2)Electrical and Computer Engineering, Abu Dhabi University, Abu Dhabi, United Arab Emirates, (3)Neurology and Pediatric Research Institute, University of Louisville School of Medicine-UL Autism Center, Louisville, KY, (4)University of Louisville, Louisville, KY

Background: Autism spectrum disorders (ASD), according to Diagnostic and Statistical Manual of Mental Disorders (DSM-5), are neurodevelopmental disorders with common impairments in social communication and interactions, restricted and repetitive behavioral. The three differ regarding severity, associated language and cognitive abilities, and symptom pattern. The Centers for Disease Control and Prevention in the US has reported that, for the last few years, ASD prevalence has been increasing, especially among children, reaching almost one in 58. The gold standard of diagnosing ASD is a combination of Autism Diagnostic Observation Schedule (ADOS) and Autism Diagnostic Interview-Revised (ADI-R). An alternative diagnostic method for ASD is the Social Responsiveness Scale (SRS), which is quickly accomplished, objective, economic, easy to use, and increasingly being used as a clinical screening without instrument

Objectives: In this study, we are classifying ASD by identifying subjects in a multi-dimensional behavioral space. A multi-dimensional behavioral space is defined by an array of SRS behavioral score for each subject. Thus, we identify location of each subject on the spectrum via identifying his severity within each behavioral module.
Methods: ABIDE II is the dataset utilized in this study. It is the second iteration of the Autism Brain Imaging Data Exchange (ABIDE), which aims to enhance the scope of brain connectomics research in ASD. ABIDE II dataset comprises 521 individuals with ASD and 593 TD subjects. First phase, we classify the severity of each behavioral category as they are defined in the SRS module (Communication, Mannerism, Cognition, Motivation, Awareness, Total). The severity levels are defined as follow: (i) TD, (ii) mild, (iii) moderate, and (iv) sever, such that mild, moderate, and sever are all considered to be ASD. Second phase, we combine the predicted severity scores for each behavioral category to get a final classification for each subject. At the end of the second phase, we propose a CAD report, illustrated on 2 randomly selected case studies from the testing set, which maps the results of phase one with the most contributing cortical features, and maps the final diagnosis of phase two with the behavioral report.

Results:

To ensure system robustness, we perform 5-fold cross-validation. ASD average classification accuracy of each of the behavioral modules of the SRS (awareness, communication, cognition, motivation, mannerism, and total) is (85%, 91%, 93%, 89%, 95%, 93%) respectively. Using each of the behavioral module to train a machine learning model to provide a global diagnosis for each subject with average classification accuracy of 94%.

Conclusions:

In this study, we propose a novel comprehensive machine learning framework to localize the morphological cortical anomalies associated with different ASD behavioral traits. The localized cortical anomalies are used to classify each subject’s behavior into multiple severity score, and aggregate those scores into a final diagnosis. In this study, we assist physicians to map ASD behavioral traits to the corresponding cortical morphological anomalies.

419.404 (Poster) Epigenetics of Autism Spectrum Disorders: A Multi-Level Analysis Combining Epi-Signature, Age Acceleration, Epigenetic Drift and Rare Epivariations Using Public Datasets

D. Gentilini, R. Cavagnola, P. Politi, M. Olivola and N. Brondino, (1)Istituto Auxologico, Cusano Milanino, Italy, (2)Department of Brain and Behavioral Sciences, University of Pavia, Pavia, Italy, (3)Department of Brain and Behavioral Sciences, University of Pavia, Pavia, ITALY

Background:

Epigenetics of Autism Spectrum Disorders (ASD) is still an understudied field. However, most studies on the topic focused on mere differences between cases and controls.

Objectives:

The aim of the study was to conduct a more in-depth analysis of the role of epigenetics in autism, using an original multi-level approach moving from genome-wide epigenetic analysis (EWAS) and meta-analysis to improve the precision and accuracy of effect estimates to the incorporation of more specific epigenetic analysis such as biological aging, epigenetic drift and rare epigenetic variations.

Methods:

We used publicly available datasets from blood (n=3) and brain tissues (n=3), which were analyzed separately. Firstly, we evaluated for each dataset and meta-analyzed the differential methylation profile between cases and controls. Secondly, we analyzed age acceleration (using the Horvath, Hannum, and GrimAge clocks), epigenetic drift and rare epigenetic variations (epi-variation). Epi-variations were identified as aberrant beta-values (defined as extreme outliers) falling outside a reference methylation range obtained by the methylation profiles of a reference population and calculated as follows: upper value=Q3+(k*IQR); lower value=Q1-(k*IQR); where Q1 is the first quartile, Q3 the third quartile, IQR (Interquartile range)=Q3-Q1 and k=3. For each case, extreme outlier values of single methylation profiles were annotated and classified as hyper-methylated or hypo-methylated to controls' relative probe median values.

Results:

A significant epi-signature of ASD was reported in blood samples but not in brain specimens. We did not observe significant age acceleration in ASD, while epigenetic drift was significantly higher compared to controls. Rare epigenetic variations (epi-variations) were reported in 41 genes, 35 of which were not associated with ASD before this study. Gene enrichment analysis showed that epimutated genes were linked to biological pathways deemed to have a role in ASD pathogenesis as well as to previously not reported molecular processes (neuropeptide Y and its receptors).
Conclusions:

Blood epi-signature could represent a potential tool for diagnosis and prognosis of ASD. The small sample of subjects with available brain specimen data could have limited the ability to detect an epi-signature also in brain tissues.

419.405 (Poster) Real-Life Pharmacological Treatment of Severe Problem Behaviors in Adults with ASD: A Longitudinal Prospective Study

N. Brondino1, M. Nola1, M. Olivola1, C. Guiot1, S. Fontana1, P. Leali1, E. Galetti1 and P. Politi1, (1)Department of Brain and Behavioral Sciences, University of Pavia, Pavia, ITALY, (2)Department of Brain and Behavioral Sciences, University of Pavia, Pavia, Italy

Background:

Autism Spectrum Disorders may be burdened by the presence of irritability and aggression. More than 20% of autistic individuals exhibit moderate to severe irritability and aggression during their life-time. These symptoms may impair access to care and treatment for autistic individuals and caregivers and represent a major negative prognostic factor for long-term outcomes. Severe irritability and aggression (both towards self and/or others) in ASD are often not responding to conventional sedation treatment and it has been reported that antipsychotics are usually burdened by more side effects compared to other clinical populations.

Objectives:

Our primary aim was to investigate treatment of severe problem behaviors in a cohort of autistic adults in real-life clinical practice.

Methods:

We enrolled all consecutive admissions for pharmacological consultation for severe problem behaviors since September 2020. Subjects should have been already diagnosed or re-assessed by a senior psychiatrist expert in ASD and behavioral intervention for problem behaviors have been ineffective or only partially effective. Before evaluating pharmacological treatment, medical problems and comorbid psychiatric disorders have been addressed and treated if present. Pharmacological treatment has been rationalized as follows: 1) if no medication was already administered, aripiprazole was started and titrated eventually up to 30 mg/die 2) if a medication history was already available, treatment was decided according to previous not efficacious treatment or presence of side effects with two potential outcomes a) optimization of present therapy with reduction of the number of medications and titration of the selected medication to the maximum dosage b) introduction of a first generation antipsychotic with low side effect (zuclopenthixol or levomepromazine). Efficacy of treatment was defined as a reduction of 30% score at the ABC irritability subscale after 2 weeks. UKU scale was used for side effect evaluation. Subjects were follow-up every month for up to two years.

Results:

Overall 50 participants were evaluated. Two individuals have comorbid medical conditions in which treatment with antibiotics and antiinflammatory drugs resulted in complete recovery. 15 were drug-naive and were started with aripiprazole with efficacy. Of note, two patients after 20 months started to display inefficacy of aripiprazole and were switched to zuclopenthixol with benefit. Of the remaining 33 subjects, nearly half (n=15) benefited from a reduction of the number of medications administered and a titration to the maximum of the antipsychotic of choice (olanzapine n=4, haloperidol n=1, levomepromazine n=4, aripiprazolo n=1, zuclopenthixol n=5). All subjects were co-administered a mood stabilizer (valproate n=10, gabapentin n=5). 18 subjects were switched to a first generation antipsychotic after inefficacy of the administered medication (risperidone n=7, quetiapine n=8, fluvoxamine n=2, cariprazine n=1).

Conclusions:

Real-life pharmacological treatment of severe problem behaviors in ASD is extremely complex. As a matter of fact, only aripiprazole and risperidone are FDA-approved drugs for irritability in ASD. However, in clinical practice and in profound autism these medications may prove potentially inefficacious. Our cohort showed a reduction in problem behaviors in all the included subjects, with optimization of the treatment already in place as well as with the introduction of first-generation antipsychotics.

419.406 (Poster) RNA Sequencing of Blood from Sex- and Age-Matched Discordant Siblings Supports Immune and Transcriptional Dysregulation in Autism Spectrum Disorder

A. M. Persico1, P. Tomaiuolo1, I. Piras1, S. Baghia Sain1, C. Picinelli1, M. Baccarini1, P. Castronovo1, M. J. Morelli1, D. Lazarevic1, M. L. Scattoni1 and G. Tonon1, (1)Child & Adolescent Neuropsychiatry, Dept. of Biomedical, Metabolic and Neural Sciences, University of Modena and Reggio Emilia, Modena, Italy, (2)Mafalda Luce Center for Pervasive Developmental Disorders, Milan, Italy, (3)Neurogenomics Division, The Translational Genomics Research Institute, Phoenix, AZ, (4)Center for Translational Genomics and
Background: Autism Spectrum Disorder (ASD) is a neurodevelopmental condition with onset in early childhood, still diagnosed through clinical observation and psychodiagnostic tools due to the lack of laboratory biomarkers. Early detection strategies would be especially useful in screening high-risk newborn siblings of children already diagnosed with ASD.

Objectives: To search for ASD-associated blood transcriptomic biomarkers possibly applicable within “high risk” families, where one child has already received an ASD diagnosis.

Methods: Total RNA was extracted from peripheral mononuclear blood cells and RNA sequencing was performed, comparing 31 ASD and 31 unaffected siblings (SIB) matched by sex and age, later reduced to 27 ASD-SIB pairs to control for pharmacological treatment. Sequencing libraries were prepared using the TruSeq Stranded mRNA kit (Illumina, Inc.) and the final library was sequenced by 100 bp paired-end sequencing on NovaSeq to generate 40 million clusters per sample. This approach delineates the coding transcriptome using Oligo-dT beads to capture polyA mRNA tails. After read alignment and transcript quantification, differential gene expression profiling was performed applying both an unpaired and a paired model, followed by Weighted Gene Correlation Network Analysis (WGCNA).

Results: Differential gene expression profiling, performed applying an unpaired model, identified two immune genes, EGR1 and IGKV3D-15, significantly upregulated in ASD patients (both p-adjust = 0.037). WGCNA identified 18 co-expressed modules. One of these modules was downregulated among autistic individuals (p = 0.035) and a ROC curve obtained using its eigengene values yielded an AUC of 0.62. Genes in this module are primarily involved in transcriptional control and its hub gene, RACK1, encodes for a signaling protein critical for neurodevelopment and innate immunity, whose expression is influenced by various hormones and known “endocrine disruptors”.

Conclusions: These results indicate that transcriptomic biomarkers can contribute to the sensitivity of an intra-familial multimarker panel for ASD and provide further evidence that neurodevelopment, innate immunity and transcriptional regulation are involved in ASD pathogenesis.
additional medical exams which would not have otherwise been prescribed, mainly including brain MRI, EEG, EKG, and/or cardiac ultrasound. A positive outcome was obtained in 12/25 (48.0%) of these additional medical tests.

Conclusions: This study confirms the satisfactory diagnostic yield of aCGH in clinical settings and the role of neuronal/synaptic genes in ASD. Furthermore, it underscores the potential contribution of aCGH for better, more in-depth care of children with autism when genetic results are analysed also with a focus on patient management.

419.408 (Poster) Measuring Autistic Burnout: A Preliminary Investigation of the Reliability, Validity and Factor Structure of the Aaspire Autistic Burnout Scale
I. Magiati, M. Bougoure, S. Zhuang, D. W. Tan, L. Taylor and M. T. Maybery, (1)School of Psychological Science, The University of Western Australia, Perth, Western Australia, Australia, (2)King’s College, London, London, Australia

Background: The autistic community has described the experience of autistic burnout as chronic exhaustion as a result of being autistic in an unaccommodating predominantly non-autistic world; autistic burnout has also been described as loss of skills and abilities, impaired thinking, increased avoidance/withdrawal and increased sensory sensitivity (Raymaker et al., 2020; Higgins et al., 2021). In social media and qualitative studies to date, autistic people report experiencing burnout as a consequence of camouflaging and minority stress, and describe it as a risk factor for poorer wellbeing. In response to the need to better understand autistic burnout, Raymaker and colleagues from the AASPIRE research team developed the first self-report measure of autistic burnout, the Autistic Burnout Scale (ABS), which shows promising preliminary measurement properties. However, their initial psychometric evaluation was underpowered to assess the measure’s dimensionality and factor structure.

Objectives: This study is part of a larger project exploring camouflaging, autistic burnout and their psychosocial correlates in autistic adults. We will psychometrically validate the ABS by exploring the measure’s internal consistency, test-retest reliability, structural validity, discriminant validity and construct validity in 350 autistic and 100 non-autistic adults.

Methods: Autistic adults (currently n=231; 19- 76 years; 69.7% Female; 81.4% White; 81.4% professionally diagnosed) have been recruited to date through Prolific, autism organizations, and social media in Australia and internationally. Data collection is ongoing and will be completed by end of November 2022 when a sample of approximately 350 autistic adults (as per COSMIN guidelines for factor analysis) and a non-autistic comparison group of approx. 100 adults will be recruited. Participants complete online self-report measures on demographic information, autistic traits, autistic burnout, camouflaging and mental health measures. A subsample of 129 participants has completed the same measures in a follow-up study 12+ months after the initial phase, and they also completed the Sydney Burnout Measure (Parker & Tavella, 2021). Reliability analyses, correlation analyses and Exploratory Factor Analysis (EFA) will be carried out. Stepwise Discriminant Functional Analysis (DFA) will explore whether the ABS can differentiate between autistic and non-autistic participants, as well as between autistic participants who reported recently having experienced or are now experiencing burnout and those who did not.

Results: Based on preliminary analyses of n=231, the ABS demonstrates excellent internal consistency (Chronbach’s Alpha .97; inter-item correlations’ range .26-.88, mean=.51) and construct validity: greater experiences of autistic burnout are associated with more autistic traits (r=.28), more camouflaging (r=.35), greater exposure to vulnerability events (r=.33) and experiences of depression (r=.45) and anxiety (r=.45). Exploratory and discriminant functional analyses will be run, and in our presentation, we will share our findings on the dimensionality of the ABS and on group differences.

Conclusions: Preliminary analyses show promising psychometric properties for the ABS. We discuss the findings in light of the study’s strengths and limitations, we consider the implications of validating the first measure of autistic burnout for use in future research, and outline some future directions for empirically exploring individual and psychosocial risk and protective factors implicated in the relationship between autistic burnout and mental health.

419.409 (Poster) Psychosocial Factors Associated with Camouflaging and Its Relationship with Mental Well-Being in Autistic and Non-Autistic People: A Mixed Methods Systematic Review
S. Zhuang, D. W. Tan, S. Reddrop, L. Dean, M. T. Maybery and I. Magiati, (1)School of Psychological Science, The University of Western Australia, Perth, Western Australia, Australia, (2)Macquarie School of Education, Macquarie University, Sydney, NSW, Australia, (3)Telethon Kids Institute, Perth, Western Australia, Australia, (4)Independent Researcher, Melbourne, VIC, Australia, (5)Autistic Consultant, Perth, Western Australia, Australia

Background: Camouflaging (i.e., hiding or masking one’s autistic traits in social situations) is consistently associated with poorer mental well-being in autistic and non-autistic people. As camouflaging is socially motivated and occurs within a sociocultural context, it is likely influenced by psychological and social experiences. Qualitative and quantitative literature has provided emerging evidence of psychological and sociocultural characteristics and experiences implicated in camouflaging and its relationship with mental health. However, no review to date has systematically integrated quantitative and qualitative evidence to identify the individual psychological or social factors implicated in camouflaging and its relationship with mental well-being.
Objectives: This mixed method systematic review aimed to critically synthesise qualitative and quantitative research on psychosocial factors associated with camouflaging and its relationship with mental well-being in autistic and non-autistic people.

Methods: This review was preregistered with PROSPERO (registration number: CRD42021264865). Six electronic databases were searched, followed by grey literature searches and hand searches of reference lists. Following a convergent integrated approach to data synthesis, quantitative data were transformed and synthesised with qualitative data to perform a thematic synthesis. Two autistic advisors provided input to ensure that the identified themes and subthemes accurately and respectfully reflected their understanding of the camouflaging experiences of the autistic community.

Results: Fifty-two studies (37 qualitative, 10 quantitative, and five mixed methods) published between 2001 and June 2022 were included. Three themes comprising seven subthemes relating to psychosocial correlates of camouflaging were identified: (1) social norms and pressures of a largely non-autistic world (subthemes: expectations to conform to social norms; societal prejudice and stereotypes), (2) social acceptance and rejection (subthemes: defending oneself from bullying and victimisation; seeking acceptance and connection), and (3) self-esteem and identity (subthemes: internalised stigma and shame; acceptance of autistic identity; disclosure and self-advocacy). An additional four themes comprising nine subthemes related to psychosocial consequences of camouflaging for mental well-being: (1) a pragmatic way of exerting individual agency and control (subthemes: achieving and functioning in a largely non-autistic world; managing others’ impressions); (2) overlooked, under-supported, and burnt out (subthemes: overlooked difficulties and unmet needs; delayed diagnosis; autistic burnout); (3) impact on social relationships (subthemes: gaining acceptance, but relationships are not authentic); and (4) low self-esteem and identity confusion (subthemes: low self-esteem; identity conflict and confusion).

Conclusions: Camouflaging is a largely socially driven response influenced by an interplay of psychological and social experiences, including non-autistic norms and expectations, stigmatisation, and the need for social acceptance. While camouflaging presents some social benefits and opportunities, it also comes with serious costs to mental well-being, as it negatively impacts one’s social relationships, self-esteem, and identity and contributes to experiences of being under-supported and burnt out. Our review calls for systemic change to create psychosocial environments where autistic individuals are accepted, valued, and empowered to drop the mask and live and relate with others in more authentically autistic ways.

419.410 (Poster) How Does Autistic Camouflaging Relate to, and Differentiate from, Social Anxiety, Fear of Negative Evaluation and Social Autistic Traits?

I. Magiati, K. McKinnon, S. Zhuang, M. Bougoure, M. J. Liang, B. Luo, L. William, D. J. Leong and D. W. Tan. (1) School of Psychological Science, The University of Western Australia, Perth, Western Australia, Australia, (2) School of Psychological Science, University of Western Australia (UWA), Perth, Western Australia, Australia, (3) School of Psychological Science, University of Western Australia, Perth, WA, Australia, (4) Department of Psychology, National University of Singapore, Singapore, Singapore, Singapore, (5) Autistic Consultant, Independent Researcher, and Multi-Artist, Singapore, Singapore

Background: Autistic people often report using a range of strategies, known as camouflaging, to mask or hide their autistic characteristics and to ‘pretend to be normal’ when navigating non-autistic social environments. Camouflaging is described as exhausting, and camouflaging has been consistently positively associated with more mental health difficulties; camouflaging can also contribute to missed autism diagnosis, and needs being overlooked. Although some researchers have argued that camouflaging may overlap considerably with related constructs, such as social anxiety, fear of negative evaluation (FNE) and social autistic traits, the construct validity of camouflaging and its potential overlap with other related constructs has not yet been empirically investigated.

Objectives: This study examined the construct validity of the Camouflaging Autistic Traits Questionnaire (CAT-Q), a widely used self-report measure of camouflaging behaviour. Specifically, we aimed to determine the relationship between camouflaging, social anxiety, FNE and social communication autistic traits; and to explore whether CAT-Q items could be disambiguated from items conceptualised to measure social anxiety, FNE and social autistic traits.

Methods: This study utilised data from a larger study exploring the psychosocial correlates of camouflaging. Data were collected in 2020 and 2021. Participants were 308 professionally diagnosed (n=265) and self-identified (n=43) autistic adults (men=88, women=189, another gender identity/gender not disclosed=31; mean age=36.2, SD=11.6, 18-76 years). We ran correlational analyses and three exploratory factor analyses combining the CAT-Q camouflaging items with items from measures of social anxiety (measured using the Social Interaction Anxiety Scale/Social Phobia Scale; SIAS/SPS), FNE (measured by the Brief Fear of Negative Evaluation scale; BFNE) and social autistic traits (measured by the Broad Autism Phenotype Questionnaire; BAPQ) respectively, to explore whether separable camouflaging and social anxiety, FNE and social autistic traits’ factors could be identified.

Results: Associations between age, sex and diagnostic status (professionally diagnosed vs self-identified) and camouflaging were small and/or non-significant. The CAT-Q total score was positively associated with the BAPQ pragmatic language and aloof subscales’ score (r=.33), with social anxiety (.45) and with FNE (.39), all with small to medium effect sizes, suggesting they are related, but also independent, variables. In the factor analyses, the CAT-Q items differentiated well from social anxiety, FNE and social autistic trait items, as the camouflaging items largely loaded together onto different factors from the social anxiety, FNE and social communication autistic
traits’ items. A few CAT-Q items, mostly from the Assimilation subscale, loaded together with social anxiety or the BAPQ social communication items.

Conclusions: The CAT-Q camouflaging items were related to, but also largely separable and clearly distinguishable from, items measuring social anxiety, FNE and social autistic traits, strengthening confidence in the construct validity of camouflaging as measured by the CAT-Q. Some individual items may require further refinement. Future research should replicate these analyses and use convergent approaches, such as network analysis, to further advance the construct validity of the CAT-Q so as to continue to improve our ways of asking about, measuring and understanding camouflaging.

419.411 (Poster) Psychosocial Predictors of Camouflaging and the Role of Autistic Identity and Social Support in the Relationship between Camouflaging and Mental Well-Being in Autistic Adults

Background: Camouflaging refers to strategies used by autistic people to hide or mask their autistic characteristics in social situations, to "pretend to be normal." While at times helpful and necessary for social survival in a largely non-autistic world, camouflaging has been consistently associated with poorer mental well-being. Although camouflaging is a social experience driven by psychosocial motivations and affects one’s well-being, identity, and relationships, most quantitative research to date has focused on exploring individual differences in camouflaging behaviours. Several qualitative studies have explored the psychosocial motivations and impact of camouflaging. However, very little quantitative research has examined the psychological or social factors associated with camouflaging or implicated in its relationship with mental well-being.

Objectives: This study, part of a larger project exploring predictors, continuity, and change in camouflaging and its relationship with well-being in autistic adults, aims to explore the following research questions: (a) Do specific theoretically and empirically supported psychological (i.e., greater fear of negative evaluation) and social experiences (i.e., more vulnerability events, perceived stigma, perceived strength of social norms and degree of tolerance for deviance in society, and one's desire to individuate or maintain social harmony) predict more camouflaging behaviours? and (b) Does autistic identity and perceived social support moderate the relationship between camouflaging and mental well-being, such that the relationship between camouflaging and poorer mental well-being is weaker for those with stronger autistic identity and perceived social support?

Methods: This study was developed in partnership with an autistic consultant. Three hundred and eight autistic adults (18-76 years; 61.4% females; 77.3% White; 86% professionally diagnosed) were recruited through Prolific, autism organisations, and social media in Singapore, Australia, and internationally between 2019 and 2021. Participants completed online self-report measures on demographic information, autistic traits, camouflaging (using the Camouflaging Autistic Traits Questionnaire; CAT-Q; Hull et al., 2017), and the aforementioned psychosocial factors. Hierarchical linear regression analyses were performed to investigate whether psychosocial factors predicted camouflaging, after controlling for age, gender, and autistic traits. Moderation analyses are currently underway to examine the moderating role of the proposed psychosocial factors in the relationship between camouflaging and mental well-being.

Results: Greater fear of negative evaluation, greater vulnerability to negative events, and perceptions of stronger social norms and lower tolerance for deviance significantly predicted more camouflaging behaviours, over and above age, gender, and autistic traits (14.1% additional variance in camouflaging explained by psychosocial factors; 28.3% of variance explained by the final model with all predictors). Moderation analyses are ongoing, and in our presentation, we will share findings from these analyses on the role of autistic identity and perceived social support in the relationship between camouflaging and mental well-being.

Conclusions: Camouflaging as a social coping strategy is likely influenced by individual psychological characteristics and perceived/ experienced sociocultural pressures to conform. We discuss our findings in light of the study's strengths and limitations and in relation to psychological and societal-level changes required to reduce the pressures on autistic individuals to camouflage.

POSTER SESSION — COMBINED TOPICS

427 - Combined Topics III

427.406 (Poster) Synaptic Density Marker, SV2A, Is Reduced in Autistic Adults
Background: Altered synaptic structure and function are thought to be key neurobiological mechanisms underpinning autism, as suggested by genetic (Bourgeron, 2015), post-mortem (Nicolini et al., 2015) and animal model (Tang et al., 2014) research. Yet, until now, synaptic density in autistic people in vivo has not been quantified.

Objectives: Here, we used the ¹⁸F-UCB-J positron emission tomography (PET) tracer to investigate synaptic density differences in autistic adults. We hypothesised 1) altered synaptic density in autistic compared to neurotypical adults in subregions of the fronto-temporal cortex (Hutsler & Zhang, 2010; Nicolini et al., 2015), the anterior cingulate cortex (Nakamura et al., 2011), and the amygdala (Schumann & Amaral, 2006) and that 2) synaptic density correlates with the extent of autistic traits.

Methods: We recruited 10 autistic adults (8 male, 2 female), aged 19–58 years, and 8 sex and age matched neurotypical controls. No participants had co-occurring physical health or developmental conditions. PET imaging was undertaken using the ¹⁸F-UCB-J radiotracer, which binds to the synaptic vesicle protein 2A (SV2A). SV2A is found on pre-synaptic boutons; therefore, higher distribution volume (Vi) of ¹⁸F-UCB-J denotes greater synaptic density (Finnema et al., 2016). We measured the extent of overall autistic traits in both groups using the AQ10, and specific autistic features in the autistic group only using the Autism Diagnostic Observation Schedule, second edition (ADOS-2).

Results: ¹⁸F-UCB-J V_i was significantly lower in autistic compared to neurotypical adults (figure 1) in the following hypothesised regions: right frontal cortex (t16 = -2.19, p = .047, d = .96), right dorsolateral prefrontal cortex (t16 = -2.27, p = .039, d = 1.01) and anterior cingulate cortex (t16 = -2.16, p = .046, d = 1.01). Additionally, lower ¹⁸F-UCB-J V_i in autistic adults was found in the right orbitofrontal cortex (t16 = -2.68, p = .016, d = 1.23), left parahippocampal gyrus (t16 = -2.73, p = .015, d = 1.30), posterior cingulate cortex (t16 = -2.38, p = .030, d = 1.13), left dorsal cerebellum (t16 = -2.78, p = .014, d = 1.31) and left nucleus accumbens (t16 = -2.43, p = .027, d = 1.12).

In all the aforementioned brain regions, and throughout grey matter, reduced synaptic density correlated with more (overall) autistic traits across groups (r = -.59, p = .012, figure 2a), and in neurotypicals alone (r = -.93, p < .001, figure 2b). Within autistic adults, lower synaptic density was particularly associated with communication challenges as measured by ADOS-2, for example in the anterior cingulate cortex (r = -.84, p = .017).

Conclusions: We report the first in vivo evidence that autistic adults have a significant reduction in synaptic density, and that this is associated with more autistic traits. Future work is required to determine how these differences arise and if they are related to variation in outcomes within autistic people.

427.407 (Poster) Genetic and Clinical Diagnoses Associated with Developmental Regression in Children with and without Autism
K. J. Furley, K. Williams, M. Hunter and M. Fahey, (1)Paediatrics, Monash University, Melbourne, VIC, Australia, (2)Monash University Department of Paediatrics, Clayton, VIC, Australia, (3)Clinical Genetics, Monash Health, Melbourne, VIC, Australia, (4)Neurology, Monash Health, Melbourne, VIC, Australia

Background: Causes of developmental regression (DR) are poorly understood. Some diagnoses are associated with DR like autism spectrum disorder (autism) and others require DR, like childhood disintegrative disorder. There are recognised monogenic causes, including Rett’s syndrome, and also epileptic, including Landau Kleffner Syndrome. Phenotyping children with DR and assessing diagnostic yield of investigations will advance best practice care. Furthermore, improving knowledge of causes of DR enables potential for novel treatment discovery.

Objectives: To describe clinical characteristics and identified diagnoses of DR, with and without pre-existing autism; to provide information about use and utility of genetic testing and neuroimaging for diagnosis

Methods: A retrospective study identified children aged 0-18 years referred to a tertiary clinical genetics service with DR by searching a clinical database using pre-determined keywords over the period 1/1/18 and 5/8/21.

Results: Of 307 children identified as possibly having DR, there were 68 duplicate entries, 117 with no documented DR and 22 aged over 18 years. The final cohort of 100 children included 69 males. 60 children with DR had a prior diagnosis of autism, 71 children had intellectual disability (ID) or global developmental delay (GDD), 39 had a diagnosis of autism and ID/GDD, and 6 children with autism out
of 15 children had pre-existing epilepsy/seizures. 86% children were aged less than 48 months at onset of DR, with a mean age of DR onset of 24.6 months for children without autism and 33.4 month for children with autism. The most frequent DR domain was speech and language loss for children with and without a diagnosis of autism, followed by loss of mixed skills >1 developmental domain. An explanatory genetic diagnosis was made for 30 children (30%) with 26 different genetic diagnoses. A further 3 children (2 children with autism) received MRI brain diagnosis after inconclusive genetic testing. Twelve (20%) children with autism and 18 children (45%) without autism obtained a genetic diagnosis thought to explain DR. Chromosomal microarray (CMA) was requested in all 100 children with 5 results, all children with autism, thought to explain DR. Genomic testing (gene panels or exome sequencing) was completed in 57 children (57%), 25 children with autism and 32 without an autism diagnosis. Genomic results were thought to explain DR for 7 children with autism (28%), and 18 children without (56%).

Conclusions: Age of onset and types of regression were similar to other studies and similar for children with and without autism. This study reports heterogeneous identified genetic and neuroimaging causes of DR in children. Genomic testing provides higher diagnostic yields than CMA and neuroimaging, and had a higher diagnostic yield for children without a pre-existing diagnosis of autism. Neuroimaging may aid diagnostic clarification for children with otherwise inconclusive genomic results. Identifying children with DR early through enhanced phenotyping, and improved awareness and knowledge of the breadth of disorders causing DR allows for earlier use of optimal high yield investigations. An earlier diagnosis enables use of evidenced-based management with potential to improve child outcomes.

427.408 (Poster) Definitions and Measures Used for Loss of Developmental Skills in Autistic Children
K. J. Furley1, K. Williams1, A. Brignell1 and V. P. Mohanakumar Sindhu1, (1)Paediatrics, Monash University, Melbourne, VIC, Australia, (2)Monash University Department of Paediatrics, Clayton, VIC, Australia, (3)Monash University, Clayton, VIC, Australia

Background:

Research and evidence informed clinical care of autistic children with developmental regression (DR) is thwarted by the heterogeneous use of different terms, definition variation and inconsistent use of measurement tools. DR in children must be identified early to facilitate early intervention and opportunities for emerging novel therapeutics and lack of an agreed definition and methods to measure DR delays identification and impacts on data collection to report incidence and prevalence rates.

Inconsistent definitions and measurement tools cause confusion for parents, caregivers, researchers and clinicians alike.

Objectives:

To describe the definitions and measures used when studying loss of skills in autistic children.

Methods:

Scoping review of studies about autistic children with skill loss in ≥1 developmental domain. Participants were any child aged up to 18 years old with loss of skills in any of the following developmental domains; language, social, motor, cognitive and adaptive skills. Use of an operational definition (a clear concise definition) and use of, and types of measures used were extracted. Data checking was completed by at least 2 experienced researchers. An extensive search strategy of synonyms of DR in PubMed, Embase, Psychinfo, Cochrane systematic reviews identified over 16 000 studies. Descriptive analysis based on final 101 included full text studies using PRISMA.

Results:

Of 101 included studies 90% used an operational definition.

45% of studies used or referred to the Autism Diagnostic Interview-Revised (ADI-R) definition (Rutter, et al 2003).

A study specific definition was used in 45%, and 9% did not describe a definition.

The ADI-R was the most used measure. There were 45 different study specific measures used including study specific questionnaires, interviews and other methods including searching medical records and home-videos. Of the study specific measures only a minority used validated tools such as the Regression Validation Interview, or Regression Supplementation Form.

Conclusions:

Most studies involving autistic children with loss of developmental skills used an operational definition, however definitions were heterogeneous in age of onset, type, and duration of skills loss. Nearly half of definitions were unique and study-specific. While the ADI-R
is the most used measure it was used in less than half of the studies. 45 different study specific measures were used and a minority used published regression questionnaires or other objective measures.

Consistent terminology, an agreed operational definition, and standardised measurement methodology across research and clinical care for autistic children with loss of developmental skills is urgently needed.

Objectives: To establish the construct validity, consumer acceptability, and clinical utility of the INCAAF for young children with neurodevelopmental conditions (NDCs).

Methods: The INCAAF was evaluated across two pilots, with modifications to the tool in between. The INCAAF collects information through clinical interview, observations, standardised measures, file reviews, and contact with other professionals. The information is then used to score the items of the ICF Core Sets for NDCs. Items were scored according to the ICF scales, except for the environmental factor scale, which was modified from a facilitator to barrier scale into two separate scales.

For both pilots, the INCAAF was administered with children (n=18 and n=18) with, or suspected of, NDCs under the age of six years (5.1 (3.4-5.9) and 3.0 (1.7-4.9) years of age respectively) and their parents (n=20 and n=20) as part of a home assessment by an occupational therapist. Between 34% and 80% of each sample had or was being considered for a diagnosis of autism. After receiving the results of the assessment, caregivers were asked to provide feedback about the INCAAF’s acceptability through an interview or online survey.

Clinical utility workshops were held with clinicians (n= 30 and n=12 respectively) who assess functioning for children with NDCs. Workshop questions were guided by the Multi-dimensional Model of Clinical Utility (MDM CU; Smart, 2006), and workshops were recorded and transcribed. The transcriptions were then analysed using template analysis with the MDMCU providing priori themes.

Results:

Construct Validity: In both pilots, there were few significant and/or strong associations between facilitator and barrier scores, supporting the measurement of the environment across two separate scales. The interview and clinical observations were the most frequently utilised sources of information for scoring items.

Consumer Acceptability: Within the first pilot, caregivers found the INCAAF acceptable, and suggested ways to improve clarity. After the INCAAF was revised, caregivers in the second pilot reported that the INCAAF was easy to understand and that they would be very likely to recommend the INCAAF to a clinician.

Clinical Utility: Clinicians generally felt the INCAAF was well suited to assessing young children with NDCs in allied health and/or multidisciplinary contexts. Clinicians described the resources and training they would like available alongside the tool.

Conclusions: The INCAAF shows good construct validity, consumer acceptability and clinical utility in the Australian context. With further revision and testing, the INCAAF is expected to be a valuable tool for clinicians when assessing young children with, or suspected of, NDCs.
This study examines the characteristics and co-occurring diagnoses of autistic older adults (age 40 and older) in a national sample.

Objectives:

The study's objectives are to (1) describe clinical and demographic characteristics, (2) identify access to healthcare systems, and (3) examine how autistic adults utilize these resources.

Methods:

Data was collected through a national survey of autistic older adults aged 40 and older. The study employed a survey questionnaire to gather information on clinical characteristics, access to healthcare systems, and utilization of health services.

Results:

The survey data revealed several key findings. Firstly, the majority of participants reported consistent access to healthcare systems. However, there was a notable variation in the type and quality of care received, with some individuals facing challenges in accessing specialized supports.

Conclusions:

The study highlights the importance of tailored healthcare interventions for autistic older adults. It underscores the need for further research to better understand the unique needs and challenges faced by this population, as well as the development of effective strategies to improve access to healthcare services.

Background:

Autistic individuals often require specialized supports as they age, which can be challenging to access. This study aims to fill gaps in our understanding of the healthcare needs of autistic older adults, providing valuable insights for policymakers and healthcare providers.
Methods:

National (US) Medicaid and Medicare claims for 2014-2016 for all enrolled autistic individuals aged 40 and older were utilized. Diagnoses were identified using validated algorithms from the Chronic Condition Warehouse (CCW). Autistic individuals included mutually exclusive groups of individuals with and without co-occurring intellectual disability, n=37,330 (ASD/ID) and n=19,955 (ASD only) respectively. A comparison group of individuals with intellectual disability (ID only, n=418,359) was constructed. Period prevalence for each chronic condition and ranked comorbidity combinations were calculated across each group for the study duration.

Results:

Most individuals across all groups relied upon Medicaid (89.3%), frequently presented with co-occurring ID (65.2%), and a greater proportion was female (32.5%) when compared to previous younger, national samples or individuals with ID (47.6% female). A greater proportion of both ASD groups were under 65 (91.4% with ID and 83.7% without ID) than the proportion of the ID group (80.9%). Autistic older adults were slightly less diverse. In the ASD/ID group, 16.5% were Black and in ASD Only 10.5% were Black (ID only group was 17.2% Black). A greater proportion of the ASD Only (72.3%) and ID Only (71.0%) groups had comorbidities than the ASD/ID group had (61.2%), and almost triple the proportion of the ASD Only group had 5 or more comorbidities (15.9%) compared to the ASD/ID group (5.8%). The most frequent combinations of comorbidities across autistic older adults (with or without ID, in order) were hyperlipidemia/hypertension, diabetes/hypertension, depression/hypertension, and hypertension/kidney disease. Anemia was a common comorbidity, in combination with hypertension and hyperlipidemia. Among all Medicaid enrollees, hyperlipidemia/hypertension was also the most common comorbidity, but Alzheimer’s and dementia/hypertension, and anemia/hypertension occurred more often than in the ASD groups, followed by diabetes/hypertension. With recently acquired data through 2019, period prevalence across comorbidities and groups will be updated.

Conclusions: To our knowledge, linked data from Medicaid and Medicare has generated the largest, national samples to date of older autistic adults. The ASD Only group was more similar to the ID Only group than the ASD/ID group, suggesting complex healthcare needs and/or barriers to accessing needed services. Comorbidities differed among the ASD groups compared to other Medicaid enrollees, suggesting differences in health risk. Population-level data are a promising path for catalyzing research advancements, especially when paired with direct engagement of autistic older adults, their caregivers, and their care providers to capture preferences and lived experiences.

427.412 (Poster) Reproductive Health Outcomes Among Autistic Individuals
L. Shea and S. Tao, (1)A.J. Drexel Autism Institute, Philadelphia, PA, (2)Drexel University, Philadelphia, PA

Background:

Reproductive health is a key component of to preventing adverse health outcomes and promoting positive health outcomes across the lifespan. Few research studies have tackled this important topic among autistic individuals. Emerging research has identified that autistic adolescents may receive less sexual education than their peers. Cross-sectional data compared to national survey data found that autistic young adults had lower rates of sexually transmitted illnesses (STI) when compared to the general population. However, other research has identified that there may be elevated rates of health-related risky behaviors among adolescents and young adults on the autism spectrum. One study conducted in the Taiwan National Health Insurance Research Database (NHIRD) found an increased rate of STI than a comparison group. This study further identified that long-term use of antipsychotics was associated with a lower risk of STI compared with nonuse and recommended clinician monitoring of behaviors and risk. Examining these trends at the population level in additional countries is needed to determine how these differing observations of risk occur across nations. Information about incidence and prevalence can drive key system changes for healthcare and reproductive health access, as well as reproductive education. Recent advancements in the US healthcare system and specifically in Medicaid, the public health insurance program, have resulted in most states covering both HIV and STI counseling and screening without payment from Medicaid enrollees required.

Objectives:

This study seeks to examine the prevalence of STI and reproductive health outcomes and service use among autistic individuals.

Methods:

National (US) Medicaid claims for 2016 for all enrolled autistic individuals aged 14 to 50 and similarly aged cohorts of individuals with intellectual disability (ID) and a random sample of Medicaid enrollees were constructed. Diagnoses of autism and ID were identified using ICD-10 and validated algorithms from the Chronic Condition Warehouse (CCW) which have also be used in the majority of autism research to date. As a preliminary step to understanding STI among autistic individuals, we examined STI among autistic birthing people compared to their peers with ID, and a random sample of other Medicaid enrollees. Childbirth was identified using a standard protocol for
Assessing the Validity of a Risk Classification Given By an Autism e-Screener When Used By Medical Providers in a Clinical Setting

M. Honaker1, T. E. Foster2, A. Swanson3, A. S. Weitlauf4, N. Sarkar2, J. W. Wade4 and Z. Warren1, (1)Vanderbilt University Medical Center - Treatment and Research Institute for Autism Spectrum Disorder, Nashville, TN, (2)Vanderbilt University Medical Center, Nashville, TN, (3)Vanderbilt Kennedy Center, Vanderbilt University Medical Center, NASHVILLE, TN, (4)Vanderbilt Kennedy Center, Vanderbilt University, Nashville, TN, (5)Mechanical Engineering; Electrical Engineering and Computer Science, Vanderbilt University, Nashville, TN, (6)Adaptive Technology Consulting, LLC, Nashville, TN

Background: The rate at which children < 36 months are accurately and efficiently diagnosed with autism spectrum disorder (ASD) has continued to be an ongoing challenge. Because early identification of ASD accelerates access to support, providing efficient and easily accessible screening tools to medical providers has proved to be essential in a clinical field. We developed a novel application (“Paisley”)
that supports medical providers in identifying early and suspected signs of ASD in toddlers by providing risk classifications, and/or the likelihood that a child could have ASD.

Objectives:

To see if the risk classifications given by the Paisley application are supported by medical providers and their diagnostic decisions following administration.

Methods: Paisley is a tablet-based app that guides its’ users through nine play-based activities. This application was used in a clinical setting by a sample of medical providers (n = 42), specifically nurse practitioners and physician residents on rotation. After an approximately 15-minute administration, medical providers were immediately asked to answer questions based entirely on their own clinical judgments and behavioral observations from each unique session. Providers received no help or guidance when answering these questions. Each provider could administer Paisley to up to 5 children, with 115 children being included in analyses. Medical providers were also asked to give their diagnostic decision after reviewing the results from the application. Immediately following Paisley administration, children received a full diagnostic evaluation with a blinded psychological examiner.

Results: Of the 42 medical providers that used the application, and the 115 total sessions, only 7 session providers (6.09%) responded “No” when asked if they agreed with the application’s risk classification. 108 session providers (93.91%) answered “Yes,” stating that they did in-fact agree with the applications given risk classification. Due to the high agreement rate with the risk classification given by our application, Paisley has shown to have a positive impact on the users that have encountered it and utilized it in a clinical setting. Of the 115 sessions, there were only diagnostic disagreements between the medical provider and the final diagnosis given by the psychological examiner in 16 of the 115 total sessions (13.91%).

Conclusions: Medical providers that used Paisley were able to learn the application in a short time frame and administer nine newly learned play-based activities. After each session, the medical providers were instructed to answer questions based solely on their observations and clinical judgments alone. Findings show that the application is easily accessible and simple to use due to the lack of knowledge and information given to the medical providers prior to using it in a real-time setting. The audio, visual and text instructions are also an aid in using the tablet during the session and have helped to accurately identify ASD in toddlers. The risk classifications given have shown to have a positive agreement rate with the medical providers using it. Further findings support the usage of app-guided technology in a clinical setting, and the impactful ways in which an e-screener could identify possible signs of ASD in toddlers.

427.415 (Poster) Leadership Education in Neurodevelopmental Disorders (LEND) Trainees As Family Navigators
T. J. Minor, N. Harris, A. S. Weitlauf, E. B. Lee and Z. Warren, (1)Vanderbilt University Medical Center, Nashville, TN, (2)Vanderbilt Kennedy Center, Vanderbilt University Medical Center, Nashville, TN, (3)Vanderbilt Kennedy Center, Vanderbilt University Medical Center, Nashville, TN, (4)Pediatrics, Vanderbilt University Medical Center, Vanderbilt Kennedy Center, Nashville, TN, (5)Vanderbilt University Medical Center - Treatment and Research Institute for Autism Spectrum Disorder, Nashville, TN

Background:

Families of young children with ASD often struggle to access community care after a diagnosis (Harvey et al., 2022). Although partly due to a lack of available service providers, especially in rural and medically underserved regions (Antezana et al., 2017), difficulty accessing care may also be due to fractured care systems – the diagnosing provider, the early intervention system, primary care providers, disability advocacy groups – that exist side-by-side without communicating. To help bridge this gap, the Vanderbilt Consortium Leadership Education in Neurodevelopmental Disorders (LEND) program collaborates with the Tennessee Cares for ASD Navigation Network to provide its trainees with a hands-on care navigation practicum that connects families of newly diagnosed children to community resources. The goal of this project is to train the next generation of leaders in neurodevelopmental care in the importance of navigation for families. However, it was unknown at project initiation how it would impact trainee knowledge and competence.

Objectives:

To determine the effect of participation in a care navigation practicum on interprofessional trainees’ skill and comfort level in providing autism-related resources to families who have recently received a diagnosis of autism for a child.

Methods:

Trainees completed a didactic module on care navigation, attended a training session with a Tennessee Cares Lead Family Navigator, and reviewed commonly available recommended resources for families of children with ASD in Tennessee. At four points within the academic year (October, November, January, February), trainees were matched with families of newly diagnosed children. Trainees had up to three points of phone contact with each family, which included reviewing standardized resources and utilizing a note-taking framework for reporting back to the lead Family Navigation Team. Trainees’ skill and comfort level in speaking with families and providing resources
was measured via a three-question, 5-point Likert scale survey completed pre- and post-practicum. Qualitative responses were collected via the note-taking framework.

Results:

Eighteen LEND trainees representing ten professions participated in the Care Navigation Practicum in 2021-22 academic year; 13 completed the pre- and post-surveys. An exact sign test demonstrated trainees reported increased ability to find autism-related services for families \( p = .02 \); comfort in discussing autism and related services with families \( p = .02 \); and confidence in helping families access autism-related services \( p = 0.035 \). Qualitative responses collected on contact reports indicated trainees’ knowledge of and comfort with care navigation increased over the course of the practicum (see Table 1).

Conclusions:

This study demonstrates the feasibility of the LEND Trainees as Family Navigators Practicum as a framework not only to orient trainees to resources, but also increase their comfort levels in talking with families. Giving future providers structured exposure to navigating families through the post-diagnostic period may increase not only knowledge, but also compassion for families within the future health work force.

---

**POSTER SESSION — COMBINED TOPICS**

**438 - Combined Topics IV**

**438.368 (Poster) Influence of Age and Gender on the Severity of Autism in Children: Truth or Myth?**

S. Gulati, P. K. Choudhary, G. Kamila, S. R. Chowdhury, R. Tiwari, S. Khan, S. Pandey, P. Jauhari and B. Chakrabarty, (1)Centre of Excellence and Advanced Research for Childhood Neurodevelopmental Disorders, Child Neurology Division, Department of Pediatrics, All India Institute of Medical Sciences, New Delhi, New Delhi, India, (2)All India Institute of Medical Sciences, New Delhi, India, (3)All India Institute of Medical Sciences, New Delhi, New Delhi, India, (4)Child Neurology Division, All India Institute of Medical Sciences, New Delhi, India, (5)Child Neurology Division, Department of Pediatrics, All India Institute of Medical Sciences, New Delhi, New Delhi, India, (6)Department of Biostatistics, All India Institute of Medical Sciences, New Delhi, India, (7)Child Neurology Division, Department of Pediatrics, All India Institute of Medical Sciences, New Delhi, India, (8)Pediatrics, All India Institute of medical sciences, New Delhi, India, NEW DELHI, India

Background: Severity in children with Autism Spectrum Disorder changes with age. Similarly, severity based on gender of children with autism has been explored and has been not found to be significant. In this study we have looked at the differences in severity of autism based on age and gender.

Objectives: Our objectives were to determine if severity differs in autism children based on gender and age. We also analysed post intervention scores of CARS and ABC to see if same is statistically significant based on age and gender.

Methods: In this retrospective analysis of children with autism presenting to a tertiary center in North India over 5 years, we collected the baseline demographic data, CARS (Childhood Autism Rating Scale), CBCL (Childhood Behavior Checklist) and ABC (Autism Behavior Checklist) scores.

Results:

A total of 2161 children were included in the study. Mean age was 5.58 years \( \pm 3.25 \) and ranged from 1-28 years. 859 children were >5 years and 1302 at the time of presentation to our centre were <5 years of age. 1828/2161 (84.6%) were males. Baseline CARS scores were mild-moderate in 1010 (46%) children and severe in 1151 (53%). Mean baseline CARS score of this cohort was 36.35\( \pm 5.6 \). Mean of CARS scores in <5 years was 36.1 \( \pm 5.6 \) and in >5 years was 36.73 \( \pm 5.7 \) and this difference in baseline CARS was significant \( p=0.01 \). Mean CARS value in males was 36.27\( \pm 5.63 \) and in females was 36.8\( \pm 5.81 \) and this difference wasn’t statistically significant \( p=0.11 \).

ABC scores were done in 2116 children at baseline. Mean ABC score for <5 years was 79.7\( \pm 17.9 \) and 81.5\( \pm 17.7 \) for >5 years and this difference at baseline was statistically significant \( p=0.02 \). The baseline ABC scores in males \( 80.6 \pm 17.8 \) and females \( 79.9 \pm 18.1 \) weren’t significant \( p=0.56 \).

CBCL scores at the baseline, 2088/2161 children (97%) were withdrawn, 599/2161 (28%) showed hyperactivity, 648/2161 children (30%) had inattention and 2120/2161 had PDD (98%).
Post intervention data of 1824 children was analysed with mean of follow-up of 13.5 months. Mean difference in CARS scores pre and post intervention was 2.51 ± 7.6 and this was statistically significant (p<0.01). This difference was statistically significant when >5 and < 5 years groups were separately analysed (p<0.00). Also the mean difference in CARS scores was statistically significant amongst males and females after intervention (p<0.01).

Conclusions:

Age has correlation with autism severity assessed on CARS and ABC while gender differences of severity aren’t significant between the males and females. Post intervention decline in severity was seen in all age groups and both genders.

438.369 (Poster) Multimodal Behaviour Analysis for Early Diagnosis of Autism in Children
A. B, J. Shukla and S. Gulati, (1)Human-Machine Interaction (HMI) Lab, Indraprastha Institute of Information Technology, New Delhi, India, (2)Centre of Excellence and Advanced Research for Childhood Neurodevelopmental Disorders, Child Neurology Division, Department of Pediatrics, All India Institute of Medical Sciences, New Delhi, New Delhi, India

Background: Early detection of autism is crucial for deciding the appropriate educational and behavioural intervention at the most suitable time. The lack of biological markers, the complexity of the diagnostic procedure, dependence on behavioural observations and developmental history, and subjective diagnosis demand the introduction of assistive technologies in diagnosing autism in children. Recent research has shown increased interest in leveraging machine learning paradigms for identifying biological and behavioural markers to aid the early detection of autism.

Objectives: Previous research has shown that linguistic biomarkers have the potential to efficiently classify children with autism (CwA) from the typically developing (TD) population. Similarly, it has also been found in the literature that the CwA exhibits atypicalities in emotional perception and expression. Accordingly, in this work, we propose a framework for multi-modal behaviour analysis, specifically the speech and facial expression behaviour in children, to aid in the early diagnosis of autism.

Methods: For the speech analysis, we used the transcripts of ASD and TD children from the Eigsti, Nadig, and Flusberg dataset provided by Child Language Data Exchange System (CHILDES) databank(MacWhinney, 2000). This consists of dyadic interaction between the child and a conversation partner of 76 children (ASD-35, TD-41). We extracted semantic and pragmatic features of the child-partner interaction for the binary classification using a Support Vector Machine (SVM) to predict if the child has ASD or not. Further, we analysed the facial expressions exhibited by the children to identify their emotional state, which could be used to enable efficient interactions during the assessment sessions. Due to confidentiality and privacy concerns, the facial expression data for autistic children was not available. Hence, for our experiments, we used a lab-curated dataset collected from YouTube, consisting of facial emotion expressions (FER) of TD children of the age group 3-10 years under the six labels - happy, sad, anger, surprise, fear and neutral. For the emotion recognition from FER data, we employed a transfer learning-based approach for classifying the emotions from the facial expression data collected as images.

Results: With the SVM classifier, the model could predict the child’s state based on their speech behavioural profile with approximately 94% which is significantly higher than the chance accuracy of 50% for the binary classification. For the multiclass of facial emotion classification, we could learn the child’s emotional state with 45% accuracy, which is higher than the chance accuracy of 16.67%.

Conclusions: The results show that speech-based biomarkers supported by a machine-learning paradigm are ideal candidates for the automatic assessment of autism. Similarly, once validated against CwA, FER can also aid the diagnosis. The next step is to develop a system to evaluate the proof of concept by integrating the modules into an assessment system and conducting a pilot study with children with autism.

438.370 (Poster) Role of Gluten Free Casein Free Diet in Children with Autism Spectrum Disorders: A Randomised Controlled Trial
S. Gulati, A. Agarwala, K. L. Gupta, S. Ojha, G. Kamila, S. Khan, P. Jauhari, B. Chakrabarty, A. Upadhyay and S. Pandey, (1)Centre of Excellence and Advanced Research for Childhood Neurodevelopmental Disorders, Child Neurology Division, Department of Pediatrics, All India Institute of Medical Sciences, New Delhi, New Delhi, India, (2)Child Neurology Division, Department of Pediatrics, All India Institute of Medical Sciences, New Delhi, India, (3)All India Institute of Medical Sciences, New Delhi, India, (4)All India Institute of Medical Sciences, New Delhi, New Delhi, India, (5)Child Neurology Division, Department of Pediatrics, All India Institute of Medical Sciences, New Delhi, New Delhi, India, (6)Pediatrics, All India Institute of medical sciences, New Delhi, India, NEW DELHI, India, (7)Department of Biostatistics, All India Institute of Medical Sciences, New Delhi, India

Background: Although the cause of ASD is not well-known, pre-and postnatal damage, nutrition, genetic, environmental, and immunological factors are reported to play a role in its pathophysiology. Gluten-free casein-free diet (GFCF) is an elimination diet and is frequently administered in ASD. It is speculated to work through gut-brain theory and attenuation of the effect of peptides on neurochemical circuitry. Various studies have shown beneficial effects of GFCF diet on behavioral profile of children with ASD but sufficient evidence is still lacking.
Objectives: To evaluate the efficacy of add-on GFCF diet compared to standard treatment in improving the core symptoms of Autism Spectrum Disorder

Methods: Children aged 3-12 years fulfilling DSM V criteria for ASD with normal hearing and who were on standard treatment for <12 weeks were screened. This is a single-blind, randomized placebo-controlled trial. Control group constituted children with a similar profile who were on standard treatment. GFCF diet was given for 12 weeks after baseline laboratory investigations. Outcome was assessed on the basis of Childhood Autism Rating Scale (CARS) and Autism Behavior Checklist (ABC) at 24 weeks. fMRI Brain was done in a subset of children of both the groups (Dietary group:11; Control group: 6). This is an ongoing study with proposed sample size of 50 children in each group. We are presenting the interim analysis of our study results.

Results: Total of 33 children in each group were analysed, 45% were <5 years and 55% were ≥5 years of age; 86% males and 14% females. Two children in the diet group were anemic (Hb<10g%), rest laboratory parameters were within normal range. The average weight at baseline in the diet and control group was 20 kg (11-67.5) and 16 kg (10-40) respectively. At 24 weeks, average weight in diet and control group was 22.5 kg (14-67) and 17 kg (12-40) respectively, showing an average increase of 2.5 kg in the diet group. The baseline mean CARS and ABC in the diet group was 35.6(3.5) and 77.6(12.9) whereas in the control group it was 35.22(3.9) and 80.06(11.6) respectively. 39.3% (13/33) in the diet and 30.3% (10/33) children in the control group had severe autism (CARS≥37) at baseline. At 24 weeks, average improvement in CARS and ABC score in the diet group was 2.5 (0.5-11) and 8.5 (2-44); and in the control group was 0.5 (0-3) and 3(1-28) respectively; showing significance [P<0.01] in both the scores. All the children (100%) with severe autism were graded in mild-moderate range at 24 weeks follow up in the diet group. Complete remission (CARS=27) was seen in one child in the diet group. No side effects were seen on GFCF diet.

Conclusions: The study shows promising results of gluten and casein elimination from diet in children with ASD showing significant improvement in behavioural profile.

438.371 (Poster) Effects of Creative or General Movement Interventions on Fine-Motor, Gross-Motor, and Functional Skills of Children with ASD

C. Cleffi, W. C. Su, S. Srinivasan and A. N. Bhat, (1)Physical Therapy, University of Delaware, Newark, DE, (2)Physical Therapy, National Institute of Health, Newark, DE, (3)Kinesiology, University of Connecticut, Storrs, CT, (4)Department of Physical Therapy, University of Delaware, Newark, DE

Background:

Recently, we reported that 87% of school-age children with Autism Spectrum Disorder (ASD) are at risk for motor coordination impairments (Bhat, 2020; Bhat et al., 2022). Our past studies showed that rhythmic movement and yoga-based interventions led to generalized and task-specific improvements in gross-motor performance (Srinivasan et al., 2015; Kaur et al., 2019).

Objectives:

The present study extends this work to compare the effects of a Creative Movement (CM) intervention combining music, dance, and yoga and a General Movement (GM) intervention using exercise and games (but no music and movement synchrony) to those of a standard-of-care, sedentary play (SP) intervention using building and art-craft, on the fine- and gross-motor coordination and functional endurance of children with ASD.

Methods:

45 children with ASD between 6 and 14 years participated in a pilot randomized controlled trial (RCT) over 10 weeks with pretests and posttests conducted during the first and tenth weeks. Children were matched on age, gender, and level of functioning and then randomly assigned to either CM, GM, or SP groups. Each child received 8 weeks of training @ 2 sessions/week. The CM group engaged in whole-body, music, dance, and yoga-based activities promoting interpersonal synchrony and multi-limb coordination skills. The GM group engaged in physical activities promoting upper/lower-limb strength and locomotor skills. The SP group engaged in tabletop activities such as reading, building, and arts-crafts to promote social interactions and fine motor skills. The Bruininks-Oseretsky Test of Motor Proficiency (BOT-2), the Test of Gross-motor development (TGMD), and the 2-minute-walk test were administered at pre- and post-tests. We also coded training-specific changes in motor coordination (unilateral, dual-limb, and multi-limb coordination) across early and late training sessions. We will also report baseline factors associated with/predictive of improvements in gross and fine motor skills post-intervention within each group.

Results:

Compared to the pretest, the CM and GM groups improved their BOT-2 body coordination (BC) and strength and agility (SA) composite scores following training (*ps < 0.05). In contrast, the SP group showed no improvements in their gross-motor composite scores (neither
Conclusions:

This study highlights the value of CM and GM interventions in promoting gross-motor coordination and endurance skills in children with ASD. Occupational therapists and physical therapists working with children with ASD can use CM and GM approaches to target their clients’ motor coordination and endurance skills. This work will provide support for the inclusion of whole-body movement experiences in the standard of care treatment for ASD.

438.372 (Poster) Effects of Creative or General Movement Interventions on Executive Functioning and Negative Behaviors of Children with Autism Spectrum Disorder (ASD)
W. C. Su1, C. Cleffi2, S. Srinivasan3 and A. N. Bhat4, (1)Physical Therapy, National Institute of Health, Newark, DE, (2)Physical Therapy, University of Delaware, Newark, DE, (3)Kinesiology, University of Connecticut, Storrs, CT, (4)Department of Physical Therapy, University of Delaware, Newark, DE

Background:

Children with Autism Spectrum Disorder (ASD) present with executive functioning (EF) challenges and also engage in repetitive behaviors. Repetitive behaviors such as sensori-motor stereotypies and negative behaviors (NBs) are known to be associated with children’s EF skills. Previous studies have reported positive effects of movement interventions on EF skills of individuals with and without ASD. In this pilot randomized controlled trial (RCT), we compared the effects of Creative Movement (CM, using music and synchronous movement), General Movement (GM, focusing on training strength and locomotor skills), and Sedentary Play (SP, standard-of-care training using building and art-craft activities) interventions on EF and NBs in children with ASD.

Objectives:

We compare the effects of CM, GM, and SP interventions on EF skills of children with ASD and investigate the relationships between EF skills and rates of NBs at baseline and post-intervention. We will also examine baseline factors associated with improvements in EF skills and NBs within each group following the training period.

Methods:

Forty-five children with ASD between 6 and 14 years were recruited and randomly assigned to the CM, GM, or SP groups. Children in all three groups received 16 training sessions (2 sessions/week), over 8 weeks. The CM group engaged in whole-body movements using music, dance, and yoga to promote interpersonal synchrony, imitation, coordination, and balance; the GM group engaged in physical activity that focused on upper/lower-limb strength and locomotor skills; the SP group engaged in tabletop activities such as reading, building, and art-craft to promote social interactions and fine-motor skills. Each child completed the Flanker task assessing inhibitory control (i.e., response accuracy and reaction time (RT) during congruent (CONG) and incongruent (INCONG) conditions) before and after the intervention. We also coded children’s rates of NBs during an early and a late training session. Within- and between-group t-tests were conducted to study intervention effects on EF and NBs. Exploratory correlational & regression analyses will be conducted to identify baseline factors (e.g., adaptive functioning, autism severity levels, motor performance) predictive of training-related improvements.

Results:

Children with better EF (i.e., shorter RT) at baseline had fewer NBs during training (RT during CONG: r = 0.43, RT during INCONG: r = 0.30). Both movement groups (CM and GM) showed training-related improvements in EF and were pooled for further analyses. Movement groups showed similar response accuracy but reduced RT during CONG and INCONG conditions post-intervention (*ps < 0.05), with no such improvements in the SP group (p > 0.05). Intervention-related reduction in RT was greater in the movement groups compared to the SP group (*ps< 0.05). Further correlational/regression analyses to identify factors predictive of training-related improvements are presently underway.

Conclusions:
Our findings replicate past research in this area and support the use of movement interventions (CM or GM) to promote EF skills and regulate NBs among children with ASD. Clinicians should consider adding whole-body movement interventions to the standard-of-care treatment for children with ASD.

438.373 (Poster) Mate Selection for Quantitative Autistic Traits and Implications for Current Trends in the Prevalence of Autism

N. Marrus, J. N. Constantino, Y. Zhang and E. Forsen, (1)Washington University in St. Louis, St. Louis, MO, (2)Children’s Hospital of Atlanta, Atlanta, GA, (3)Washington University School of Medicine, St. Louis, MO, (4)Carolina Institute for Developmental Disabilities, Washington University School of Medicine, Chapel Hill, NC

Background: Autism spectrum disorder (ASD) prevalence has continued to rise in the US over several decades (Maenner et al., 2021), including among minority Hispanic children, for whom prevalence is now starting to outpace that of the non-Hispanic white (NHW) population (Shaw et al., 2021). These trends pose the question of whether enhanced awareness and broadened diagnostic criteria fully account for this ongoing increase. Mate selection based on inheritable trait similarity is one factor that can increase the proportion of offspring with traits at higher and lower phenotypic extremes. While ASD is a categorical diagnosis, subthreshold quantitative autistic traits (QATs) exist in a continuum across the general population, are highly inheritable, and share genetic factors with ASD diagnosis. Assortative mating based on QATs, manifested by higher-than-expected spousal QAT correlations, has been repeatedly documented in prior general population cohorts and in parents of children with ASD, where spousal QAT intraclass correlations (ICC) have been on the order of 0.39 (Constantino et al., 2005; Virkud et al., 2009), with the highest ICC (ICC=0.60) observed in a sample of Hispanic spousal pairs of children with ASD (Page et al., 2016). Further, in a separate large epidemiologic cohort, parental pairings in the upper quintile for QATs were associated with twice the rate of ASD among offspring (Lyall et al., 2014), supporting an association between assortative mating and clinically significant aggregation of inherited ASD liability in offspring.

Objectives: To leverage two contemporary, simultaneously-ascertained epidemiologic cohorts of parents in Missouri and California to provide updated information on the degree to which spousal pairs exhibit correlations in autism-related trait variation in Hispanic (California) and non-Hispanic (Missouri) US populations.

Methods: QAT data on parents of epidemiologically ascertained toddler twins were collected as part of the Early Reciprocal Social Behavior Study (HD068479) in Missouri and California. Birth records identified all twin pairs born between 2011-2013 in these states. Parents were randomly selected for recruitment from pools of self-identified English-speaking Hispanic families in California and NHW families in Missouri. Parental QATs were measured using the Social Responsiveness Scale-2 (SRS-2), with mothers reporting on fathers and fathers reporting on mothers. ICCs quantified the strength of QAT relationships between spousal pairs.

Results: Ninety-five Missouri spousal pairs and 93 California spousal pairs completed the cross-informant-report SRS-2. There were no documented demographic differences in parents across states except for higher maternal education in the Missouri cohort. Mean SRS-2 scores did not significantly differ between California and Missouri mothers (CA=28.7 (17.1), MO=25.7 (18.5), p=.25), while California fathers showed significantly increased mean SRS-2 scores, signifying higher QATs compared to Missouri fathers (CA=26.6 (18.4), MO=19.6 (15.6), p=.005). ICCs for QATs were equal to 0.43 and 0.44 among spousal pairs in California and Missouri, respectively (see scatterplot in Figure 1).

Conclusions: These data provide strong confirmatory evidence of the persistence of mate selection for QATs in two contemporary, epidemiologically-sampled US subpopulations. Overall, findings suggest that quantifying and tracking spousal correlations across time may capture important underlying features of transgenerational mechanisms contributing to changes in ASD prevalence.

438.374 (Poster) Relationships of Joint Attention to Cognitive and Adaptive Functioning Scores in African American Toddlers with ASD

A. Abbacchi, K. Lineback, Y. Zhang, R. Pope, J. Love, C. Klaiman, S. P. White, S. Molholm, A. Klin, J. N. Constantino, D. Geschwind and N. Marrus, (1)Washington University School of Medicine, St. Louis, MO, (2)Semel Institute, University of California, Los Angeles, Los Angeles, CA, (3)Emory University, Atlanta, GA, (4)Marcus Autism Center, Emory University, Atlanta, GA, (5)99 Reade St., Bronx, NY, (6)Marcus Autism Center, Emory University School of Medicine and Children’s Healthcare of Atlanta, Atlanta, GA, (7)Children’s Hospital of Atlanta, Atlanta, GA, (8)Washington University in St. Louis, St. Louis, MO

Background: Epidemiological studies have highlighted disparities in clinical care for autism spectrum disorder (ASD) among Non-Hispanic black children, with findings including delays in identification and services, as well as twice the likelihood of comorbid intellectual disability (ID) versus Non-Hispanic white children (Constantino et al., 2020; Maner et al., 2021). Characterizing associations between early-emerging aspects of core ASD features and cognition as well as adaptive function could inform assessment and treatment planning in this underserved population. Joint attention (JA), the coordination of attention between individuals, represents a compelling candidate to explore, given its role in social communication and previously documented relationships with cognition and adaptive function (Klin et al., 2002; Mundy et al., 2017).

Objectives: To examine the relationship of joint attention to cognitive and adaptive functioning scores in African American (AA) toddlers with ASD.
Results: Baseline JA impairment was inversely correlated with VABS-3 ABC (r_{baseline} = -.51, r_{follow-up} = -.43, p < .001) and MSEL ELC (r_{baseline} = -.48, r_{follow-up} = -.43, p < .001). Regression models (Table 2) showed that JA scores contributed 19% of the variance to concurrent MSEL ELC cognitive scores when accounting for ASD severity and 3% of VABS-3 ABC when accounting for ASD severity and cognition. Baseline JA contributed 12.2% of the variance in follow-up MSEL ELC when accounting for ASD severity. While baseline JA accounted for 12.3% of variance in follow-up VABS-3 ABC as a sole predictor, the relationship was not significant after accounting for ASD severity and cognition.

Conclusions: Joint attention showed specific relationships, over and above ASD severity, to concurrent cognition and adaptive function at baseline, as well as cognition at follow-up. These findings suggest that further delineation of the relationships between core features of ASD and cognitive outcomes during toddlerhood, a high-impact period for intervention, could enhance identification of actionable assessment and intervention targets and address disparities in clinical management of ASD and associated comorbidity in the AA population.

438.375 (Poster) “It’s Definitely Better Than Not Having Anything”: Autistic Children’s Lived Experiences with Online and in-Person Delivery of Kontakt® Social Skills Group during the COVID-19 Global Pandemic

B. Afshtarnejad, M. H. Black, T. Alach, A. Fridell, C. Coco, M. Johnson, S. Bolte and S. J. Girdler, (1)School of Allied Health, Curtin University, Bentley, Western Australia, Australia, (2)Center for Neurodevelopmental Disorders & Center for Psychiatry Research, Dept. of Women’s and Children’s Health, Karolinska Institutet, Stockholm, WA, Sweden, (3)Cooperative Research Centre for Living with Autism (Autism CRC), Long Pocket, Brisbane, Australia, (4)CAP Research Center, Department of Women’s and Children’s Health, Karolinska Institutet, Center for Neurodevelopmental Disorders at Karolinska Institutet (KIND), Stockholm, Sweden, (5)Department of Women’s and Children’s Health, KIND Karolinska Institutet Center of Neurodevelopmental Disorders, Stockholm, Sweden, (6)Autism Association of Western Australia, Shenton Park, Western Australia, Australia, (7)Center for Neurodevelopmental Disorders at Karolinska Institutet (KIND), Department of Women’s and Children’s Health, Karolinska Institutet, Stockholm, Sweden, (8)School of Allied Health, Curtin University, Bentley, Western Australia, Australia

Background: While internationally, there is interest in the potential benefits of delivering interventions via online platforms, telehealth is particularly relevant in Australia, where great distances impact access to services for more than a quarter of the population. The onset of the COVID-19 pandemic further heightened interest in these approaches. While emerging evidence suggests that online interventions for autistic children are equivalent to or even better than in-person services, research findings have been obtained predominantly from programs delivered to caregivers, parent-child dyads, teachers or care staff. Further, the few studies exploring the effect of online interventions for autistic children have been short (with sessions lasting for 10 minutes) and delivered to small groups of 2-3 children supervised by a parent. The present study emerged from a feasibility evaluation of the manualised 16-session KONTAKT®, a social skills group program (SSGP) developed for in-person delivery to autistic children aged 8 to 12 years. The onset of the COVID-19 lockdown coincided with the seventh session of KONTAKT®, necessitating that the final 9 sessions be delivered online, providing a unique opportunity to examine autistic children, their parents and the group trainers’ experiences and preferences when attending an SSGP.

Objectives: This study aimed to understand the lived experiences of autistic children, their parents and KONTAKT® trainers with the content and delivery mode of the program.

Methods: This focus group study was conducted with nine autistic children aged 8 to 12 years (M=10.87, SD=1.04; 67% male) participating in sixteen 60-minute KONTAKT® sessions, their parents and KONTAKT®. In response to the onset of COVID, the research teams adapted the program to online delivery. Children were advised to attend the sessions (delivered via Zoom) in a distraction-free space while wearing headphones for confidentiality purposes. After completing KONTAKT®, stakeholders’ experiences were collected via focus group, and data were analysed using thematic analysis.

Results: Thematic analysis findings revealed that regardless of the delivery format, participants were satisfied with KONTAKT®, expressing that “We had a lot of fun, especially when we all got to be there”, comparing their group members to “a family that doesn’t fight.” Four themes emerged from this study. Experience with the Structure and Content of the program, including recommendations on how KONTAKT® could be further modified to meet the participants’ needs. Group Context informed the stakeholders’ opinions about how COVID-19, trainer’s flexibility and having autistic peers as groupmates had affected their perception of the program. Online Delivery

267
Conclusions: Findings indicated that regardless of stakeholders’ satisfaction with the SSGP, the in-person delivery is still perceived as more acceptable and beneficial. Future research would benefit from a child-centric randomised controlled trial comparing the two delivery formats, providing evidence for the efficacy of the telehealth-delivered interventions for autistic children.

438.376 (Poster) ‘I Had a Dream ...’ Coproducing and Re-Imagining Shakespeare’s Midsummer Night Dream from a Neurodiverse Perspective

S. Figueiredo1,2, B. Afsharnejad1,3, D. Dye, V. Berg, B. Phillips1 and S. J. Girdler1,4,7,8, (1)Curtin Autism Research Group, Curtin University and Autism CRC, Bentley, Western Australia, Australia, (2)Curtin Medical School, Curtin University, Bentley, Western Australia, Australia, (3)School of Allied Health, School of Allied Health, Curtin University, Bentley, Western Australia, Australia, (4)Cooperative Research Centre for Living with Autism (Autism CRC), Brisbane, QLD, Australia, (5)Curtin Autism Research Group, Curtin University, Bentley, Western Australia, Australia, (6)Edith Cowan University, Perth, Western Australia, Australia, (7)School of Allied Health, University of Western Australia, Crawley, Western Australia, Australia, (8)School of Allied Health, Curtin University, Bentley, Western Australia, Australia, (9)Karolinska Institutet, Stockholm, Sweden

Background: While there is a large body of evidence examining the efficacy of social skills programs employing explicit strategies in teaching social skills to autistic youth in clinical settings, a more limited body of research has examined the role of implicit programs employing theatre in community-based settings. These approaches also align with the neurodiversity paradigm which has been a catalyst in shifting the focus of autism research from a deficit-focused model to a strength-based one. The neurodiversity paradigm highlights the importance of empowering autistic individuals by incorporating their views and values in support programs and interventions. Theatre-based programs (TBP) are social group programs delivered in an informal, community setting utilising implicit teaching strategies such as role-playing a character from a play and improvisational games. These programs aim to improve social skills through providing opportunities for socialising, shared learning, and opportunities for building social confidence through performing.

Objectives: This realist evaluation study aimed to identify the active ingredients (context, mechanisms, and outcomes) of TBP, ‘Reimagining Shakespeare’s Midsummer Night’s Dream’.

Methods: Participants were recruited for this realist evaluation using convenience sampling. Seven autistic adults aged between 17 to 49 years (M = 28 years, SD = 10.9; 71% female) participated in the 24-session TBP. Three facilitators delivered the program through three phases: theatre games (ten 2-hour sessions), scriptwriting (ten 5.5-hours sessions) and four 8-hour acting and stage production rehearsal sessions. The program culminated in a community performance of a reimagined ‘Midsummer Night’s Dream’ from a neurodiverse perspective. Three facilitators lead and supported the sessions. Data was obtained through participant observations and separate interviews at the end of each phase with autistic youth and facilitators. The semi-structured audio-recorded interviews were conducted online (via google meet). The recordings were then transcribed verbatim and analysed in NVivo following the realist evaluation approach (context-mechanism-outcome framework).

Results: Findings revealed six themes relating to the context (attitudes towards neurodivergence, context, facilitators, familiarity within the group, perceptions of Shakespeare’s work, previous experience with art), nine relating to the mechanisms (acceptance of neurodiversity, accommodating for disability, group dynamics, having a choice, predefined roles, passions and interests, seeking and receiving support, sharing ideas and sharing interests), and six relating to the outcomes (creation of an inclusive play from a neurodiverse perspective, increased skills and learning new ones, interest in future drama programs, making new friends, sense of achievement, sense of belonging) of the program.

Conclusions: Findings of the current study highlighted the importance of understanding the mechanisms that influence the outcomes for autistic individuals when attending a TBP. Notably, the results also contributed to defining a strength-based approach for coproducing a TBP, adding to the current body of knowledge. This study also highlighted the utility of plays, and specifically Shakespeare, as a platform supporting autistic youth in developing their social skills in a fun, community-based and age-appropriate setting. Future research would benefit from assessing the efficacy of such programs via randomised control trials.

438.377 (Poster) Objective Measurement of Inclusive Preschool Classroom Social Networks: Effects of Sex and Developmental Delays and Disabilities

R. M. Fasano1, L. Vitale1, D. S. Messinger2 and L. K. Perry1, (1)Psychology, University of Miami, Coral Gables, FL, (2)University of Miami, Coral Gables, FL

Background: Developmental disabilities/delays (DD), particularly autism spectrum disorder (ASD), are often characterized by deficits in communication and interaction, and are more prevalent in boys than girls. Much previous research on DD, including research on real-world contexts like preschool classrooms, has focused on boys and not addressed how girls and boys with DD may differ in their interactions with
peers. Overall, children’s language abilities are positively associated with their centrality to peer networks; however, it remains unknown if this is equally important for boys and girls with and without DD.

Objectives: Use automated measures to create preschool social networks and objectively measure how girls and boys with DD differ from each other and their typically developing (TD) peers in their social interactions. We also explore the extent to which language abilities are predictive of the social interactions of girls and boys with and without DD.

Methods: Participants included 77 children (DD=47 [ASD (5 girls, 19 boys) grouped with developmental delay (7 girls, 16 boys)] and TD=30 [20 girls, 10 boys]). During monthly observations, children wore vests equipped with LENA recorders to measure vocalizations and two Ubisense tags to measure location/orientation. Ubisense measures of proximity/orientation were used to determine social contact, and synchronized to LENA data to assess each child’s social language output to peers and input from peers. Children’s language abilities were assessed by the Preschool Language Scales (PLS-5). Data were aggregated to create classroom social networks based on the frequency of dyadic language-mediated interactions (Figure 1). Social network analysis yielded measures of modularity, or cohesiveness of groups (i.e., DD/TD) within the class, and each child’s degree centrality, or the social ties children have to their peers based on their rate of co-talk, which is the sum of the rates of language input from and output to peers (in hours). We also assessed how children’s PLS-5 scores were associated with their interactions and role in the classroom network.

Results: Data have been collected for an additional 52 participants (DD=39 [ASD (3 girls, 8 boys), developmental delay (17 girls, 11 boys)] and TD=13 [7 girls, 6 boys]) to be included in final analyses. Preliminary findings indicated the TD group had higher modularity than the DD group (p=.049). Follow-up pairwise comparisons revealed TD girls had the highest within-group modularity, which was significantly higher than DD boys’ modularity (p<.02). TD children were more central to classroom networks than children with DD (p=.01), indicating that TD children produced more vocal output and received more input from peers than children with DD, but there was no significant interaction between sex and group. However, there was a significant interaction between TD boys and PLS-5 scores (p=.01) in predicting centrality, suggesting that language abilities may be an especially important factor in supporting co-talk for boys (Figure 2).

Conclusions: Objective measurement provides a clearer understanding of children’s vocal interactions, indicating that both group and sex are crucial components of classroom network formation. These findings suggest that sex is a crucial factor in designing and implementing interventions in inclusion classrooms.

**438.378 (Poster) Objective Measurement of Social Approach: A Scaffold for Intervention in Inclusion Classrooms**

C. Banarjee, Y. Tao, R. M. Fasano, C. Song, L. Vitale, L. K. Perry and D. S. Messinger, (1)University of Central Florida School of Medicine, Orlando, FL, (2)University of Miami, Miami, FL, (3)Psychology, University of Miami, Coral Gables, FL, (4)University of Miami, Coral Gables, FL

Background: After 3 years of age, inclusion classrooms, in which children with developmental disabilities (DD) are educated alongside typically developing (TD) children, are a best practice intervention context for children with disabilities, particularly children with autism spectrum disorder (ASD). Children with ASD have lower quality social interaction than their typically developing peers (Lord & Magill-Evans, 1995). Although teachers play an important role in facilitating evidence-based practices to support peer interactions, social interactions between children with ASD and their TD peers may be more likely to take place in the absence of adults (Hume et al., 2019). Physical movement supports social interaction in the classroom, which is frequently facilitated when partners and in proximity to one another. Yet we have little objective data on how children with ASD approach and are approached by their teachers and peers.

Objectives: Utilize automated measurements of velocity to quantify child-teacher social approach and peer-peer social approach in children with ASD, DD, and TD.

Methods: 77 children (M=48.26 months, SD=7.47), including 24 children with ASD, 23 children with DD (unspecified), and 30 TD children, and 12 teachers were observed in 8 inclusion preschool classrooms. All classrooms contained TD children and children with ASD. Four classrooms contained children with DD. Children were observed on 3.52 mean occasions (SD=1.32) for a mean duration of 138.2 minutes per occasion (SD=63.6). Objective measurements of position and orientation were collected using ultra-wide radio frequency identification (Ubisense) sensors, which tracked a right and left tag worn by each individual in a specially-designed vest (a fanny pack for teachers). Social approach was measured continuously as the distance each individual moved toward the initial position of each partner, weighted by distance, orientation, and angle of movement. Higher weight was given to more direct approaches occurring over closer distances.

Results: Children with ASD (p < 0.001) approached teachers at higher velocities than their TD peers, and were approached by teachers at higher velocities than their TD peers (p < 0.001, see Figure 1). Children with DD did not approach their teachers at higher velocities than their TD peers (p = 0.057), nor were they approached by their teachers at higher velocities to their TD peers (p = 0.125). Within peers, children with ASD (p = 0.063) and DD (p = 0.609) did not differ from TD children in the velocity with which they approached other children (see Figure 2). However, children with ASD (p = 0.001) were approached by other children at lower velocities than TD children.
Conclusions: Multi-hour, objective measurements in preschool inclusion classrooms indicated that children with ASD approached their teachers and were approached by their teachers more quickly than DD and TD children. This suggests that children with ASD require and receive more interaction from their teachers than TD children. By contrast, children with ASD were slower to be approached by other children, suggesting a deficit in peer interaction. The results suggest the need for interventions in inclusion classrooms that target the peer interactions of children with ASD.

**Communication and Language**

### PANEL DISCUSSION — COMMUNICATION AND LANGUAGE

#### 211 - Multisensory Perception in Autism: Crucial to Language, Promising for Improvement

**Panel Chair:** Robert Jertberg, Vrije Universiteit Amsterdam, Amsterdam, Netherlands

Integrating information from different sensory modalities allows the brain to make sense of a constant barrage of diverse inputs by recognizing similarities across domains. This is essential to basic perceptual processes like detection and recognition of stimuli, but also to more complex features like speech. Mounting evidence linking impairment in multisensory integration (MSI) to language deficits in children with autism spectrum disorders (ASD) highlights it as a potential target for interventions meant to ameliorate the associated communicative and social issues. Promisingly, our research falls in line with a burgeoning body of evidence suggesting that the impoverished MSI seen in children with autism may be resolved by adulthood. This discussion will synthesize findings from psychology and neuroscience underlining the importance of MSI to speech and the promise it holds for improvement in ASD. It will also emphasize the significance of studying ASD in adults as well as children so as to understand how symptoms develop over time and identify propitious targets for interventions. Given the profound and pervasive deleterious effects of language deficits, and the room for growth in MSI, it is a prime candidate, and early interventions that expedite the process could provide cascading positive effects for individuals with autism.

#### 211.001 (Panel Discussion) Behavioral and Neural Indices of Multisensory Processing in Autism: A Developmental Perspective

*S. Molholm* and *J. J. Foxe*, (1)99 Reade St., Bronx, NY, (2)The Ernest J. Del Monte Institute for Neuroscience, University of Rochester Medical Center, Rochester, NY

**Background:** Redundant and complementary multisensory cues are well-known to enhance perception, improving processes such as object detection, localization, and identification. There is significant empirical support that multisensory processing is reduced in children with autism. However, evidence for impaired multisensory processing in autistic adults is less compelling. This suggests that multisensory processing “improves” over the course of development in autism.

**Objectives:** Here we sought to characterize the developmental course of multisensory processing in autism.

**Methods:** Using a cross-sectional approach, we characterized multisensory processing in children and adults (N=364) with and without a diagnosis of autism. Reaction times and electrophysiological (EEG) data were recorded while participants performed a simple reaction time task in response to auditory, visual, and audio-visual stimuli.

**Results:** Using simple, non-social audiovisual stimuli we found that deficits in multisensory processing were observed in high-functioning autistic children and teenagers but not in adults with the condition. Computational modelling was consistent with multisensory processing transitioning from a default state of competition to one of facilitation, over the typical course of development, and a delay in this transition in autism.

**Conclusions:** Impaired multisensory processing in autistic children but not autistic adults suggests that there may be a recovery of multisensory function in autism over the course of development. We consider the need to develop effective interventions so that this “recovery” can be shifted earlier in the developmental trajectory, such that multisensory functions are available at developmentally appropriate stages of development (e.g., for various language and communication competencies), to facilitate the emergence of functions typically impaired in this population.

#### 211.002 (Panel Discussion) The Special Role of Multisensory Integration in Speech Perception in Autism

*J. J. Foxe*, L. A. Ross and S. Molholm, (1)The Ernest J. Del Monte Institute for Neuroscience, University of Rochester Medical Center, Rochester, NY, (2)Neuroscience, University of Rochester, Rochester, NY, (3)99 Reade St., Bronx, NY

**Background:** In face-to-face communication, such as simple conversations, we perceive what speakers are saying not only through our auditory (hearing) but also our visual (seeing) system. Seeing a speaker's facial movements can increase our understanding substantially, especially in noisy conditions, and is vital in understanding speaker intentions, emotions and motivations. This “multisensory
enhancement” is an important aspect of social communication and we have shown that this ability is greatly impaired in individuals on the autism spectrum (Foxe, et al., 2015). Interestingly, we also found that this deficit ameliorates over time which indicates that it can be subject to therapeutic intervention.

Objectives: One important question that arises from these findings is what part of the network of brain regions involved in multisensory speech perception gives rise to this deficit. Is there impairment in regions known to integrate sounds and visual signals such as the posterior superior temporal sulcus (pSTS) or at other, perhaps earlier stages in the visual system such as areas that process natural (biological) motion? To answer these questions, we needed to understand the network of brain regions involved in multisensory speech perception first.

Methods: For this, using functional magnetic resonance imaging (fMRI) we recorded brain activity from a sample of 53 neurotypical adults while observing a recording of an actress telling the story “The Lorax” by Dr. Seuss. The story was presented in auditory only (no facial articulation), visual only (no sound) and audiovisual (both sound and facial articulation) conditions. We compared the resulting brain activity between our multisensory and unisensory conditions to identify brain regions showing multisensory gain where brain activity to the multisensory condition was larger than in both unisensory conditions.

Results: We found multisensory enhancement in brain regions associated with speech and language perception, multisensory integration (pSTS), emotion (amygdala) and along the early sensory pathways in the thalamus (Ross et al., 2022). This network was considerably more extensive than previously shown. We conducted the same study in children and teenagers with ASD and compared them to a TD sample of the same age. Both groups showed largely similar brain responses to the unisensory and multisensory presentations of the story. However, when comparing the magnitude of multisensory enhancement, we found that ASD children showed significantly less pronounced enhancement than their neurotypical peers. These differences were located in brain regions associated with multisensory integration and semantic processing. We also compared a group of adults on the Autism Spectrum with a neurotypical control sample. We found that the differences between groups were not as pronounced in adults as in our young samples and were located in similar regions. These findings suggest that multisensory enhancement in brain activity as measured by fMRI might change over age in Autism Spectrum Disorder mirroring our previous behavioral findings. This development unfolds in regions along the superior temporal sulcus that are well known to be associated with multisensory integration and semantic processing.

Conclusions: Multisensory speech integration processes may be a major contributor to social communication deficits in multi-speaker and noisy environments in ASD.

211.003 (Panel Discussion) Temporal Dynamics of the McGurk/Macdonald Effect in Adults with and without Autism

R. Jertberg, B. Chakrabarti, S. Begeer, H. M. Geurts and E. van der Burg, (1)Vrije Universiteit Amsterdam, Amsterdam, Netherlands, (2)Centre for Autism, University of Reading, Reading, UNITED KINGDOM, (3)Clinical Developmental Psychology, Amsterdam, Netherlands, (4)University of Amsterdam, Amsterdam, Netherlands, (5)Universiteit van Amsterdam, Amsterdam, Netherlands

Background:

In autism spectrum disorders (ASD), impairments of both temporal processing and multisensory integration (MSI) have been thoroughly established among children, and are thought to be crucial to broader symptomatology, particularly with regard to speech processing. At the intersection of MSI and speech perception lies the McGurk effect, wherein presentation of incongruent phonemes and visemes leads to an illusory percept that lies somewhere in between them. This is considered a hallmark of MSI, and is indeed found significantly less often in children with autism. However, McGurk findings with adult ASD samples are quite mixed, and often suffer from poorly controlled methodology and small sample sizes. Additionally, the role of temporal dynamics in governing the effect, and how their influence might differ between adults with and without autism, is poorly understood, and could speak to the nature of multisensory temporal processing in ASD.

Objectives:

To address these shortcomings, we have recruited the largest sample to date of autistic adults and neurotypical controls, and provided a uniquely controlled version of the McGurk task, with the goal of determining whether the differences seen in children in both the propensity to integrate auditory and visual speech stimuli and precision of temporal processing persist into adulthood.

Methods:

Autistic and neurotypical participants (numbering over 300) were both presented with videos and corresponding audio of congruent (ga/ga) or incongruent (ba/ga) phonemes and visemes. Stimulus onset asynchrony of the stimuli was manipulated so that the audio was either simultaneous with the video, or led/followed it by 250 or 500 milliseconds. Participants were asked first to respond to whether they heard a ga, ba or da (McGurk fusion) pronounced, and then to make a simultaneity judgment on whether the video and audio were synchronized.

Results:
The reduced susceptibility to the McGurk effect and impairments in temporal processing found in children with autism were not replicated with our large sample of adults. Additionally, in a novel finding, for both autistic and neurotypical participants, the incongruence of the audio/visual streams led to a profound interference in simultaneity judgments, one that applied even when the illusion was perceived.

Conclusions:

Our findings resonate with the burgeoning body of research suggesting that the MSI deficits evident in children with autism are resolved by adulthood. This is very promising, as it suggests that a key deficit associated with speech perception and the related social factors may be subject to an improvement that might be facilitated via early interventions. Additionally, our novel findings with regard to the manner in which incongruence between audio and visual streams can produce a massive interference in simultaneity judgments (and the illusion can occur despite recognition of asynchrony) challenge the notion that perceived synchrony of the sensory streams is an immutable foundation upon which their interactions are built. Together, these findings have profound implications both clinically, in terms of our understanding of the development of MSI in ASD, and theoretically, in terms of our understanding of the reciprocal relationship between temporal processing and MSI.

211.004  (Panel Discussion) No Differences between Adults with and without Autism in Audiovisual Synchrony Perception
E. van der Burg, R. F. Weiland, T. J. Polderman, D. Smit and S. Begeer, (1) Universiteit van Amsterdam, Amsterdam, Netherlands, (2) Vrije Universiteit, Amsterdam, Netherlands, (3) Clinical Developmental Psychology, Vrije Universiteit Amsterdam, Amsterdam, Netherlands, (4) Amsterdam Medical Centre, Amsterdam, Netherlands, (5) Clinical Developmental Psychology, Amsterdam, Netherlands

Background: To facilitate multisensory processing, the brain binds multisensory information when presented within a certain maximum time lag (temporal binding window). In addition, and in audiovisual perception specifically, the brain adapts rapidly to asynchronies within a single trial and shifts the point of subjective simultaneity. Both processes, temporal binding and rapid recalibration, have been found to be altered in individuals with an autism spectrum disorder diagnosis.

Objectives: Here, we used a large adult sample (autism spectrum disorder: n = 75, no autism spectrum disorder: n = 85) to replicate these earlier findings.

Methods: In this study, audiovisual stimuli were presented in a random order across a range of stimulus onset asynchronies, and participants indicated whether they were perceived simultaneously. Based on the synchrony distribution, their individual temporal binding window and point of subjective simultaneity were calculated.

Results: Contrary to previous findings, we found that the temporal binding window was not significantly different between both groups. Rapid recalibration was observed for both groups but did not differ significantly between groups. Evidence of an age effect was found which might explain discrepancies to previous studies. In addition, neither temporal binding window nor rapid recalibration was correlated with self-reported autistic symptoms or sensory sensitivity.

Conclusions: We did find that both processes develop over age, and since previous studies tested only young people (children, adolescents, and young adults), and we tested adults from 18 to 55 years, this might explain the different findings.

ORAL SESSION — COMMUNICATION AND LANGUAGE
315 - From Preverbal to Bilingual: Exploring Language Heterogeneity

Moderator: Rhiannon Luyster, Communication Sciences and Disorders, Emerson College, Boston, MA

315.001  (Oral) Highlighting the Importance of Early (pre)Verbal Productions: Language Outcomes of Young Autistic Children
P. Maes, B. Busson and M. Kissine, ACTE — Center of research in Linguistics — ULB Neuroscience, Université libre de Bruxelles, Brussels, Belgium

Background: Studies on predictors of language outcomes in autism usually assess the effects of child characteristics (e.g., cognitive abilities, receptive and expressive language, autism severity) obtained from standardized assessments on subsequent development of verbal skills. However, these traditional predictors may overshadow a lot of variability, especially because of floor effects in children who are minimally verbal at the time of assessment. In a previous study (Maes et al., 2022), 3- to 5-year-old autistic children’s language abilities were described based on their vocal and verbal production during un- and semi-structured adult-child interactions. Using cluster analysis, each preschooler was assigned to one of five subgroups with qualitatively different patterns of vocal production. Based on these patterns of vocal productions, two clusters were identified as being composed of verbal children and the remaining three of minimally verbal children.
Nonverbal Communication Experiences of Autistic Adults: A Qualitative Analysis of Online Discussion Forums

H. Radford, B. Reidinger, S. K. Kapp and A. de Marchena; (1) Psychology, University of Portsmouth, Portsmouth, United Kingdom, (2) The Children's Hospital of Philadelphia, Philadelphia, PA, (3) Department of Psychology, University of Portsmouth, Portsmouth, United Kingdom, (4) A.J. Drexel Autism Institute, Drexel University, Philadelphia, PA

Background: Atypical nonverbal communication is required for a diagnosis of autism at any age (APA, 2013), yet very little is known about how autistic adults use gestures, facial expressions, and other nonverbal behaviours in social interactions (de Marchena et al., 2019; Georgescu et al., 2020). Even less is known about autistic adults’ experiences of using nonverbal communication in interactions; qualitative studies suggest that both internal and external factors affect autistic adults’ communication experiences across contexts (Cummins, Pellicano, & Crane, 2020; Nicolaidis et al., 2015).

Objectives: The objectives of this study were: (1) to understand autistic adults’ experiences of using nonverbal communication in interactions, (2) to understand how nonverbal communication impacts autistic people’s lives, and (3) to understand how autistic adults manage nonverbal communication differences.

Methods: 27 threads from the internet discussion forum wrongplanet.net, all containing dialogue focused on nonverbal communication, were subjected to qualitative analysis. Inductive and deductive coding were used to identify excerpts relevant to miscommunication experiences, communication strengths, and compensatory strategies (Braun & Clarke, 2006). A total of 362 excerpts were coded (kappa = .79). Coded excerpts were then extracted and examined for themes, using member checking.

Results: Major themes included: (1) Cognitive differences resulting in autistic adults requiring more time and energy to manage nonverbal communication in interactions; (2) Miscommunication related to nonverbal communication is mutual; (3) Nonverbal communication differences can negatively impact the lives and wellbeing of autistic adults; and (4) Skills and strategies used by autistic adults to manage nonverbal communication. See Table 1 for illustrative quotations. Some respondents reported avoiding nonverbal communication in favour of preferred, more direct communication strategies such as writing. Many autistic respondents described internalising blame for both miscommunications and negative judgements from others, despite the bilateral nature of communication.

Conclusions: Findings support the ‘double empathy problem’ model that communication breakdowns occur between autistic and non-autistic people yet predominantly impact autistic people (Milton, 2012), applying it to nonverbal communication. Several of our themes, including mutual miscommunication and negative impacts of atypical communication, are consistent with previous qualitative work on communication experiences of autistic adults. The current findings provide new insight into the internal and external factors influencing the nonverbal communication experiences of autistic adults, in particular the cognitive processes involved. We advocate for solutions that shift the responsibility for effective communication onto all members of society, instead of trying to ‘fix’ the autistic person. For example, sharing and accepting preferred communication modalities, and checking in about whether a message was received correctly instead of making assumptions, are two strategies endorsed by respondents.
Investigating the Abandoned End of the Spectrum: Clinical Features of Non-Verbal and Minimally-Verbal Children on the Autism Spectrum

C. Shelton, C. Molfetta, R. Vyas, L. Kam, V. Vought, M. J. Conlan, K. Sidwell, J. Shenouda and W. Zahorodny, (1)Department of Pediatrics, Rutgers--New Jersey Medical School, Newark, NJ, (2)The College of New Jersey, Ewing, NJ, (3)Department of Pediatrics, Rutgers University, Newark, NJ

Background: Despite the increased interest in autism spectrum disorder (ASD) research over the past three decades, limited research about non-verbal (NV) and minimally verbal (MV) children with ASD is available. We previously determined that nearly 1 in 5 children with autism lacked spontaneous and functional language by age 8 years, a significant minority despite early intervention. Due to the pervasive challenges that NV/MV children will face, understanding this population is of particular importance. That said, this is the first population-based study in a large, diverse US metropolitan area to examine the differences in clinical features and ASD-related factors between NV/MV and verbal children with ASD.

Objectives: The main objective of this population-based study was to detect any potential risk factors, and/or behavioral outcomes linked to verbal inability. Clinical factors, such as intellectual ability and ASD impairments, as well as ASD-associated factors, such as aggression, self-injurious behaviors (SIBs), temper tantrums, and low frustration threshold, were included in analyses to examine variation based on these factors.

Methods:

Data were collected from an active ASD surveillance in 2016 representing children born in 2008 and residing in NJ in 2016. Retrospective information on clinical features and verbal ability was collected for each child from medical and special education records.

Verbal ability at or after age 48-months was defined by the following case definitions: verbal, the child can answer and speak in sentences; minimally verbal, the child can speak in 1 and/or 2-word phrases, and non-verbal, the child can produce sounds but not intelligible words.

Pearson Chi-square was used to compare differences between verbal and NV/MV cases. Data was further stratified by clinical factors and ASD-associated features.

Results:

Overall, we identified 188 out of 1055 ASD children as NV/MV (prevalence: 5.7 per 1,000). Of the NV/MV children, 67.6% (n=127) had co-occurring intellectual disability compared to 17.1% (n=139) of verbal ASD children (p<0.0001). Among NV/MV children, 20.21% had mild ASD severity, 40.96% had moderate ASD severity, and 38.83% had severe ASD severity. Among verbal children, 52.65% had mild ASD severity, 31.32% had moderate ASD severity, and 16.03% had severe ASD severity (p<0.0001). NV/MV children were more likely to experience regression in their early developmental milestones than verbal children (22.3% vs 12.3%; p<0.0004).

Overall, NV/MV children had lower frequencies of temper tantrums 53.7% (n=101) and mood abnormalities 66.5% (n=125) compared to verbal children, 61.5% (n=499) and 78.3% (n=635), respectively. Additionally, we found no differences between NV/MV and verbal children when assessing self-injurious behavior and aggression.

Conclusions: NV/MV children with ASD were demonstrated to have a higher degree of ASD severity and intellectual disability than verbal children with autism. This information may be utilized by clinicians to screen and connect children on the spectrum presenting with early language deficits to preventive behavioral and psychological services. Further research from population-based studies with large sample sizes is warranted to understand the risk factors for NV/MV children and develop strategies for interventions as well as addressing health disparities.

Discrepancies in Receptive and Expressive Language Profiles in Minimally Verbal Autistic Children and Adolescents

Y. Chen, B. E. Siles, G. R. Liberti and H. Tager-Flusberg, Department of Psychological and Brain Sciences, Boston University, Boston, MA

Background: Approximately 30% of autistic individuals fail to acquire spoken language and remain minimally verbal (MV) into adulthood (Tager-Flusberg & Kasari, 2013). While a growing body of work focuses on defining MV autism based on expressive language, less is known about their receptive language skills and the proportion for whom receptive language is significantly higher than their expressive language. It is also important to investigate which factors contribute to the potential receptive advantage.

Objectives: To investigate the concurrent predictors of receptive language skills in MV autistic individuals, their receptive-to-expressive language discrepancy, and the predictors of a subgroup of MV autistic individuals with significantly better receptive language skills.
**Methods:** Data were obtained from the National Database for Autism Research (NDAR) and the SFARI Base from the Simons Foundation Autism Research Initiative. 1579 MV autistic individuals (321 Female; $M_{age}$=8.75 years, $SD=3.6$, range=5-18) were included in this study. The inclusion criteria were 1) met the Autism Diagnostic Observation Schedule (ADOS) Module 1 cut-off; 2) had an age-appropriate Vineland Adaptive Behavior Scales (VABS); 3) between 5 and 18 years old. Four empirically selected variables were included as potential predictors of receptive language in MV autistic individuals: nonverbal IQ (NVIQ) from Mullen or the Differential Ability Scales (DAS-II); autism symptom severity represented by the ADOS calibrated severity score; social skills reported by parents on the VABS; and motor skills reported on the Developmental Coordination Disorder Questionnaire (DCDQ). A significant receptive-to-expressive discrepancy was determined using the VABS pairwise-comparison critical values.

**Results:**

Chronological age was significantly correlated with VABS receptive language, $r(1386)=-.386$, $p<.001$, and was controlled for in subsequent analyses. Partial correlations controlling for age showed that NVIQ, autism symptom severity, social skills, and motor skills were all significantly correlated with VABS receptive language, $p<.05$. When considering these variables’ predictive values on VABS receptive language, a significant regression model emerged, $R^2=.44$, $F(5, 224) = 35.38$, $p<.001$. Social skill was the only salient factor predicting receptive language skills concurrently, $\beta=.102$, $p<.001$.

Regarding the receptive-to-expressive language discrepancy, VABS receptive language was significantly higher than expressive language, $t(1379)=39.05$, $p<.001$. Using the VABS pairwise-comparison critical values, 343 MV autistic individuals (24.9%) demonstrated significantly higher receptive than expressive language skills. A logistic regression was performed to investigate the effects of NVIQ, autism symptom severity, social skills, and motor skills on the likelihood that MV autistic individuals had significantly better receptive language or not. A significant model emerged, $\chi^2(5) =58.08$, $p<.001$, $R^2=.31$, and correctly classified 80% of cases. Increasing motor skills on the DCDQ was associated with an increase in the likelihood of better receptive language, odd ratio=1.04, 95% CI [1.01, 1.08], $p = .008$.

**Conclusions:** This study is the first to investigate the receptive-to-expressive language discrepancy in MV autistic individuals. Findings reveal that around 25% of MV autistic individuals demonstrated better receptive than expressive language skills. Social and motor skills contribute significantly to language comprehension in MV autistic individuals. Future interventions should consider targeting these two areas to optimize the outcomes of improving receptive language in MV autistic individuals.

**POSTER SESSION — COMMUNICATION AND LANGUAGE**

**412 - Communication and Language I**

**412.148 (Poster) A Comparison of Speech Entrainment Patterns in Autistic and Neurotypical Adolescents**

_C. J. Wynn, Communication Sciences and Disorders, University of Houston, Houston, TX_

**Background:**

Speech entrainment describes the tendency for interlocutors to modify their speech behaviors (e.g., articulatory precision, fundamental frequency, articulation rate) to more closely align with the behaviors of their conversation partner. In neurotypical individuals, entrainment is predictive of conversational efficiency, conversational quality, and stronger interpersonal relationships (e.g., Borrie et al., 2019; Wynn et al., 2022; Pardo et al., 2012). Entrainment requires a high level of social perception—one must recognize, understand, and adapt to social cues in the communicative behaviors of their conversational partner (Chartrand and Bargh, 1999; Delaherche et al., 2012). Accordingly, deficits in these areas may lead to differences in the entrainment patterns of autistic individuals compared with their neurotypical peers.

**Objectives:**

While a few studies have examined the speech entrainment patterns of autistic adolescents (Patel et al., 2022; Lehnert-LeHouviller et al., 2020), these studies have all focused on conversations in which adolescents spoke with an adult such as a parent or research confederate. Accordingly, information regarding speech entrainment patterns of autistic adolescents in conversations with their peers is currently unknown. Given the importance of conversation in adolescence, and the role of entrainment in conversational outcomes, research in this area is important. The purpose of this study is to examine the differences between the speech entrainment patterns of autistic and neurotypical adolescents in peer-based conversations.

**Methods:**

Currently, we have collected conversations from 51 conversational dyads (with additional data collection ongoing). All participants were adolescents between the ages of 10 and 17 years. Participants spoke English as their primary language and had no reported history of
hearing impairments. Participants were paired-up to form age-matched dyads consisting of either two neurotypical participants or one autistic and one neurotypical participant. Conversations were elicited using the Diapix Task, a task in which dyads must communicate with one another to identify 12 differences between sets of pictures. To analyze data, we use annotated Praat textgrids to extract acoustic-prosodic features representing rhythmic, articulatory, and phonatory aspects of speech. We then calculate scores for entrainment by taking the absolute difference between two speakers acoustic feature values on adjacent turns. Linear mixed models are used to compare differences between autistic and neurotypical speakers’ entrainment scores.

Results:

Data analysis is ongoing and will involve multiple acoustic-prosodic features. Preliminary analysis of articulatory precision showed a significant difference between the entrainment patterns of neurotypical and autistic interlocutors ($b = .21, p = .04$). That is, neurotypical speakers entrained more to their conversation partner than autistic individuals. There was no significant difference between neurotypical speakers in neurotypical-neurotypical and autistic-neurotypical dyads, indicating that neurotypical speakers entrained to a similar degree regardless of the neurotype of their conversation partner.

Conclusions:

Preliminary findings indicate that the entrainment patterns of neurotypical and autistic adolescents differ from one another. Given the role of entrainment in successful conversations (at least in neurotypical populations), these differences may be partially responsible for breakdowns in conversations between neurotypical and autistic adolescents. Future research should examine the relationship between entrainment and conversational outcomes within this population.

412.149 (Poster) A Linguistic Analysis of Autistic and Non-Autistic Adult Women’s Productions: Written Narratives of Emotional Autobiographical Memories

F. Merken and P. Geelhand, (1)ACTE, Université libre de Bruxelles, Brussels, Belgium, (2)ACTE — Center of research in Linguistics — ULB Neuroscience Institute, Université libre de Bruxelles, Brussels, Belgium

Background:

Narrative research has been identified as a great tool in linguistic studies, as it ecologically reveals qualitative and quantitative differences in individuals experiencing communicative difficulties - but who still show good structural language skills (Geelhand et al., 2020; Manolitsi & Botting, 2011). Narrative research within the autistic population has until now included predominantly male samples, but it is nowadays argued that the communicative profile of autistic women might differ from men’s (Sturrock et al., 2020). However, the nature of this ambiguous profile of autistic women is still poorly understood. Moreover, most narrative studies rely on oral tasks; given that autistic adults tend to prefer written or computer-mediated communication (Gillespie-Lynch et al., 2020), it is surprising that the written communication of autistic adults hasn’t been thoroughly investigated yet.

Objectives:

This study aims at offering a better perspective on the specific challenges that autistic women face compared to non-autistic (NA) women, through a semi-structured written task that resembles everyday narrative situations (i.e., sharing memories).

Methods:

Participants were 15 autistic and 15 non-autistic (NA) cisgender women, pairwise matched on age ($M(\text{age}) = 34.73$). As the study took place during the height of the lockdown, recruitment and testing were done online and in writing. Participants were asked to write 4 autobiographical memories, based on 4 emotional cue words. No time limit was given, but a minimum and maximum number of characters were allowed for each narrative (1000-1800).

Results:

Groups differences were found in all aspects of the analysis, the first being the microstructure: autistic women wrote longer narratives, used more unique and infrequent words and showed greater vocabulary productivity than NA women. On the macrostructure level, autistic women showed reduced use of explicit causal connectives. As for the internal state language, autistic women used less cognitive state terms but slightly more perceptual terms than NA woman.

Conclusions:
Background: Emotional prosody provides acoustical cues that reflect a communication partner’s emotional state and is crucial for successful social interactions. Many children with autism have deficits in recognizing emotions from voices, however the neural basis for these impairments is unknown. Two hypotheses have emerged to explain the deficits in interpreting vocal-emotional cues in autism. The first hypothesis proposes that children with autism have a sensory processing deficit in which abnormal sensory processing of emotional prosody cues precludes access to downstream systems that evaluate and categorize these acoustical features. A second hypothesis posits that acoustical processing of emotional prosody cues is largely intact in children with autism, however impairments in social cognitive and evaluative processes preclude the accurate interpretation of emotional information from these vocal cues.

Objectives: We aimed to examine brain circuit features underlying emotional prosody processing deficits and their relation to clinical symptoms of autism. Understanding the relative contribution of auditory sensory and social cognitive systems to emotional prosody perception deficits in children with autism would provide important information regarding the nature of this communication impairment and may provide insight into its remediation.

Methods: We used an event-related fMRI task to measure neural activity and connectivity during processing of sad and happy emotional prosody and neutral speech in 22 children with autism and 21 matched control children (7-12 years old). We employed functional connectivity analyses to test competing theoretical accounts which attribute emotional prosody impairments to either sensory processing deficits in auditory cortex or theory of mind deficits instantiated in temporoparietal junction (TPJ).

Results: Children with autism showed specific behavioral impairments for recognizing emotions from voices. They also showed aberrant functional connectivity between voice-sensitive auditory cortex and bilateral TPJ during emotional prosody processing. Neural activity in bilateral TPJ during processing of both sad and happy emotional prosody stimuli was associated with social communication impairments in children with autism. In contrast, activity and decoding of emotional prosody in auditory cortex was comparable between autism and control groups and did not predict social communication impairments.

Conclusions: Our findings support a social-cognitive deficit model of autism by identifying a role for TPJ dysfunction during emotional prosody processing. Our study underscores the importance of “tuning in” to vocal-emotional cues for building social connections in children with autism.

Acoustic Analysis of Conversational Prosody in Individuals with ASD and First-Degree Relatives

S. Crawford, J. Guilfoyle, J. C. Lau, G. E. Martin and M. Losh, (1)Communication Sciences and Disorders, Northwestern University, Evanston, IL, (2)Communication Sciences and Disorders, St. John’s University, Staten Island, NY, (3)Communication Sciences and Disorders, Neurodevelopmental Disabilities Lab, Northwestern University, Evanston, IL

Background: Prosody is a crucial component of pragmatic (i.e., social) language that includes modulating intonation, rate, rhythm, and volume of speech, and relays important meaning about speaker intent and affect. Entrainment, a natural phenomenon where speakers become more similar to each other in communication style over the course of an interaction, is observed along prosodic dimensions, and is an important ingredient in social-communicative success. In autism, differences in aspects of prosody can impact social communication in important ways, including a lack of prosodic entrainment that may contribute to pragmatic challenges in autism more broadly. Similar, but subclinical, prosodic differences among parents of autistic individuals suggests that prosody, and reduced prosodic entrainment, may reflect a genetic influence. To investigate this possibility, and understand the significance of prosodic differences in ASD, a necessary next step is the acoustic characterization of prosody outside of structured contexts, that permit the study of prosody and entrainment in more naturalistic contexts that pervade our daily lives.
Participants included autistic individuals, parents of autistic individuals, and respective control groups (ASD=29, ASD-Par=58, Control=22, Control-Par=32). Conversational samples, derived from semi-structured social interactions with an examiner, were transcribed and utterances were coded for communicative intent (e.g., question, response, statement, acknowledge). Acoustic measurements of volume (intensity) and pitch (fundamental frequency; f0) were extracted at .01ms intervals. Mean volume and pitch variability (the range and standard deviation of f0) were calculated for each utterance. Utterances were analyzed based on communicative intent (e.g., question vs. statement), which influences expected prosodic contours. Entrainment was calculated as the difference between speakers’ acoustic features across the interaction. Group effects were examined between ASD/Control and ASD-Par/Control-Par groups. Secondary analyses explored parent groups by sex.

Results: The ASD group demonstrated a greater pitch variability when responding to examiner questions (p<0.05) and when asking questions (p<0.05) relative to controls. Differences in the ASD-Par group were exclusive to mothers, who exhibited greater pitch variability (p<0.05) when asking questions compared to Control-Par mothers. No significant differences were observed between ASD-Par fathers and controls. All groups were similar in volume of speech (p>0.2). Finally, the ASD group entrained less in measures of pitch than Controls (p<0.01). No differences were observed in parents’ entrainment patterns.

Conclusions: Findings revealed differences in acoustic measures of prosody in conversation, among autistic individuals and more subtly in their mothers, where greater variability in pitch was observed relative to controls. This pattern may reflect a “sing-song” intonation quality that is consistent with qualitative descriptions of prosodic patterns in autism. Such subtle differences observed in mothers, but not fathers, contribute to emerging evidence documenting patterns of lineality consistent with maternal inheritance for some pragmatic language features. Reduced entrainment of prosody was observed in autism, suggesting that a reduced tendency to align prosodic behaviors with social partners may contribute to the social-communicative profile of autism.

Background:

Autism Spectrum Disorder (ASD) is characterized by wide clinical heterogeneity including language skills. Existing morphosyntactic comprehension assessment tasks are inadequate for many autistic children. Accurately objectifying individual language skills in toddlers, and especially those with ASD, requires appropriate assessment, because language production is often minimal or nil at that age.

Objectives:

The aim of this study was to develop a passive assessment task of syntactic skills, suitable for French-speaking autistic toddlers, requiring neither expressive language nor behavior like pointing. In addition, this task should be sensitive to the remarkable evolution in syntactic skills observable in typically developing children between ages 2 to 5, in order to pinpoint evolving syntactic comprehension in young autistic children.

Methods:

We developed an intermodal preferential looking paradigm task with eye-tracking, to assess morphosyntactic comprehension. This task is adapted from previous work using a behavioral Intermodal Preferential Looking Paradigm for English-speaking autistic children (Naigles & Fein, 2017). Our task is composed of simple, short sentences testing the comprehension of four structures: intransitive verbs in SV sentences (subject + verb), word-order in simple transitive SVO sentences, with reversible animate agent and patient, accusative clitic pronouns, and present and past tense in transitive sentences. Two videos are displayed, one by one, and then simultaneously on either side of the screen. Children’s gaze direction is recorded when (s)he hears a target sentence congruent with one video. The only explicit instruction is to look at the screen. Data were analyzed by defining Areas of Interest (AOI) in eye recordings, corresponding to the location of each video, and fixation duration was measured on each AOI. Here, we consider items selected after validation, based on different criteria (total duration fixation > 1000 msec, duration fixation for congruent video > for distractor video, significantly tested with chi2 method). We calculated the percentage of successful items, per child, per structure, meeting the selection criteria.

Participants were all-comer children aged 30mo to 71mo recruited in day care centers and kindergartens (N = 48, mean age = 51.92 ± 12mo.); autistic children are currently being tested.
Results:

According to selection criteria, the majority of the children (73%) succeeded most items of most conditions: the fixation duration in the congruent AOI is significantly longer than in distractor AOI. An ANCOVA with age as covariate showed a significant age effect (F(1, 187) = 10.02, p<.01): the older the children, the more items they looked more at the target video, for all four structures.

Conclusions:

This task appears to be an appropriate assessment of the morphosyntactic comprehension in toddlers. Most of the children looked significantly more at congruent videos compared to distractor videos, for the most of the items. Variances analyses showed an effect of age on success. The evolution of the children’s success at this task appears to reflect syntactic development in this age range.

Autistic toddler testing under way should confirm the relevance of this task for autism research on early steps in development.

**412.153 (Poster) Associations between Bilingualism, Executive Function, and Core Autism Traits**

**Background:**

The concept of a ‘bilingual advantage’ suggests individuals fluent in two languages develop cognitive advantages, particularly within the executive function (EF) domain. Bilingualism in children with autism spectrum disorder (ASD) is understudied. Previous work revealed associations between bilingualism and EF skills and between EF skills and autism traits, including perspective taking difficulties, social communication difficulties, and repetitive behavior. However it remains unknown whether bilingual children with ASD can compensate for autism-related difficulties, and what role EF plays in this process.

**Objectives:**

We investigated the role of EF in the relationship between bilingualism and autism traits in children with and without ASD. This work has three research aims: 1) Replicate prior work suggesting an ASD bilingual advantage for EF skills, 2) Assess whether bilingual children have less severe ASD traits than monolingual children, and 3) Investigate whether EF is a mediator between bilingualism and core ASD traits.

**Methods:**

Participants included 53 children with ASD (21 bilingual) and 63 typically developing (TD) children (38 bilingual). All children were between the ages of 7-12 years. The Behavior Rating Inventory of Executive Function (BRIEF) was utilized to measure EF. These ratings are more reflective of caregivers’ EF concerns across contexts than lab-based measures. Parents completed the Children’s Empathy Quotient (EQ-C; to assess perspective taking), Social Communication Questionnaire (SCQ; to assess social communication) and Repetitive Behavior Scale-Revised (RBS-R; to assess repetitive behaviors) to quantify the degree or severity of ASD symptoms. All statistical analyses included covariates of age, full-scale IQ, and social status. The first set of models predicted EF skills from diagnosis and bilingual status. The second set of models predicted ASD symptoms from diagnosis and bilingual status. The final set of models tested whether EF skills mediated an indirect association between bilingualism and reduced ASD symptoms. We focused our examination of EF on the Inhibit, Shift, and Emotional Control subscale scores due to the previously hypothesized mechanistic role of bilingualism on control and switching processes.

**Results:**

Compared with TD children, children with ASD had significantly more EF difficulties, as evidenced by higher BRIEF subscale scores, p<.05. Regression analyses predicting Inhibit and Emotional Control scores revealed significant interactions between diagnosis and bilingual status, such that bilingualism seemed to work as a protective factor supporting inhibition (p=.003) and emotional control (p=.034) skills in children with ASD, but not TD children (Figure 1). The model predicting EQ scores revealed a marginally significant main effect of bilingualism (p=.050) suggesting a direct effect of bilingualism on perspective taking, such that bilingual children regardless of diagnosis have a somewhat improved ability for understanding how others feel. Finally, all three tested EF subscales mediated significant indirect effects of bilingualism on perspective taking, social communication, and repetitive behaviors (Table 1).

**Conclusions:**
Together the results suggest that one potential path towards mitigating core ASD symptoms may be through stronger EF skills bolstered by bilingual experience. These results are the first to our knowledge to demonstrate the cascading supportive influences bilingual experience can have on reducing ASD related symptoms.

412.154 (Poster) Feasibility of Longitudinal Telephone-Based Voice Sampling in Autistic Children and Teens

Background: Voice biomarkers of neurodevelopmental conditions like autism are a key component of large-scale digital phenotyping efforts aimed at inexpensively and densely monitoring treatment progress and predicting long-term outcomes. Although voice biomarkers are often touted as context-independent “objective” markers (in contrast to semantically-rich-but-context-dependent lexical or language features) the stability of these markers over time in autistic children, and their sensitivity to changing conditions from day-to-day, are not well understood.

Objectives: (1) Assess the feasibility of a 10-week telephone-based study for collecting home-based naturalistic language samples from 6-17-year-old children with or without autism and their parent/caregiver (target: 48 participants, half with autism and half without autism, half male and half female, IQ>75 stratified by age), and (2) To improve future retention, identify causes of attrition or failure to complete the study after enrolling.

Methods: Potential participants aged 6-17.99 years were identified using an electronic health record system at a large hospital-based academic medical center in the U.S., flyers and inquiry forms, and internal databases. After families responded with interest, study staff made informational telephone calls. Following these calls, interested families scheduled a telephone screening interview (TSI) with study staff (~40-60 minutes) to assess eligibility. If children were eligible to participate, an electronic consent form was completed prior to scheduling video call-based clinical assessments to measure language skills and generate IQ estimates. Following study consent, a record review (i.e., past evaluations, medical records) was conducted by a clinician to confirm diagnostic group status for the autism group (ASD intake), while typically developing controls did not require this step (TDC intake). Voice collection occurred once per week for seven weeks (~30-60 minutes per session), while clinical assessments typically required an additional three weeks (10 weeks total). Participants were compensated for their time.

Results: One hundred twelve (112) telephone screening interviews were conducted between November 2020 and August 2022. After completing the telephone screening interview, 58 families consented to participate by signing an electronic consent form (51.79%), and 54 did not (48.21%; see Tables below). Among consenting families, 47 completed all seven voice collection calls and additional study components (81.03% completion rate), while 11 were re-assigned to the “Not Currently Participating” category (18.97% attrition rate; 7/11 were originally in the autism group; see Tables). Primary reasons for withdrawal after consenting to participate included time and scheduling issues (n=3), ineligibility after record review (n=4), and loss of contact (n=4).

Conclusions: Home-based telephonic collection of naturalistic voice samples from autistic children and teens is highly feasible, even with a 10-week timeline. Although just over 50% of interested families continued past the telephone screening interview, 81% of enrolled participants ultimately completed the study. As voice interactions are important for success in educational and employment contexts, understanding voice-based markers of autism could lay important groundwork for maximizing successful integration in these domains. Finally, evidence of feasibility in longitudinal naturalistic voice sampling protocols for individuals on the autism spectrum lends credence to its promise as an inexpensive, high-frequency method for monitoring progress due to interventions or developmental change.

412.155 (Poster) Autistic Girls and Boys Employ Different Strategies during Natural Conversations

Background: Autistic girls are under-diagnosed compared to boys, even when they experience comparable clinical impact. Previous studies suggest that autistic girls present with distinctive symptom profiles in a range of areas, including natural speech, which may make it more challenging to identify and diagnose girls and provide them with appropriate social support. To improve our understanding of
Objectives: To investigate potential sex differences in the temporal dynamics of verbally fluent autistic children’s speech during natural conversations with a novel interlocutor.

Methods: Forty-five autistic children (16 girls, mean age: 11.5±2.8 years, mean full-scale IQ: 105.8±12.1, mean ADOS-2 total: 6.4±2.0) and 47 NT children (24 girls, mean age: 10.1±2.8 years, mean full-scale IQ: 108.6±12.3, mean ADOS-2 total: 1.2±0.4) participated in a 5-minute “get-to-know-you” conversation with a novel young adult interlocutor who was unaware of children’s diagnostic status. Groups were matched on the sex ratio and IQ scores, but not on age. Autistic boys and girls did not differ on any other demographic or clinical characteristics. Recordings were time-aligned and orthographically transcribed by trained annotators, and turns were defined based on speaker change during conversations. Several duration measures, including total speech time, overlapping speech duration, mean speech segment duration, between-turn pause durations, and total number of words were calculated. Groups were compared using analysis of covariance models, controlling for age.

Results: Autistic girls spoke longer in total than autistic boys (p=0.002; Fig.1A) and produced longer speech segments on average than all other groups (vs. autistic boys: p=0.011; vs. NT boys: p=0.038; vs. NT girls: p=0.008, Fig.1B). Autistic girls produced significantly more words in total than autistic boys (p=0.026), but they did not differ from NT children in total word counts or speaking rate. In contrast, autistic boys spoke more slowly than NT children (vs. NT girls: p=0.046, vs. NT boys: p=0.027) with fewer words in total than NT boys (p=0.049). Autistic boys interrupted interlocutors’ speech less often than autistic girls (p=0.025) and NT children (NT boys: p=0.025; NT girls: p=0.004; Fig.2A) and produced longer between-turn pauses (i.e., longer latency duration to respond; Fig.2B) than autistic girls (p=0.012), NT boys (p=0.029), and NT girls (p=0.004).

Conclusions: Results suggest that verbally fluent autistic girls and boys have different natural language profiles, even when matched on autism symptoms. Establishing the exact nature of verbal communication differences paves the way for the development of sex-sensitive screening and diagnostic tools to more quickly and precisely identify autistic girls and boys. This method may also be used to guide the development of individualized interventions that enhance both short- and long-term social communication outcomes for autistic children.

412.156 (Poster) Autistic Teenagers Lexically Align at Similar Rates to Typically Developing Peers

G. Corrigan, J. Carmona, R. Fusaroli, E. Weed; D. A. Berger and L. R. Naigles (1)Psychological Sciences, University of Connecticut, Storrs, CT, (2)Aarhus University, Aarhus, Denmark

Background: Lexical alignment refers to speakers’ matching the language their conversation partner uses.[1] Because lexical alignment relates to effective social communication,[2] individuals with Autism Spectrum Disorder (ASD; characterized by deficits in social communication) may underperform compared to typically developing (TD) individuals. However, no significant differences in lexical alignment have emerged between school-age TD children and highly verbal children with ASD.[1,3]

Objectives: We aim to replicate previous research [1] with older participants and with an autistic sample ranging broadly in verbal ability. We incorporate measures of language and social communication to examine how these factors relate to lexical alignment.

Methods: The sample included 17 TD and 13 autistic teenagers who ranged from low-verbal to highly verbal (as measured by the CELF-5; Table 1). The participants and investigator played the “Snap” game,[1] wherein players take turns naming items in picture cards. The investigator primed each target item with either its preferred (e.g., cat) or dispreferred (e.g., kitten) name. Two turns later, the participant would see and name the same target image. Targets were either natural kinds (e.g., rabbit/bunny; n=7) or artifacts (e.g., couch/sofa; n=13). The participant’s word choice for each target item was coded as 1 (matching the investigator) or 0 (non-matching). Overall matching scores were calculated as the number of matched trials out of 20 target items. A difference score for each participant was calculated by finding the absolute value of dispreferred name use after preferred primes minus dispreferred name use after dispreferred primes; higher difference scores indicated greater alignment on dispreferred terms (Table 1).

Results: Paired-samples t-tests by diagnostic group revealed that both groups produced the dispreferred term significantly more often when primed with the dispreferred term (M(SD)TD = 0.48(0.19); M(SD)ASD = 0.50(0.22)) than when primed with the preferred term (M(SD)TD = 0.06(0.08); M(SD)ASD = 0.04(0.06)). The TD group’s difference scores were not significantly different from the autistic group’s (t(28) = -0.49, p = .636). A mixed-model ANOVA compared difference scores by item type and diagnostic group, yielding a main effect of item type: difference scores for natural kinds were higher than difference scores for artifacts (F(1,28) = 4.78, p = .037), with no significant interactions (p = .636). The TD group’s difference scores did not correlate with their total CELF-5 scores (Figure 1a), nor with their ADOS-2 social interaction/communication (SC) scores (Figure 1b). The autistic group’s difference scores yielded a marginally significant positive correlation with their total CELF-5 scores (Figure 1c), as well as a marginally significant negative correlation with their SC scores (Figure 1d).
Conclusions: Our findings in this study indicate that autistic individuals, even into their teenage years and young adulthood, lexically align at the same rates as TD individuals during a structured task. We additionally demonstrated that language and social communication, as measured by the CELF-5 and ADOS-2, respectively, are unrelated to lexical alignment in TD teens but may be related in autistic teens. Finally, TD and autistic teens may find the preferred and dispreferred names for natural kinds more interchangeable than those for artifacts.

412.157 (Poster) Autistic and Neurotypical Children’s Social Impressions of Off-Topic and Delayed Responding
L. McGuinness, K. Abbot-Smith, and C. Gambi, (1)University of Kent, Canterbury, United Kingdom, (2)University of Warwick, Coventry, United Kingdom

Background:
On average, autistic groups are more likely than non-autistic groups to respond in an off-topic manner (Sng et al., 2020), and/or to leave significantly longer turn-taking gaps (Ochi et al., 2019). Exhibiting unconventional conversational behaviours could result in negative social impressions of autistic children from their neurotypical peers (e.g., Place & Becker, 1991). However, it is possible that autistic individuals do not make the same social judgments due to different communicative preferences (Granieri et al., 2020).

Objectives:
This study aimed to determine whether autistic children pattern similarly or differently to their neurotypical peers in rating off-topic or delayed responding as a deterrent to friendship or interaction, and if not, whether they are aware of the societal dispreference for these behaviours.

Methods:
Current results are based on twenty-eight participants (N=14 per group), but the final (pre-registered) sample will include thirty-six neurotypical and thirty-six autistic children. All participants are aged between 9:0 and 13:11-years, and groups are matched on chronological age, gender ratio, core language ability, and non-verbal reasoning skills. Participants listened to several short audio clips of conversations containing six conversational turns between two children. For each conversation, participants rated four statements on a 0-100 scale: two capturing their personal preferences, such as “I would enjoy chatting to the [target speaker]”, and two regarding their perceptions of “Most other people’s” impressions. A conversation production measure was also used to observe participants’ tendency to provide off-topic or delayed responses themselves.

Study 1 manipulated the typicality of the target speaker’s responses via the content of their utterances (On-topic vs. Off-topic). One example of an off-topic response to the statement “I went to that new restaurant in town last night” is “Oh no, I think my library books are due in today”. Study 2 manipulated the timing of the target speaker’s conversational turns. That is, the responses were all on-topic, but either came 200-msec after the offset of the preceding utterance (Typical) or 3000-msec after (Delayed).

Results:
Linear mixed effects models were conducted to compare participants’ ratings for On-topic vs. Off-topic conversations, and for Typical vs. Delayed conversations. In Study 1, participants rated On-topic conversations significantly more favourably ($M = 73.67$) than Off-topic conversations ($M = 46.37$) ($p<.001$). Similarly, in Study 2, there was a significant main effect of Timing (Non-delayed $M = 73.67$, Delayed $M = 64.68$, $p = .014$). For both studies, there was no interaction, and no effect of Diagnostic Group (Autistic $M = 59.97$, Neurotypical $M = 63.17$), with a small effect size for both the Topic ($d = .02$) and Timing ($d = .19$) analyses.

Conclusions:
The absence of interaction effects and main effects of Diagnostic Group (with very small effect sizes) suggests that autistic children are just as likely as their neurotypical peers to dis-prefer speakers who provide ‘atypical’ conversational responses. While it is possible that some autistic adults may develop a preference for atypical communication styles, it appears that the preferences of autistic children are not only indistinguishable from that of neurotypical children, but also align with their perceptions of societal norms.

412.158 (Poster) Automatic Speech Recognition for Autism Using the Open-Source Whisper Model from Openai

Objectives:
Individuals do not make the same social judgments due to different communicative preferences (Granieri et al., 2020).

Methods:
Linear mixed effects models were conducted to compare participants’ ratings for On-topic vs. Off-topic conversations, and for Typical vs. Delayed conversations. In Study 1, participants rated On-topic conversations significantly more favourably ($M = 73.67$) than Off-topic conversations ($M = 46.37$) ($p<.001$). Similarly, in Study 2, there was a significant main effect of Timing (Non-delayed $M = 73.67$, Delayed $M = 64.68$, $p = .014$). For both studies, there was no interaction, and no effect of Diagnostic Group (Autistic $M = 59.97$, Neurotypical $M = 63.17$), with a small effect size for both the Topic ($d = .02$) and Timing ($d = .19$) analyses.

Conclusions:
The absence of interaction effects and main effects of Diagnostic Group (with very small effect sizes) suggests that autistic children are just as likely as their neurotypical peers to dis-prefer speakers who provide ‘atypical’ conversational responses. While it is possible that some autistic adults may develop a preference for atypical communication styles, it appears that the preferences of autistic children are not only indistinguishable from that of neurotypical children, but also align with their perceptions of societal norms.
Methods: 90 parent-child dyads (20 female) (M age=74.96 months, SD=12.85, Age range=49–95). participated in study conducted whether these relationships differed for minimally verbal compared to verbal children.

Results: Whisper significantly outperformed the commercial solution across all cohorts (p<0.05) by approximately 10%, resulting in an average WER of 20% (Figure 1). The largest increase in performance was observed in autistic individuals with IQs < 70, with an increase of ~17%. However, this cohort still had significantly higher error rates than the others, with an average WER of 25%.

Conclusions: ASR is rapidly improving: the recently released algorithm from OpenAI outperforms last year’s front-running commercial solution. Importantly, the largest improvement was for autistic individuals with IQs < 70. These results show the promise of objectively and automatically evaluating communication abilities in autism.

Background: Challenges in social communication and interaction are a core symptom domain in autism. Novel therapies are under development to help individuals with these challenges. However, commonly used clinical measures lack the sensitivity to assess potential improvements in communication ability, and are often time-consuming and subjective. Expressive Language Sampling (ELS) through structured conversations has emerged as a promising way to measure expressive communication abilities. ELS is typically performed in a clinical setting with a trained conversation partner or physician. Here, we aim to probe naturalistic conversations with family members in home settings that may be more representative of everyday life. At-home assessments can be performed multiple times throughout a study to minimize the impact of day-to-day variations without the added burden and costs associated with in-clinic visits.

While several studies have used automated acoustic and linguistic analysis methods to study autistic speech, they require manual transcripts from trained professionals as a first processing step. In order to bypass this time-consuming and costly process, automatic speech recognition (ASR) is required. While major progress has been achieved in this field, particularly with the input of major tech companies, the applicability of ASR to natural conversations in real world environments with individuals with irregular speech patterns has been lacking. Recently, an open-source ASR algorithm called Whisper has been released by OpenAI that appears to outperform its competition.

Objectives: We investigate the performance of OpenAI’s Whisper in transcribing the speech of autistic individuals during natural conversations, and compare it with a cloud-based commercial solution which we have previously found to be the front-runner for ASR in autism.

Methods: 90 autistic individuals and 45 neurotypical controls (NTCs) between the ages of 5 and 45 were enrolled into a non-drug observational study (NCT03611075). They were asked to record a 5 minute conversation at home with a conversation partner once per week over a 12-week period. Autistic individuals were categorized based on IQ (threshold of 70) to assess the utility of the ASR algorithms for participants that vary on this dimension. Manual transcripts were obtained for 294 conversations from 59 participants. Automatic transcripts were obtained using Whisper and the commercial solution. Performance was measured using the word error rate (WER; %) which is typically on a scale from 0-100, with lower numbers indicating better performance. All paired statistical comparisons were performed using Wilcoxon Signed Rank tests.

Results: Whisper significantly outperformed the commercial solution across all cohorts (p<0.05) by approximately 10%, resulting in an average WER of 20% (Figure 1). The largest increase in performance was observed in autistic individuals with IQs < 70, with an increase of ~17%. However, this cohort still had significantly higher error rates than the others, with an average WER of 25%.

Conclusions: ASR is rapidly improving: the recently released algorithm from OpenAI outperforms last year’s front-running commercial solution. Importantly, the largest improvement was for autistic individuals with IQs < 70. These results show the promise of objectively and automatically evaluating communication abilities in autism.

Background: Fine motor skill is associated with expressive language outcomes in infants with an autistic sibling and in young autistic children. Few studies have focused on school-aged children even though around 80% have motor impairments (Bhat, 2021) and 30% are minimally verbal (MV) into their school years (Norrelgen et al., 2015). Moreover, expressive language is not a unitary construct, but it is lacking. Recently, an open-source ASR algorithm called Whisper has been released by OpenAI that appears to outperform its competition.

Objectives: We investigate the performance of OpenAI’s Whisper in transcribing the speech of autistic individuals during natural conversations, and compare it with a cloud-based commercial solution which we have previously found to be the front-runner for ASR in autism.

Methods: 90 autistic individuals and 45 neurotypical controls (NTCs) between the ages of 5 and 45 were enrolled into a non-drug observational study (NCT03611075). They were asked to record a 5 minute conversation at home with a conversation partner once per week over a 12-week period. Autistic individuals were categorized based on IQ (threshold of 70) to assess the utility of the ASR algorithms for participants that vary on this dimension. Manual transcripts were obtained for 294 conversations from 59 participants. Automatic transcripts were obtained using Whisper and the commercial solution. Performance was measured using the word error rate (WER; %) which is typically on a scale from 0-100, with lower numbers indicating better performance. All paired statistical comparisons were performed using Wilcoxon Signed Rank tests.

Results: Whisper significantly outperformed the commercial solution across all cohorts (p<0.05) by approximately 10%, resulting in an average WER of 20% (Figure 1). The largest increase in performance was observed in autistic individuals with IQs < 70, with an increase of ~17%. However, this cohort still had significantly higher error rates than the others, with an average WER of 25%.

Conclusions: ASR is rapidly improving: the recently released algorithm from OpenAI outperforms last year’s front-running commercial solution. Importantly, the largest improvement was for autistic individuals with IQs < 70. These results show the promise of objectively and automatically evaluating communication abilities in autism.
Controlling for adaptive behavior (VABS-3 standard score) and age. Finally, simple linear regression adjusted for multiple comparisons was used to test for differences between minimally verbal and verbal groups.

Results: Fine motor skill significantly predicted percent intelligible utterances. Fine motor skill and adaptive behavior were significant predictors of mean length of utterance in morphemes. Adaptive behavior, but not fine motor skill, predicted number of conversational turns. Simple linear regressions by group (minimally verbal versus verbal) corrected for multiple comparisons showed that fine motor skill predicted intelligibility for minimally verbal but not verbal children (see Figure 1). Fine motor skill and adaptive behavior predicted mean length of utterance for both minimally verbal and verbal children (see Figure 2).

Conclusions: Fine motor skill affects expressive language for autistic children into their early school years. Speech is more affected for minimally verbal children, and structural language is affected for both minimally verbal and verbal children. These findings suggest that autistic children may benefit from supports targeting fine motor along with speech (for minimally verbal) and language (for minimally verbal and verbal) into their school years.

412.160 (Poster) Can Minimally Verbal Individuals with Autism Read? Hidden Literacy Revealed Via Eye Movements
K. Ellert*, N. Shefer - Kaufmann and Y. S. Bonneh; (1)School of Optometry and Vision Science, Horvevi Tsiyon 57, Ramat-Gan, Israel, (2)School of Optometry and Vision Science, Bar-Ilan University, Ramat-Gan, Israel, (3)Clalit Health Care Services, Tel-Aviv, Israel, (4)School of Optometry and Vision Science, Bar-Ilan University, Ramat Gan, Israel

Background: Autistic children and adults with little or no spoken language who are considered 'minimally verbal' (mvASD) are estimated as 30% of the spectrum. They are typically judged as 'low functioning' or cognitively impaired due to low scores in the conventional assessments of cognitive abilities. However, it is unclear whether these failures reflect an actual cognitive impairment, or alternatively, a severe deficit in behavioral expression of cognitive skills such as reading. To explore this alternative, we hypothesized that some or many of these individuals have a severe deficit in the initiation and control of reliable voluntary actions, which calls for using involuntary or effortless measures such as small eye gaze lateralization. We further hypothesized that the deficit could originate from a deficit in recruiting phasic arousal. Preliminary results from this study were presented in INSAR 2019 and 2021.

Objectives: Assess basic reading and lexical-semantic knowledge in young adults with mvASD using eye-movement measures in comparison to pointing performance and investigate transient pupillary responses as a measure of phasic arousal.

Methods: A group of adolescents or young adults (N=27), 15-30 years old, diagnosed with ASD and with little to no functional language (less than 30 communicative words) were tested on a novel "cued looking" paradigm (adaptation of "looking-while-listening"; Fernald et. al., (2008)). Participants watched a sequence of stimuli while their eyes were tracked. In each trial, a text word was presented at fixation (1s), followed by a pair of familiar object pictures presented (1s) side by side, with next trial following after 800ms. There were 4 short runs (<1 min) repeated 3-6 times in random order. In a second experiment, the written words were replaced by recorded words. In a third (reading) and fourth (listening) experiments, the same pictures and text were used on 20 cards to measure performance via pointing. We analyzed the lateralization of the eye-gaze according to target side as well as pupil dilation.

Results: 22 of the 27 mvASD participants (81%) showed a significant effect of reading as reflected by correct lateralization (~85% group average), with similar results obtained for spoken words. In a striking contrast, most of the MVs who showed significant reading via eye gaze, were at or near chance level in pointing (group average <60%) making their reading skills “hidden” to standard testing. To investigate the cause for this anomaly, we analyzed the transient pupil dilation associated with the eye gaze, which we found to be reduced in the mvASD group compared to controls.

Conclusions: These results provide the first systematic evidence for reading ability in mvASD individuals typically assumed to be severely language and cognition impaired. The results also demonstrate a striking anomalous gap between pointing performance and eye-gaze, which opens the way for uncovering unknown cognitive abilities in mvASD. Our results of reduced pupil dilation provide a first hint at the possible cause of the anomaly in terms of reduced phasic arousal subserving many cortical circuits that drive behavior.

412.161 (Poster) Child and Parental Gesture As a Precursor to Executive Function and Language in Autism Spectrum Disorder
A. B. Choi1, M. Tsou1, Z. Cai1, Y. Otto and S. Faja1; (1)Seoul National University Hospital, Seoul, MA, Korea, Republic of (South), (2)Boston Children’s Hospital, Boston, MA, (3)Boston Children’s Hospital, Boston, MA

Background:

It is well-known that gesture precedes and predicts language (Iverson & Goldin-Meadow, 2005, Rowe et al., 2008). Emerging evidence indicates that gesture is also predictive of executive function (EF), with language mediating the relation between gesture and EF (Kuhn et al., 2014). These findings suggest the important role of gesture in the development of language as well as cognitive abilities. While these
associations have been investigated in neurotypical children, it is unknown whether similar relations among gesture, language, and EF are found in toddlers diagnosed with autism spectrum disorder (ASD). In addition, we could identify no studies that have examined whether parental gesture use is related to EF abilities in ASD toddlers.

Objectives:
The objective of this study was to examine associations among gesture use by ASD toddlers and their parents, language, and EF abilities.

Methods:
Data were collected as part in an ongoing study to chart the trajectory of EF in ASD and identify its predictors at multiple levels. Participants included 51 parents and their toddlers diagnosed with ASD (Mage = 30.9 months; SDage = 3.8). Children (37 boys, 14 girls) and their parents engaged in a 10-minute free play interaction in lab where they were asked to play as they normally would at home. Gestures from ASD toddlers and parents were reliably coded from videotaped sessions of parent-child interactions following previous research (Choi et al., 2019; Özçalışkan & Goldin-Meadow, 2009). Children’s language skills were measured using the Mullen Scales of Early Learning (Mullen, 1995), and EF skills were assessed using seven tasks that were designed to measure three dimensions of EF in young children: set-shifting (e.g., spatial reversal, Preschool EF Battery [PEFB] flip book; Garon et al., 2014), inhibition (e.g., PEFB tricky box), and working memory (e.g., PEFB hide-and-seek).

Results:
Child gesture use was significantly, positively related to receptive language (r(49) = .369, p = .008), and this association remained significant even when controlling for child sex and parent education. Child gesture was positively related to set-shifting, although this was approaching statistical significance in this preliminary dataset (r(40) = .300, p = .053). Receptive language was significantly, positively correlated with set-shifting. In addition, parent gesture use was significantly, positively related to their toddlers’ gesture use (r(49) = .283, p = .040) as well as set-shifting (r(40) = .377, p = .014).

Conclusions:
These findings indicate that ASD toddlers who gestured more had better language and EF skills and that language may play a mediating role in the relation between communicative gestures and EF abilities in ASD toddlers similar to neurotypical children. Parents who gestured more had children who gestured more and who also were more efficient when shifting between responses. This preliminary analysis examined concurrent relations among gesture, language, and EF; however, our prospective longitudinal design will allow us to further explore whether these variables influence each other over time. Findings from our work will have both theoretical and clinical implications to enhance our understanding of relations among communication, language, and cognition and to inform the design of ASD interventions.

412.162 (Poster) Communicative Individual Variance Using Resting-State Functional Magnetic Resonance Imaging
M. Mahal, K. Bendtz, W. Thompson and J. Uddén, (1)Department of Psychology, Stockholm University, Stockholm, Sweden, (2)University of Gothenburg, Gothenburg, Sweden, (3)Department of Psychology, Stockholm University, Stockholm, (4)Department of Linguistics, Stockholm University, Stockholm, Sweden

Background: Communication in dialogue requires skills that go beyond structural language abilities. This includes tailoring your message to the conversational partner and making inferences beyond the literal meaning of utterances, abilities that have been investigated as part of pragmatics. It has been noted that speakers with ASD underperform on most pragmatic measures, even when the comparison group has been matched for structural language skills (Volden, 2017).

Objectives: Our aim was to investigate neural markers of pragmatic individual differences, using resting state fMRI-data. We capitalized on individual variation in pragmatic skills in the general population.

Methods: We created groups (High score vs Low score) from the CIV (Communicative Individual Variance) sample, consisting of N=199 participants including measurements of two behavioural pragmatic tasks, also including 61 participants (age 18-36, 28 males) with fMRI-data (with a third pragmatic task and resting state, see Bendtz et al. (2022)). Experimenter were blind to the group-status of the participant.

The study design, including a pilot phase, was recorded at OSF prior to analysis (https://osf.io/keqws/). We used previously not analyzed resting-state fMRI-data acquired just before task data, in the CIV-sample. We here focus (see OSF for all questions) on the functional connectivity between two cortical clusters defined by the pragmatic task data from the CIV-sample (see Bendtz et al. 2022); (1) left superior and inferior lateral parietal cortex, and (2) bilateral dorsal precuneus. In Bendtz et al. (2022), individuals with higher pragmatic skills showed greater activation compared to individuals with lower pragmatic skills, in these two regions. We asked whether the High
score group would show increased connectivity between these two regions, compared to the Low score group, prior to performing any pragmatic task.

To obtain a single BOLD signal time course for each region of interest (ROI), the voxel-wise time courses were averaged. In the Conn-toolbox, the two ROIs were correlated against one another with a Pearson’s product-moment bivariate correlation, representing the level of functional connectivity between those regions, also known as ROI-to-ROI connectivity.

Results: Our results in both pilot study and the main study (see Graphics) show that individuals with higher pragmatic ability had significantly greater functional resting state connectivity between the two investigated clusters, than individuals with low pragmatic skills.

Conclusions: We show that the functional connectivity of the ParPrec-clusters during a resting-state scan is modified by pragmatic skill, showing a potentially relevant new neural marker for pragmatic individual differences. The relevance of the coordination in this pair of regions, for highly skilled pragmatic processing, is strengthened if also considering the already published results in Bendtz et al. (2022). Note that this mini-network represents a neural marker of communication outside the language network. Thus, the neural individual variability we point to may in the future be investigated in ASD, to understand the underlying cause for why pragmatic problems are disproportionally observed in ASD, over and above structural language difficulties.

412.163 (Poster) Correlations between Auditory-Perceptual Speech Features and Language Skills in Low and Minimally Verbal Autistic Individuals

M. F. Maffei1, K. V. Chenausky1, H. Tager-Flusberg1 and J. R. Green1; (1)Speech and Feeding Disorders Lab, MGH IHP Speech and Feeding Disorders Lab, Boston, MA, (2)Communication Sciences and Disorders, MGH Institute of Health Professions / Harvard Medical School, Boston, MA, (3)Department of Psychological and Brain Sciences, Boston University, Boston, MA, (4)Speech and Feeding Disorders Lab, MGH Institute of Health Professions, Boston, MA

Background: A wide range of language skills is well documented in autism spectrum disorder (ASD). The factors underlying this variance remain unclear. Identifying valid predictors of language skills in ASD would directly inform early detection of language impairments and the development of high-quality interventions. We hypothesize that some children with ASD exhibit abnormal speech motor control and that these deficits are associated with decreased language skills.

Objectives: (1) Determine the presence, nature, and severity of auditory-perceptual signs of dysarthria among low and minimally verbal (L/MV) autistic individuals; (2) Determine if auditory-perceptual signs of dysarthria are correlated with expressive and receptive language abilities among L/MV autistic individuals.

Methods: 54 L/MV autistic individuals aged 4–18 were videotaped completing Section 2 of the Kaufman Speech Praxis Test, which involves imitating speech sounds ranging from single phonemes to two-syllable words. Expressive language was quantified as the number of different words (NDW) spoken during a natural language sample. Receptive language was quantified using the Peabody Picture Vocabulary Test-4 (PPVT). Three experienced speech-language pathologists rated each participant’s speech for 13 auditory-perceptual features reflecting specific aspects of speech production or overall speech effectiveness (i.e., vocal quality, intensity, pitch, consonant accuracy, vowel accuracy, resonance, stress, rate, coordination, consistency, listener effort, intelligibility, and overall severity). Ratings were made on a 5-point dichotomous-ordinal scale ranging from “no impairment” to “profound impairment,” with an additional option for “cannot judge.” Inter-rater reliability was measured with Kendall’s coefficient of concordance, intra-rater reliability was measured with weighted Cohen’s kappa, and internal consistency was measured with Cronbach’s alpha. A Rasch analysis was performed to (1) examine each child’s overall speech production skills, (2) examine the relative prevalence of aberrant speech features in the sample, and (3) handle missing data related to participants’ L/MV status.

Results: Inter-rater reliability ranged from W = .37 (pitch) to W = .83 (vowel precision). Intra-rater reliability ranged from κ = .46 (rate) to κ = .93 (vowel precision). Cronbach’s alpha for the 13 speech features was α = .94. Rasch analysis revealed that features related to articulatory control (e.g., vowel precision, consonant precision, consistency, intelligibility) were significantly more impacted than features related to laryngeal, respiratory, or velopharyngeal control. Features strongly correlated with expressive language included intelligibility (ρ = .78) and vowel precision (ρ = .73). Features strongly correlated with receptive language included consonant precision (ρ = .81) and intelligibility (ρ = .79). Overall speech production ability across features was strongly correlated with PPVT scores (ρ = .70) and NDW (ρ = .62), p < .001 for all correlations mentioned above.

Conclusions: Features varied in reliability given participants’ limited speech production; however, the internal consistency of the 13 auditory-perceptual features was very high. Using an innovative analysis technique, individual speech features and overall speech production ability were found to be significantly correlated with expressive and receptive language. These results have significant potential to advance our understanding of language development in ASD, aid early assessment of language skills, and contribute to the development of high-quality language interventions.
Disfluency Use As a Window to Pragmatic Language Competence in Bilingual Children with and without Autistic Spectrum Disorders

N. Meir and M. Beradze, (1) Department of English Literature and Linguistics, Bar-Ilan University, Ramat Gan, Israel, (2) Bar-Ilan University, Ramat Gan, Israel

Background: Speech disfluencies may serve pragmatic purposes such as signaling upcoming delays to the listener. Recent studies show that monolingual autistic children produce fewer filled pauses and prolongations than their non-autistic peers (Wiklund & Laakso, 2020). Although bilingualism has been reported to be beneficial with regard to pragmatic abilities, little research has been conducted on how disfluencies can serve pragmatic functions in bilingual autistic and non-autistic children. A comparison of narratives in both languages allows better identification of language-specific vs. language-universal usage of disfluencies in children.

Objectives: This study aimed to investigate how bilingual autistic children (BI-ASD) and their non-autistic peers (BI-TLD) use typical disfluencies in both languages (Heritage (HL-Russian) and Societal (SL-Hebrew) languages). The second aim was to determine whether children’s usage of disfluencies differed across their two languages.

Methods: Participants included HL-Russian SL-Hebrew autistic children (BI-ASD, n=21) and their bilingual non-autistic peers (BI-TLD, n=30) aged 5-9 years. Narratives from the LITMUS-MAIN battery (Gagarina et al., 2012) were transcribed and coded in HL-Russian and SL-Hebrew for eleven disfluency types. Between-group (BI-ASD vs. BI-TLD) and within-group (HL-Russian vs. SL-Hebrew) comparisons of eleven disfluency types were conducted.

Results: By comparing disfluency use in both languages of bilinguals, this study demonstrated that HL-Russian posed an additional processing cost resulting in more disfluencies in both groups. Furthermore, both groups produced more errors in their weaker HL-Russian
than in SL-Hebrew. This study confirmed fewer listener-oriented filled pauses production in HL-Russian, as previously reported for monolingual autistic children with ASD (Heeman et al., 2010; MacFarlane et al., 2017) whereas in SL-Hebrew, no significant differences were observed between the two groups. Comparisons of disfluency types across the two languages showed consistent patterns in both languages in the BI-ASD group, while children with BI-TLD varied their disfluency use patterns in accordance with language-specific constraints of each language, probably reflecting a higher degree of pragmatic ability to adapt to a listener's language.

Conclusions: A higher total disfluency ratio in the weaker HL-Russian as compared to SL-Hebrew confirms the link between disfluencies and proficiency in both BI-ASD and BI-TLD groups. Following previous findings for monolingual autistic children, filled pauses may function as markers to differentiate ASD and TLD, yet only when the linguistic and cognitive load is high. Furthermore, cross-language comparisons in both groups support the pragmatic nature of disfluencies. Disfluency usage in bilingual autistic children was rather language-universal (i.e., affected by clinical status), rather than language-specific (i.e., affected by language properties), as in case of non-autistic bilingual children. Little variation in the disfluency patterns in autistic children indicates less reliance on the pragmatic advantages that each language offers, for instance, in SL-Hebrew prolongations are allowed rather than filled pauses, but only non-autistic bilingual children implemented this pragmatic advantage of continuity. The use of listener-oriented filled pauses and prolongations may further benefit speaking ability by helping bilingual and monolingual autistic children to hold their conversational turns and to improve their pragmatic skills.

412.166 (Poster) Disrupted Audio-Motor Synchronization of Speech in Autism and First-Degree Relatives.

J. Guilfoyle, J. C. Lau, K. Nayar, F. Assaneo and M. Losh, (1)Communication Sciences and Disorders, Northwestern University, Evanston, IL; (2)Rush University Medical Center, Chicago, IL; (3)Universidad Nacional Autónoma de México, Mexico City, DF, Mexico; (4)Communication Sciences and Disorders, Neurodevelopmental Disabilities Lab, Northwestern University, Evanston, IL

Background: The unconscious tendency to align one’s behavior with external stimuli, or spontaneous synchronization, supports many aspects of human cognition and behavior. Especially crucial for social communicative success is synchrony across elements of speech and language. Recent evidence suggests that autistic individuals demonstrate reduced speech prosody synchronization (e.g., rhythm, pitch) with their social partners, which contributes to broader pragmatic language difficulties. Similar patterns have also been observed among their first-degree relatives, suggesting a genetic link. Yet, the neurocognitive basis of such differences, and whether a lack of spontaneous synchronization of speech is evident at a fundamental level in autism (i.e., independent of social contexts) remains unclear.

Synchronization of non-social speech rhythm in the general population is particularly robust, demonstrating a bimodal pattern of variability wherein some people tend to align speech output spontaneously and effectively with external rhythms, while others do not. Such variability is also associated with underlying neural architecture and language-related skills. Studying how such variability in rhythmic synchronization, devoid of social influence, may differ in autistic and broad autistic populations may provide important insights into the genetic and neuro-mechanistic underpinnings of core speech/language difficulties in autism.

Objectives: To examine spontaneous audio-motor synchronization of speech to external rhythms among autistic individuals and their first-degree relatives as a potential mechanism underlying broader speech/language difficulties.

Methods: Participants include 12 autistic individuals (ASD), 15 parents of autistic individuals (ASD-Par), and 7 adult controls (Controls) (data collection is ongoing and a more robust sample is expected at the time of presentation). A separate sample of 271 controls, whose data have been previously published, is also included. The spontaneous speech synchrony (SSS) task was used to assess rhythmic synchronization to an external rhythmic syllable stream. Phase locking values (PLV) between the envelopes of the produced speech and the stimuli characterize the degree of synchrony. A gaussian mixture model, fit to the bimodal distribution of synchrony values from existing data have been previously published, is also included. The spontaneous speech synchrony (SSS) task was used to assess rhythmic synchronization to an external rhythmic syllable stream. Phase locking values (PLV) between the envelopes of the produced speech and the stimuli characterize the degree of synchrony. A gaussian mixture model, fit to the bimodal distribution of synchrony values from existing normative data of typically developing adults, was used to determine the probability of a participant falling in either the “high” or “low” synchrony groups for dichotomization.

Results: A disproportionate number of ASD and ASD-Par participants were classified as low synchronizers at 83% and 73%, respectively, as compared to 40% of Controls ($X^2 = 14.43, p < .001$). The average PLVs of the ASD and ASD-Par groups were not statistically different from one another ($p=.89$), but were both significantly lower than the Control group (PLVs, ASD: .298, ASD-Par: .299, Control: .436, ps<.05).

Conclusions: Results of this study provide compelling early evidence of disruptions in spontaneous rhythmic synchronization of speech in autism in a non-social context. Such mechanistic differences may underlie downstream speech and pragmatic language characteristics, including speech prosody and synchronizing one’s prosody with that of their social partner’s. That this pattern emerged in clinically unaffected parents suggests that it may be influenced by genetic variability associated with autism. Taken together, spontaneous audio-motor synchronization offers an objective, measurable, potential endophenotypic marker of autism, warranting further investigation on its impact on broader clinical and language features.

412.167 (Poster) Do Personal Interests Support Word Learning? a Study with Autistic and Non-Spectrum Children

R. J. Luyster, A. Steele, T. Pelletier and S. Arunachalam, (1)Communication Sciences and Disorders, Emerson College, Boston, MA; (2)New York University, New York, NY; (3)Communicative Sciences and Disorders, New York University, New York, NY
Background: Intense interests are often associated with autism, but they are not exclusive to autistic individuals. Up to half of nonspectrum children may have intense personal interests. Despite suggestions that these interests are detrimental across both autistic and non-spectrum children, personal interests in fact seem to support learning of conceptual, factual, and social information. Although it has been noted that intense interests seem to be over-represented in children with strong language skills, few studies have directly addressed the link between personal interests and language learning.

Objectives: We asked whether for children on and off the autism spectrum—learning of new words was more robust when visual stimuli included the personal interest of the child relative to neutral images.

Methods: A Zoom-based study enrolled two groups of children: autistic children (n = 48; mean age 58 months) and non-spectrum children (n = 48; mean age 35 months). Groups did not differ significantly on expressive vocabulary on the MCDI3.

Each child observed two counterbalanced word-learning trials. Trials presented an object/character performing an action (e.g., spinning) and an utterance including a novel word (e.g., “Look, he is kibbing!”). For one trial, the object/character depicted the child’s personal interest (previously determined via caregiver report). In the other trial, the object/character was of neutral interest to the child (per caregiver report).

After each trial, children were tested on their learning of the novel word. Children saw the previous, target action (e.g., spinning) and a different action (e.g., bouncing) side-by-side on the screen. Their gaze was recorded; attention to the target scene when directed to “find kibbing” served as the measure of learning.

Results: Mixed-effects regressions were conducted for each condition within each group with the proportion of looking to the target scene (empirical logit transformed) as the dependent measure. Intercept parameter estimates were evaluated to determine whether children preferred the target scene at above-chance levels. For the autistic group, target preference was above chance in both conditions (neutral \( \beta = 0.52 \), \( p = .014 \); personal interest \( \beta = 0.50 \), \( p = .0086 \)). However, for the non-spectrum group, target preference was only above chance in the neutral condition (\( \beta = 0.53 \), \( p = .0084 \)) (personal interest condition \( \beta = 0.046 \), \( p = .81 \)).

Conclusions: For the non-spectrum children, the incorporation of personal interests resulted in failure to learn a novel word, although they succeeded when stimuli relied on neutral images. These unanticipated results may be due to the conceptual disconnect between the stimuli and the word—that is, the word was not thematically related to the interest. Non-spectrum children may have found this use of their personal interest distracting; future research should explore this possibility.

In contrast, for autistic children, personal interests did not interfere with language learning; invoking these interests resulted in robust mastery of a new word. The critical role of early language for a variety of outcomes indicates the importance of supporting linguistic skills in children with autism; invoking personal interests may be one avenue for supporting this critical skill.

412.168 (Poster) Early Use of Manner and Result Verbs in Autism and Typical Development
K. J. LeGrand and L. R. Naigles, Psychological Sciences, University of Connecticut, Storrs, CT

Background:

Substantial heterogeneity exists in language profiles in autism spectrum disorder (ASD; Pickles et al., 2014). One area of language that might help illuminate this heterogeneity is verb production, as childhood verb diversity predicts language outcomes in ASD (LeGrand et al., 2021). However, semantic components of early verb vocabulary in ASD have not been explored. Recent studies reported that late talkers use a higher proportion of result verbs (e.g., break, clean) than manner verbs (e.g., run, dance), while typically developing (TD) toddlers show the opposite pattern (Horvath et al., 2019, 2021). Given the frequent presence of language delay in ASD, children with ASD might also show differences in manner and result production compared with language-matched TD peers.

Objectives:

This study investigates the early production of manner, result, and internal (e.g., believe, listen, pretend) verbs via analysis of naturalistic language samples.

Methods:

44 children (ASD n=22, TD n=22) participated in six parent-child play sessions, each four months apart; ASD and TD groups were initially matched on expressive language (Table 1). Play sessions were transcribed, and verbs were coded as manner, result, or internal. Verbs that did not fall into these categories were excluded for these analyses. Timepoints at which a child produced zero verbs were excluded for that
child. Here, each datapoint represents one child’s verb usage in one of the semantic categories (as a proportion out of total verb types) at one timepoint, yielding 223 datapoints total in each semantic category.

For group difference analysis, datapoints were binned by children’s total verb vocabulary size: 1-10 verbs (75 datapoints in each semantic category), 11-20 verbs (44 datapoints), 21-30 verbs (51 datapoints), 31-40 verbs (35 datapoints), and 41-50 verbs (15 datapoints). Within each bin, the ASD and TD groups were compared on proportion of manner, result, and internal verbs.

We ran two linear mixed effects models, one predicting proportion of manner verbs and the other predicting proportion of result verbs. In both models, verb vocabulary size (continuous), group (ASD and TD), and the interaction between verb vocabulary size and group were random effects, and participant was a fixed effect.

Results:

No significant group differences emerged in any verb vocabulary bin for manner or result proportions (Figure 1a). For internal verb proportion, the groups differed significantly only in verb vocabulary bin 21-30 (p=.008).

Verb vocabulary size significantly predicted manner and result proportions (p<.001), while group did not significantly predict manner proportion (p=.203) or result proportion (p=.826; Figure 1b). The interaction between group and verb vocabulary size was not significant in either model.

Conclusions:

Overall, as verb vocabulary increased, proportion of manner verbs also increased while proportion of result verbs decreased. ASD diagnosis did not affect this pattern. ASD and TD groups produced comparable proportions of internal verbs at most verb vocabulary levels. These results indicate that early verb vocabulary in ASD and TD is similar with respect to these components of lexical semantics. Broadly, these results support the idea that structural language in ASD and TD may be more similar than different.

412.169 (Poster) Evaluating the Social Communication Development of Multilingual Children with Autism: A Medical Record Review Study

S. Vanegas, Texas Center for Disability Studies, University of Texas at Austin, Austin, TX

Background: Across the world, there are over 7,100 languages spoken (Ethnologue, 2022). However, to date, most research on language development and human cognition has primarily focused on monolingual, English-speaking children and adults (Blasi et al, 2022; Kidd & Garcia, 2022). This focus also persists in autism research (Sweileh et al., 2016; Zeidan et al., 2022); however, an emerging field of study has centered on multilingual language experiences in children with autism (Valicenti-McDermott et al., 2012; Vanegas, 2019). These studies have shown that there may be some benefits conferred to multilingual children (e.g., gestures, math skills). However, much remains to be known about the early social communication development of multilingual children with autism.

Objectives: This study aims to evaluate and characterize the social communication development of multilingual children with autism.

Methods: The data presented here is part of a larger study that examined the clinical profiles of racially/ethnically and linguistically diverse children with autism. Medical records of children between 3 and 12 years of age who visited a developmental disabilities clinic in a large city in the United States were reviewed. Overall, 340 children with autism were included in the present study (83.8% male, 16.2% female), representing Latino (54.1%), Black/African-American (26.5%), white (16.2%), Asian (1.8%), and multi-racial (1.5%) communities. The sample included children who were minimally verbal (29.7%), monolingual (33.2%), and multilingual (37.1%). Languages spoken within this sample include English, Spanish, Akan (Twi), Arabic, Ashanti, Cantonese, Garifuna, Greek, Hindi, Igbo, Italian, Korean, Polish, Portuguese, Punjabi, Romanian, Slovak, and Urdu. Demographic, cognitive, and adaptive behavior data, along with qualitative descriptions of children’s social communication were extracted from the medical records, written reports, and other clinical assessment measures. Qualitative descriptions were coded to allow for synthesis and analysis.

Results: Preliminary analyses showed that minimally verbal children (M = 3.74, SD = 1.56) received their first autism diagnosis earlier than monolingual (M = 5.29, SD = 2.69) and multilingual (M = 5.24, SD = 2.32) children, p < .001. Multilingual children were more likely to reside in a multilingual household (55.6%) than minimally verbal (27.7%) and monolingual children (2.7%), p < .001. Children’s expressive language was coded into developmental phases (Tager-Flusberg et al., 2009), see Figure 1. No differences in developmental phases emerged between monolingual and multilingual children (all p’s > .05); however, both groups were less likely to be in the preverbal and first words phase than minimally verbal children, p < .001. Multilingual children (87.1%) were more likely to point to objects than minimally verbal (48.7%) and monolingual (64.2%) children, p < .001. Additional analyses will evaluate receptive, expressive, pragmatic, and play-based communication and the role of monolingual and multilingual households on social communication among multilingual children.
Conclusions: This study contributes to our understanding of social communication among children with autism who experience life in multiple languages. Studying large, diverse samples of multilingual children with autism is essential to understanding the intersectionality between language and communication development, culture, and autism. These efforts are critical for addressing inequities in autism research.

412.170 (Poster) Examining Multiple Modalities and Forms of Communication in Minimally Verbal Autistic Children during Parent-Child Interactions
C. La Valle, L. Butler, S. Shen, C. Lie, and H. Tager-Flusberg, (1)Department of Psychological and Brain Sciences, Boston University, Boston, MA, (2)Department of Speech, Language, and Hearing Sciences, Boston University, Boston, MA, China, (3)Psychological & Brain Sciences, Boston University, Boston, MA

Background: Social communication is a central feature to the diagnosis of autism spectrum disorder (APA, 2013) and includes verbal and nonverbal behaviors used during social interactions (Anagnostou et al., 2015). The scope of understanding how minimally verbal (MV) autistic individuals are using their communication skills during social interactions remains extremely limited, even though this group comprises one-third of diagnosed autistic individuals (Kasari et al., 2013). Prior work has focused on their difficulties in speech production; however, social communication extends beyond speech (Wetherby et al., 2007; La Valle et al., 2021). The proposed study employs a strengths-based approach to examine how MV autistic children are using multiple modalities and forms of communication and in what ways this influences the parent-child interaction.

Objectives:
- Examine how the child’s modality and form of communication influences parent responsivity.
- Explore whether the parent’s modality of response matches the child’s modality of communication.

Methods: Natural language samples (NLSs) of remote parent-child interactions were collected. NLSs of 20 MV autistic children (Mage=83.90 mo., 13 males) were analyzed using SALT software (Miller et al., 2011). MV was defined as using 20 different spontaneous words in a 15-minute sample (Butler et al., 2022). Families were recruited through the SPARK match registry. Child communication modality (La Valle et al., 2020; Özçalışkan et al., 2016): gesture, speech, gesture+speech combinations, and AAC. Child communication form: precise forms included: reach/point gestures, intelligible speech, and supplementary gesture+speech combinations (gesture contributes additional information to the speech); imprecise forms included: reach/point approximations, partially intelligible speech, and other gesture+speech combinations (unintelligible speech accompanied by a gesture). Parent response type: contingent-parent verbal or nonverbal response is related to the child’s social communication; non-contingent-unrelated to the child’s social communication; and no response (Choi et al., 2020). Parent responses that are contingently related to the child’s communication can support language development (Tamis-LeMonda et al., 2014). Parent response was coded in the two utterances immediately following the child’s social communication. Parent modality of response: gesture, speech, gesture+speech, and AAC.

Results:
For gesture, speech, gesture+speech, and AAC modalities, of the 20 participants, 15% used four modalities, 45% used three modalities, 30% used two modalities, and only 10% used one modality of communication. 1) The highest proportion of contingent parent responding occurred for child-initiated gesture+speech combinations (Fig.1A). Child gesture+speech combinations was related to more contingent responses (r=.871, p=.001). The proportion of contingent and non-contingent responses did not differ by form (z=-.40, .16, p=.690, .867; Fig.1B). 2) Across the child’s modalities of communication, parents most frequently responded using speech (Fig.2A-2D).

Conclusions: MV autistic children are using multiple modalities and forms of communication during the parent-child interaction. The incorporation of gesture which adds semantic information to the speech assists in augmenting parent responsivity; however, the precision of the child’s communication form does not influence how the parent responds. Findings highlight the importance of focusing on their communicative strengths and extending beyond only aspects of speech to consider multiple modalities of communication to obtain a more comprehensive understanding of their social communication abilities.

412.171 (Poster) Examining the Implementation Feasibility and Adherence of LENA Technology in a Multi-Site Sample of Toddlers with Social Communication Delays and/or ASD
M. Jiménez, N. Nadwodny, W. L. Stone, A. Wainer, B. R. Ingersoll, and A. S. Carter, (1)Psychology, University of Massachusetts Boston, Boston, MA, (2)Psychology, University of Washington, Seattle, WA, (3)Department of Psychiatry, Rush University Medical Center, Chicago, IL, (4)Psychology, Michigan State University, East Lansing, MI, (5)Department of Psychology, University of Massachusetts Boston, Boston, MA

 outliers were excluded from the analysis. LENA recordings were analyzed using the LENA software. Results: A total of 61 toddlers (Mage=24 months, 30 males) were included in the analysis. The LENA recordings were made in the child’s home environment, and the recordings were transcribed and analyzed. The findings showed that toddlers with social communication delays and/or ASD had lower levels of speech and activity levels compared to typical toddlers. Conclusions: This study highlights the importance of using LENA technology to assess social communication in toddlers with social communication delays and/or ASD.

Results:
The LENA recordings were analyzed using the LENA software. Results: A total of 61 toddlers (Mage=24 months, 30 males) were included in the analysis. The LENA recordings were made in the child’s home environment, and the recordings were transcribed and analyzed. The findings showed that toddlers with social communication delays and/or ASD had lower levels of speech and activity levels compared to typical toddlers. Conclusions: This study highlights the importance of using LENA technology to assess social communication in toddlers with social communication delays and/or ASD.

Conclusions: This study contributes to our understanding of social communication among children with autism who experience life in multiple languages. Studying large, diverse samples of multilingual children with autism is essential to understanding the intersectionality between language and communication development, culture, and autism. These efforts are critical for addressing inequities in autism research.
Background: Families of children with social communication delays and/or suspected autism spectrum disorder (ASD) often struggle to navigate barriers associated with standardized assessment and early intervention services (e.g., waitlists, costs,) (Bivarchi et al., 2021). The Language ENvironment Analysis (LENA) System is a wearable audio-recorder that captures linguistic input and output within the home (Dykstra et al., 2012). Previous literature has demonstrated this technology’s feasibility among preschoolers with suspected ASD; however, few to none have reported comprehensive demographic data that demonstrates accessibility across an ethnorracial, socioeconomic, and linguistically diverse sample (Sulek et al., 2020; Pawar et al., 2017). In this abstract, we examine the feasibility and adherence of LENA technology across a multisite, community-based sample, which is not replicated by other literature.

Objectives: Our aim was to outline potential barriers, if any, that exist in navigating LENA, a supplemental and naturalistic insight into the child’s linguistic environment. To demonstrate adherence to LENA technology among participants of various identities, we examined demographic data across those who completed and didn’t complete LENA procedures.

Methods: Data collection and coding are ongoing (to date, n=49, 9 girls, age 25 to 60 months) with an anticipated sample of n=85. All participants filled out the demographics form in either English or Spanish. Approximately three-quarters of families provided LENA data. Moreover, no specific demographic characteristics significantly deterred families from accessing the materials and procedures. This demonstrates general adherence to LENA technology in a cross-site community-based sample. Future directions include assessing LENA data as a supplement or even substitution for standard assessment of language ability to increase evaluation accessibility among families.

Results: Chi-squared analyses were run to determine any significant demographic differences between those who completed LENA and those who did not. Neither race (χ²=1.88, p=.171) nor ethnicity (χ²=4.050, p=.132) were significantly related to LENA protocol completion. Similarly, LENA adherence was no different among families below the poverty line (χ²=1.25, p=.263) or below the sample's median income (χ²=0.39, p=.844). Lastly, an independent sample t-test was run to determine whether child age had a significant effect on LENA completion, which yielded no significant differences between groups, with t(77)=-1.471, p=.263, d=-.375.

Conclusions: These results support current literature on the feasibility of remote LENA implementation with toddlers with social communication delays and/or ASD in a diverse sample living in urban and rural regions in the USA. Findings suggest good engagement as approximately three-quarters of families provided LENA data. Moreover, no specific demographic characteristics significantly deterred families from accessing the materials and procedures. This demonstrates general adherence to LENA technology in a cross-site community-based sample. Future directions include assessing LENA data as a supplement or even substitution for standard assessment of language ability to increase evaluation accessibility among families.

A. Pellegrino, A. Jones, S. Dvorak, G. Schnur and S. Faja, (1)Boston College, Boston, MA, (2)Laboratories of Cognitive Neuroscience, Boston Children’s Hospital, Brookline, MA, (3)Harvard College, Cambridge, MA, (4)Boston Children's Hospital, Boston, MA

Background: The Brief Observation of Social Communication Change (BOSCC) was designed as an observational instrument with fine-grained scoring that is sensitive to the level of autism features during parent-child interactions (Grzadzinski et al., 2016). Executive functioning has been linked to the expression of autism features in older children but has received relatively little research attention among toddlers and preschoolers.

Objectives: This study aims to examine whether social communication and repetitive behavioral features of autism are related to concurrent language, cognitive skills, and executive functioning between the ages of 2 and 4 years.

Methods: Data collection and coding are ongoing (to date, n = 49, 9 girls, age 25 to 60 months) with an anticipated sample of n=85. All children were diagnosed with an autism spectrum disorder, which was confirmed via the ADOS-2 and ADI-R. Verbal and nonverbal developmental quotients were computed from Mullen scores. During the parent-child interaction (PCI), children and one of their parents played freely with a variety of toys and were recorded for 10 minutes. BOSCC ratings were applied to yield total, social communication delays and/or ASD in a diverse sample living in urban and rural regions in the USA. Findings suggest good engagement as approximately three-quarters of families provided LENA data. Moreover, no specific demographic characteristics significantly deterred families from accessing the materials and procedures. This demonstrates general adherence to LENA technology in a cross-site community-based sample. Future directions include assessing LENA data as a supplement or even substitution for standard assessment of language ability to increase evaluation accessibility among families.

Results: We first examined concurrent predictors of overall BOSCC scores. Nonverbal developmental quotient (p=.001), verbal developmental quotient (p<.001), and set shifting (p=.066) correlated with overall BOSCC scores. In the full regression model, language significantly predicted BOSCC levels (β=-.43, p=.01). Next, we examined the BOSCC SC subdomain and found significant correlations
with nonverbal developmental quotient ($p=.003$), verbal developmental quotient ($p<.001$), and working memory ($p=.03$). In the full regression model, language ($β=-.56, p=.003$) and working memory ($β=-.36, p=.04$) significantly predicted BOSCC social levels. Finally, we examined the BOSCC RRB subdomain and found significant correlations with nonverbal ($p=.02$) and verbal ($p=.01$) developmental quotients. In the full regression model, neither nonverbal ($β=-.20, p=.27$) nor verbal ($β=-.24, p=.18$) developmental quotient significantly predicted the BOSCC RRB.

Conclusions: Our preliminary results suggest that features of autism expressed while playing with a familiar person are predicted by language, cognition, and executive function. Interestingly, overall features were predicted by language ability, whereas social features were predicted by both language and working memory ability. Although repetitive features correlated with nonverbal and verbal developmental level, these abilities appear to account for shared variance in predicting RRB features. These initial findings suggest that assessing – and potentially targeting with intervention – language, cognition, and executive function may support the functioning of autistic toddlers and preschoolers.

**412.173 (Poster) Experiences of Individuals with Autism in Communicating with Others with and without Autism**

**H. De Laer, A. D. Nijhof and J. R. Wiersema**, (1)Faculty of Psychology and Educational Sciences - Ghent University, Ghent, Belgium, (2)Department of Experimental Clinical and Health Psychology, Ghent University, Ghent, Belgium

Background: Having social interaction difficulties is one of the main criteria for the diagnosis of autism. However, according to the double empathy theory (Milton, 2012), these social interaction difficulties do not only stem from the individual with autism, but are rather due to a mismatch between neurologically different interaction partners. This would mean that in addition to individuals with autism finding it difficult to interact with neurotypical individuals, neurotypical individuals also find it difficult to communicate with and interpret the behavior of individuals with autism. According to the theory, individuals with autism are also expected to find it easier to communicate with other individuals with autism. The research on this topic is however limited and mainly based on anecdotal evidence.

Objectives: The goal of this study is to gain insight into the experiences of a large sample of adults with autism of their communication with adults with and without autism.

Methods: An online questionnaire was constructed and distributed through different social media channels. 415 individuals with an autism diagnosis from Belgium and the Netherlands filled out the questionnaire. The participants consisted of 100 male participants, 302 female participants, 5 non-binary participants, 2 trans male participants and 6 participants who preferred not to disclose their gender with ages ranging from 18 to 75 years and a mean age of 40. The questionnaire consisted of demographic questions, 14 closed questions, in which they directly compared the communication of adults with and without autism and 6 open-ended questions where they were asked to mention a particular person with or without autism they know, and what makes interaction more difficult or easier with that person.

Results: The closed questions were analyzed using two proportion z-tests and ordinal logistic regression. Overall, answers on the closed questions revealed that adults with autism find it significantly easier to communicate with other individuals with autism compared to neurotypical individuals on different communication domains. This was the case for preference to communicate and being more inclined to communicate with someone with autism but also feeling better understood, better able to understand and estimate someone’s thoughts and feelings, being at ease and being themselves, having to camouflage less, being less tired during and after communication and finding it easier to interpret unspoken rules when their interaction partner also had autism. For body language however, there was no significant difference in the ease with which they could understand the body language of individuals with or without autism. The results of the open-ended questions supported our findings from the closed questions and revealed various interesting themes on the differences in communication between individuals with and without autism. For example, many individuals with autism indicated they camouflage a lot less when they know they interact with another individual with autism.

Conclusions: Our findings indicate that adults with autism experience verbal communication to be easier with other adults with autism than with adults without autism.

**412.174 (Poster) Exploring Interactions in Inclusion Classrooms: The Case of Vicarious Accounts**

**K. Bottema-Beutel** and **S. LaPoint**, (1)Lynch School of Education and Human Development, Boston College, Chestnut Hill, MA, (2)University of North Carolina-Chapel Hill, TEACCH Autism Program, Carrboro, NC

Background: Autistic students are often on the periphery of social networks (Locke et al., 2010). Traditional views of autism draw causal connections between autistic children’s social-communicative repertoires and their social inclusion. However, contemporary research has explored the role of non-autistic people in interaction, including how they construe mundane characteristics (e.g., appearance) as evidence that autistic people are less suitable social partners than non-autistic people (Sasson et al., 2017). These interpretations may negatively impact autistic people's social opportunities. In this study, we focus on how non-autistic social partners— such as paraprofessionals and classmates— make sense of autistic students’ social conduct in classroom interactions. Autistic students are often assigned paraprofessionals to assist with academics and facilitate peer interactions. However, it is not clear that paraprofessional support actually improves autistic children's social opportunities; instead, they may inadvertently deflect peer engagement (Giandreco et al., 2010).
In this conversation analytic (CA) study, we describe how paraprofessionals are involved in interactions between autistic students and non-autistic classmates. CA is a sociolinguistic method for analyzing social conduct, which assumes interactive moves are sequentially and contextually embedded. Social behavior can be systematically analyzed to determine how interlocutors co-construct interactions. One type of social action that featured prominently in our dataset is accounts, which are provided to address unanticipated behavior (Scott & Lyman, 1968). Rejections, departures from routines, or violations of preference organization are often preceded or followed by accounts (Raevaara, 2011).

Objectives: To explore how accounts are made relevant to classroom interactions, and the interactional consequences of those accounts.

Methods: Teachers, paraprofessionals, and students from three elementary classrooms participated. Classrooms were video-recorded three times, for thirty minutes each session. Participants’ talk and non-verbal conduct were transcribed using (CA) conventions (Jefferson, 2004). We selected transcripts of small-group activities that included autistic students (n = 4; 3 female; 3 White, 1 Hispanic), a paraprofessional (n = 4 White females), and non-autistic classmates (n = 7; 6 female; 3 White, 3 Hispanic), and analyzed them on a turn-by-turn basis.

Results: 66% of all identified accounts were provided to explain autistic students’ conduct, and 44% of these accounts were provided vicariously; that is, by someone other than autistic students. Vicarious accounts are unusual in CA research on non-disabled adults, as interlocutors generally avoid claiming epistemic authority over others’ conduct (Heritage & Raymond, 2005). Vicarious accounts have interactional consequences because they are often provided to a third party (e.g., non-autistic classmates). This shifts participation frameworks so the person whose behavior is deemed accountable becomes the topic of talk, rather than a participant in talk (Goffman, 1981). Interestingly, paraprofessionals provided accounts for autistic students’ mundane social actions—such as cutting paper, retrieving materials, or describing events with unexpected specificity—that were not discernible as threatening intersubjectivity.

Conclusions: Because autistic children’s behavior can depart from normative expectations, vicarious accounts are an informative phenomenon for understanding how perceived deviations are made relevant to interaction, and how construing mundane behavior as accountable can position autistic students as outsiders to interaction. Our findings have relevance for paraprofessional training.

412.175 (Poster) Expressive Communication in Naturalistic Conversations: Objective at-Home Assessment of Lexical Maturity, Morphosyntactic Complexity, and Talkativeness in Autism

Background:

Challenges in social communication and interaction are a core symptom domain in autism. Novel therapies are under development to help individuals with these challenges. However, standardized measures often lack the sensitivity to detect subtle improvements in communication ability over time, and are both expensive to administer and reliant on human judgment. Expressive Language Sampling (ELS) through structured conversations has emerged as a promising way to measure expressive communication abilities (ECA) in autism. ELS is typically performed in a clinical setting with a trained conversation partner or physician. Here, we examine naturalistic conversations with family members in home settings that may be more representative of everyday speech.

Objectives:

Quantify ECA in autistic individuals using transcriptions of natural conversations recorded at home. Assess relationships between morphosyntactic complexity, lexical maturity, and talkativeness, and establish convergent validity with clinical anchors.

Methods:

90 autistic and 45 neurotypical NT individuals between the ages of 5 and 45 participated in a non-drug observational study (NCT03611075). Participants were asked to record a 5-minute conversation at home with a conversation partner once per week over a 12-week period. Manual transcriptions were obtained for 51 autistic and 19 participants. A neural network pipeline from STANZA1 was applied to transcriptions from 385 conversations to classify part-of-speech (PoS) tags. Morphosyntactic complexity was assessed through relative usage of PoS classes. Lexical maturity was quantified by calculating the average Age of Acquisition (AoA) using previously
published ratings. Finally, total words spoken was used as a measure of talkativeness. Clinical anchors were the Expressive Communication subscale of the Vineland Adaptive Behavior Scale (VABS) and the verbal component of the Stanford-Binet Intelligence scales abbreviated battery IQ (SB5 ABIQ-verbal). Convergent validity of the quantitative features was tested using Pearson’s R against clinical scales.

**Results:**

For all three measures of ECA, we identified features showing convergent validity against one or both clinical scales. Average AoA of words from the most common PoS classes (nouns, verbs, adverbs, adjectives) was significantly correlated with verbal IQ. Relative usages of PoS classes on the other hand, were significantly correlated with both verbal IQ and expressive communication where higher abilities were associated with increased adverb and reduced noun usage. Total words spoken per conversation were associated with both anchors, although inspection of the scatterplots indicates that this likely reflects greater talkativeness in participants with higher communication and verbal abilities. Finally, for all aforementioned features, we found a clear separation between NT and autistic participants with lower ECA but failed to distinguish between NT and autistic participants with higher ECA.

**Conclusions:**

It is feasible to quantify various aspects of ECA from dyadic conversations recorded by autistic individuals and their study partners at home. In this study, we showed that key lexical features gathered using ELS methodology correlate significantly with established measures of language and communication (parent report and direct assessment). ELS carries great potential as a method to monitor subtle changes in social communication behavior during clinical trials.

**412.176 (Poster) Extraction and Analysis of Acoustic Features from Italian-Speaking Children with Autism Spectrum Disorder**

**F. Beccaria**, G. Gagliardi and D. Kokkinakis,
(1)Autism in Context. Theory and Experiment (ACTE), Université Libre de Bruxelles, Brussels, Belgium, (2)Department of Classical Philology and Italian Studies, University of Bologna, Bologna, Italy, (3)Department of Swedish, Multilingualism, Language and Technology, University of Gothenburg, Gothenburg, Sweden

**Background:** The persistent difficulties in social interaction and communication that characterize Autism Spectrum Disorder can be accessed by investigating the quality of language. Indeed, these deficits involve the presence of anomalies in speech production and understanding, which find an expression at the acoustic and prosodic levels of linguistic analysis.

**Objectives:** The main aim of this work is to propose a speech pipeline for the extraction of Italian speech biomarkers typical of ASD by conducting an acoustic and phonological analysis. Moreover, we will highlight the strengths and difficulties of this kind of investigation introducing new topics for further research.

**Methods:** The poster will present the analysis of a speech corpus of 14 Italian-speaking children with ASD and 14 controls (C). The corpus is demographically balanced (age 6-10, 8;1 ± 1;3. Sex: 3F, 11 M) and homogeneous at the diatopic level (origin: Prato, Pistoia, Florence).

First, we extracted the acoustic features by using eGeMAPS (openSMILE; Eyben et al., 2015), specifically ideated for the study of impaired speech. Then, we implemented the Mann-Whitney U-test to select the features with the most statistically significant distance in the production of the two groups.

Secondly, we conducted a parallel extraction regarding the pitch (F0 mean and standard deviation). We propose this additional analysis because pitch varies according to some demographic traits of the speaker (sex, age, height) and the literature presents opposite trends. For this task, we used Praat to have more flexibility in the manipulation of the extraction. We set the F0 range between 70 and 400 Hz (Patel et al., 2020).

Finally, we conducted a comparison between the results of the two methods excluding female participants to verify if the trend of pitch changes when the participants are not mixed.

**Results:** Table 1 shows the features selected between the ones extracted. They are related to prosody, quality of voice, loudness, and spectral distribution.

Jitter, shimmer and HNR are usually investigated together to describe the emotional prosody and the quality of voice. The same trend found on our corpus is recorded in previous studies on languages other than Italian (Bone et al. 2015; Kissine & Geelhand 2019). Moreover, spectral flux is usually investigated together with shimmer and jitter to describe speech impairments (Haider et al., 2019). Nevertheless, if we consider the studies related to autistic speech, there are few that describe this feature because of the different methodologies used during the extraction.
Finally, the values of pitch extracted by eGeMAPS and Praat show the same trend. It is higher in ASD than in controls, both if we considered the corpus mixed and the one with only the male speakers. However, the pitch does not show a statistically significant difference between the two groups (Table 2).

Conclusions: These results, although preliminary, seem to confirm the presence of phonetic alterations of speech associated with the disorder. Further studies could improve the accuracy of the pipeline proposed by doing a qualitative analysis of the results and considering other linguistic and paralinguistic domains (e.g., morphological, pragmatic, and gestural analysis).

412.177 (Poster) Facial Expression Production in Young Children with ASD

L. Baran, I. Dinstein, T. Barami, C. Sofer and L. Soskin, (1)Negev Autism Center, Ben Gurion University of the Negev, Israel, Beer Sheva, Israel, (2)Cognitive and Brain Sciences Department, Ben Gurion University, Beer Sheva, Israel, (3)Ben Gurion University in the Negev, Beersheba, Israel, (4)Ben Gurion University of the Negev, Beer Sheva, Israel

Background:

Children with Autism Spectrum Disorder (ASD) have difficulties in social communication that include, among other symptoms, qualitative and quantitative impairments in producing facial expressions. Previous studies have reported that individuals with ASD display fewer facial expressions that often look odd/atypical and are not directed at others, in contrast to typically developing controls. These studies have mostly relied on manual coding of video recordings of individuals with ASD interacting in natural or artificial situations.

Objectives: To examine whether children with ASD differ from children with typical development (TD) in their production of facial expressions as captured in video recordings from Autism Diagnostic Observation Schedule, 2nd edition (ADOS-2) assessments, and analyzed using automated facial analysis software.

Methods:

We examined video recordings from 20 children with ASD and 8 children with TD ages 3-8 years old who completed assessments using modules 2 or 3 of the ADOS-2. These modules include tasks that require the child to sit at a table, making their face more clearly visible to a stationary camera. All children with ASD and none of the TD children reached the ADOS-2 cut-off for ASD. Video recordings were then analyzed using Py-feat software that detects the movement of different facial muscles (i.e., action units) and a pre-trained algorithm that identifies the presence of specific facial expressions (e.g., happiness, anger, surprise, etc...) on individual frames.

Results:

Happiness was the most dominant expression across children, which was present in .07-.08 percent of video frames in the ASD and TD groups respectively (other expressions were rare and were not analyzed). Groups did not differ in the frequency or duration of smiles. However, significant differences were apparent in the quality of smiles across groups. This was apparent in significantly stronger activation of several AUs including the inner brow raise, jaw drop and eye widening. We further analyzed smile quality by representing each smile as a vector of the activated AU and then measuring the Euclidian distance between smile vectors of individuals in the two groups. Smiles of individual children with ASD differed from the average of their group significantly more than smiles of individual TD children (ASD: mean=.49, sd=.15, TD: mean=.3, sd=.05, p>.005), demonstrating that children with ASD smile in an idiosyncratic, activating different sets of AUs.

Conclusions:

These findings suggest that when assessing facial expressions during social interaction with an adult, children with ASD tend to produce smiles that look different from those of TD children and are more unique and idiosyncratic compared to TD controls. These results indicate the importance of examining not only the presence of facial expressions but also their shape (i.e., pattern of activated facial muscles) to quantify and examine the “uniqueness” of expressions in young children with ASD.

412.178 (Poster) Factors Affecting Parental Concerns: Evidence from India

S. Suswaram, T. Liu, B. Perelmutter and A. Bhattashali, (1)Psychological and Brain Sciences, Boston University, Boston, MA, (2)Boston University, Sargent College, Boston, MA, (3)University of Kansas, Lawrence, KS

Background:

Health care systems in many Low- and Middle-Income Countries (LMICs) require parents to fund and advocate for their autistic children’s developmental needs; for example, behavioral interventions are out-of-pocket expenses for those living in India. Levels of parental
concerns drive parents’ advocacy efforts and shape child development. Parental factors like childrearing supports and child abilities, such as communication skills, may influence parental concerns, which in turn rely on families’ cultural backgrounds. Current data on parental concerns emerge from a Western context. Without an understanding of the factors affecting parental concerns in LMICs, research aimed at supporting children and their families might have limited applicability.

Objectives:

We examined (1) if parental concerns about various aspects of their children’s behavior were related to parent factors like childrearing supports and (2) children’s communication skills affected this relationship within the context of India.

Methods:

This survey data is part of a larger mixed-methods study aimed at understanding parent perspectives on early intervention and quality of life. Eighty-two parents of children with Autism Spectrum Disorders (aged 3 to 8 years) rated their concerns over their child’s communication abilities, behavioral meltdowns, social skills, and self-injurious behaviors using a scale ranging from 0 to 100. Parents also provided information regarding their marital status, childrearing supports, employment, education, and household income (parent factors). Parent-reported child communication abilities were categorized into those relying on non-verbal or single-word communication (minimally verbal; \( n=47 \)) and those producing at least phrase-level speech (verbal; \( n=35 \)). Correlations were drawn using the Spearman’s rho correlation, as the data were ordinal and continuous. Due to the exploratory nature of the study, we do not correct for multiple comparisons.

Results:

In an exploratory analysis, first we investigated if parental concerns could be treated as a unified construct. Using correlation matrices, we found that different aspects of parental concerns were indeed positively correlated (Table 1). In our second step, we examined the associations of parental concerns as a whole with parent factors (Table 2). Parental concern held a significant moderate positive correlation with childrearing supports, \( r=.258, p=.019 \). Parents’ employment, education, household income, and marital status did not significantly correlate with parental concerns. Childrearing supports did not significantly correlate with parental concerns among parents of children who were minimally verbal, but held a significant high positive correlation with parental concerns, \( r=.466, p=.005 \) (Table 2).

Conclusions:

The findings suggest that childrearing supports substantially influence parental concerns; however, the relation varies based on parent-reported child communication abilities. Surprisingly, parents receiving childrearing supports were more concerned about their children’s behavior. Possibly, type of childrearing supports may influence levels of parenting concerns. For example, some childrearing supports may provide respite and allow parents to notice more areas of concerns in their children. Future confirmatory research should examine types of childrearing supports and their impact on parent and child variables, including communication skills in India and other LMIC contexts. Further, we also need research examining the lack of association between parental concerns and parent factors and the role of culture in this relationship.

412.179 (Poster) Both Children with and without Autism Commonly Align Their Language with That of Their Caregivers

R. Fusaroli, E. Weed, D. A. Berger and L. R. Naigles; (1)Aarhus University, Aarhus, Denmark, (2)Psychological Sciences, University of Connecticut, Storrs, CT

Background: Linguistic repetitions are a controversial topic in Autism Spectrum Disorder (ASD). ASD has long been associated with echolalia, the persistent repetition of one’s interlocutor’s utterances. The literature on echolalia suggests that children with ASD repeat a lot, without there being a communicative or language-learning purpose. At the same time, research on linguistic repetitions in typically developing (TD) children and adults is increasingly showing that repeating is a skillful social activity, and it helps create shared engagement, common ground and even scaffold language acquisition. Depending on which literature is accessed, children with ASD might be expected to repeat more or less than typically developing ones.

Objectives: We take a systematic and nuanced stance on linguistic repetitions in children with and without ASD: we distinguish exact repetition, rate, and level, as well as lexical, syntactic, and semantic repetitions in a large quasi-naturalistic corpus.

Methods: We analyzed spontaneous speech in 67 parent-child dyads from a longitudinal corpus (30 minutes of play activities, 6 visits over 2 years). We included 32 children diagnosed with ASD and 35 linguistically matched TD children (mean age at recruitment respectively 32.76 and 20.27 months). Alignment was calculated using the ALIGN Python library (Duran et al., 2019). We first contrasted child alignment in actual conversations with that in surrogate pairs formed by a parent and a child from two different dyads. We used Bayesian multilevel zero-and-one-inflated beta regression models. This accounts for the propensity of children to align at all (rate), the proportion of the caregiver’s utterance repeated when the children actually align (level), and exact repetitions, as a function of diagnostic group and visit.
Control analyses adjust for Vineland Socialization (VS), Mullen Expressive Language (MEL) and Visual Reception (MVR). Lexical repetitions were regressed out from syntactic and semantic repetitions to minimize confounds.

Results: We found a small number of exact repetitions in both groups (roughly 1% of utterances); moreover, children with ASD increased their use of repetitions over time (at final visit, 1.2% in ASD vs. 0.7% in TD). Partial repetitions were much more frequent: children reused caregivers’ words at high rates regardless of diagnostic group (24% of utterances at first visit). Partial repetitions of words increased in frequency (but not level) over time, and did so faster for TD children (at final visit: 33% for ASD and 40% for TD); and the same happened for partial repetition of syntax (from 20% of utterances at first visit to 23% for ASD and 43% for TD at last visit) and semantic alignment (from 0.34 semantic similarity at first visit to 0.37 for ASD and 0.44 for TD at last visit). See figure below.

Conclusions: Children with and without ASD commonly re-used the words, syntax and topics of their caregivers. However, they did so in a productive way: building new utterances on partial repetitions only (as qualitative analyses reveal). Interestingly, children with ASD developed this skill at a slower rate than those without, contrary to previous findings using less fine-grained methods.

412.180 (Poster) Autistic Children Are Faster at Turn-Taking, More Strongly Driven By Their Own Tempo, and Less Coordinated with Their Interlocutor Than Neurotypical Controls

Background: Turn-taking during communication is a near-universal phenomenon that requires tight coordination between interlocutors, and functions as a key driver of perceived interaction quality (NguyenEtAl2021). A number of studies have found delayed turn-taking in autistic individuals (i.e., longer response latencies) relative to neurotypical (NT) controls, but results are surprisingly heterogeneous. More importantly, it remains unclear whether atypical latencies can be attributed to: (1) basic linguistic factors, (2) autism-related socio-cognitive impairments, or (3) an altered pattern of reciprocal online adjustments during natural conversation.

Objectives: Assess whether autistic children present slower or faster turn-taking latencies compared with NT peers during telephone-based voice sample collection, and whether this might be due to atypical dynamics of interpersonal adjustment between interlocutors.

Methods: 18 autistic children (5 females; mean age=9.33±2.4 years; mean IQ=115±16; 62 recordings) and 16 NT NT children (11 females; mean age=9.75±2.84 years; mean IQ=116±12; 61 recordings) children, matched on age (p=0.65), and IQ (p=0.85), participated in 3 brief telephone-based conversations about birthday party planning with a research assistant and played a face-to-face matching game with their parents three times (N.B., longitudinal data collection from 7 sessions for 48 participants will be reported in May 2023). Response latencies were modeled following an ex-gaussian distribution (LindsayEtAl2019), while interpersonal adjustment was modeled using dyadic coupling (FerrerEtAl2013), which separates self-regulation (the tendency to maintain one’s specific average response latency, so that a longer latency is followed by a shorter one and vice versa) and adjustment (the tendency to follow the interlocutor’s previous response latency).

Results: Autistic participants responded slightly faster than NT controls across tasks (e.g. during a Matching game, autistic: 1180ms, 95%CI 473ms-1887ms; NT 1350ms, 761ms-1989ms, evidence ratio for the difference (ER): 4). Adult interlocutors of autistic children also responded more quickly (autistic: 930ms, 95%CI 210ms-1620ms; NT: 1160ms, 620ms-1660ms; difference: 230ms, -40ms-570ms, ER=4).

Autistic participants had a higher tendency to self-regulate (negative autocorrelation of successive response latencies): -0.09, 95%CI -0.15--0.03, ER=44, Fig1A; and a lower tendency to adjust to others than NT participants: -0.07, 95%CI -0.14-0.02, ER=11, Fig1B. Adult interlocutors of autistic participants had a higher tendency to self-regulate: -0.03 95%CI -0.1-0.03, ER=4.84, Fig1C. Adult interlocutors displayed a weak tendency to compensate for their partner’s tempo regardless of their diagnostic group (difference: -0.02 95%CI -0.12-0.09, ER=1.49, Fig1D): faster response latencies were responded to more slowly and vice versa.

Conclusions: In contrast to prior research, autistic participants and their interlocutors displayed slightly faster turn-taking. Their response latencies were more driven by the individual’s baseline tempo, and showed less adjustment to their interlocutor. Crucially, the results hold across familiar and unfamiliar interlocutors, telephone and face-to-face conversations.

Nguyen et al. (2021). A systematic review and Bayesian meta-analysis of the development of turn taking in adult-child vocal interactions. Child Development

412.181 (Poster) Natural and Unexpected Bilingualism in Autism
N. Meir and I. Hindi, (1)Department of English Literature and Linguistics, Bar-Ilan University, Ramat Gan, Israel, (2)Bar-Ilan University, Petch Tikva, Israel

Background: It has been suggested that around 62.5% of children with ASD demonstrate unusual islet of abilities or “splinter skills” which represent relative strengths compared to peers with typical development (Zhukova. Talantseva, & Grigorenko, 2021). There is evidence of several cases of independent and spontaneous acquisition of languages among individuals with ASD (Smith & Tsimili, 1995). Recently, a case study of an eleven-year-old boy who spontaneously acquired English was described in the literature (Zhukova et al., 2021). Unlike other bilingual children who acquire their second language via interaction with close family members, this group of children accomplishes second-language learning independently and spontaneously.

Objectives: The current study investigated language and Theory of Mind (ToM) abilities in autistic children who acquire their languages via naturalistic input and those autistic children who show ‘unexpected bilingualism’, in which one language is learned via non-interactive sources such as the Internet and/or TV.

Methods: In the current study, forty English-Hebrew-speaking children (aged 4-10) participated: 8 autistic children who learned English via the Internet, 12 autistic children and 20 children without ASD for whom English was the home language. Detailed background questionnaires were administered to all children in the study. Verbal and non-verbal ToM skills were measured via a battery of tasks. Morpho-syntactic skills were measured using LITMUS Sentence repetition tasks (Marinis & Amron-Lotem, 2015). All children were tested twice (once in Hebrew and once in English). Children and parents were interviewed regarding the mode of acquisition and language preferences. Additionally, children were assessed using ADOS-2 (Lord & Rutter, 2012) to re-establish their diagnosis and to evaluate their severity of autism.

Results: A large variation in performance was observed across all the groups, yet no significant differences were found between the groups on any of the measures.

Conclusions: The findings of current study show that bilingualism does not impede language and cognitive development in autistic children. Thus, parents of bilingual children should be advised to maintain dual language exposure for their children. Furthermore, we show that paths to language acquisition can be different: children can acquire their two languages via interactive input at home and in educational settings (as in the case of natural bilinguals with and without autism) and via non-interactive media (as is the case for autistic children who acquired English via Internet).

430.031 (Poster) Formal Language and Non-Verbal Intellectual Skills in Autistic Adults: Exploring Profiles across the Spectrum
M. Manenti, S. Ferre, L. Tuller, E. Houy-Durand, F. Bonnet-Brilhault and P. Prévost, (1)UMR iBrain 1253, Inserm, University of Tours, Tours, France, (2)UMR 1253, iBrain, Université de Tours, Inserm, Tours, France, (3)Exac-T, Centre universitaire de pédopsychiatrie, CHRU de Tours, Tours, France, (4)UMR iBrain 1253, Inserm, University of Tours, Tours, France

Background: While many autistic children have difficulties with formal language, notably phonology (sound structure) and morphosyntax (sentence structure) (LeGrand et al., 2021), linguistic outcomes vary greatly across children, and some variability has also been reported for autistic adults (Magiati et al., 2014). However, studies on adults are limited and suffer from methodological and sampling shortcomings. Language tasks are generally ill-adapted to the autistic population (due to pragmatic/memory demands), including adults, and individuals with language impairment (LI), as well as those with Developmental Intellectual Disorder (DID), are rarely integrated into experimental cohorts (Girolamo & Rice 2022). Consequently, there is a lack of understanding of formal language abilities and the interplay between linguistic and non-linguistic intellectual skills in autistic adults. While heterogeneous and homogeneous profiles have been attested in autistic children (Silleresi et al., 2020; see also ICD-11, WHO 2019), research is needed to determine which and how many profiles can be identified in adults (Bradshaw et al., 2020).
Objectives: Our study meant to fill this gap by using a sentence repetition (SR) task and a nonword repetition (NWR) task specifically designed to ensure controlled assessment of morphosyntax and phonology respectively. These tasks, LITMUS-SR-FR-Adults (Tuller et al., 2021) and the adult module of LITMUS-NWR-QU-FR-Adults (Ferré et al., 2022), were built after child repetition tasks that have proven to be efficient for identifying LI in autistic children (Silleresi et al., 2020).

Methods: The repetition tasks were administered to 41 French-speaking autistic adults (ages 18-56, M=30.7), half of whom had been diagnosed in adulthood, either with (14/41) or without DID, and to 41 age-matched controls. Receptive vocabulary, working memory (WM), and nonverbal IQ (NVIQ) were also assessed. Information about autism severity was gathered via the SRS-2 (Constantino & Gruber, 2012).

Results: Results on morphosyntax and phonology showed greater variability in autistic individuals (Interquartile Range (IQR) = 24.9 and 25.3 respectively) compared to controls (IQR = 4.5 and 8.3) (Figure 1). Although performance on SR and NWR correlated significantly with WM and NVIQ, the strongest correlations were found across language variables (SR, NWR, and vocabulary). After controlling for language variables, correlations with WM and NVIQ were no longer significant. A K-means cluster analysis performed on nonverbal abilities and formal language revealed two profiles (Figure 2), with mainly homogeneous results (i.e., nonverbal and language scores either both high/average or both low). Only four individuals, at the edge of the clusters, showed more incongruent profiles. No significant difference was found between the clusters for autism severity. Finally, additional analyses conducted separately for morphosyntax and phonology yielded similar clusters.

Conclusions: SR and NWR tasks informed by linguistic theory are robust measures of formal language abilities allowing for exploration of cognitive profiles across the spectrum. Profiles in adulthood seem mostly homogeneous, in line with the hypotheses of ability alignment (Howlin et al., 2014; Simonoff et al., 2020). Further testing currently underway and subtype validation strategies (van Rentergem et al., 2021) should reveal whether incongruent profiles remain infrequent. Importantly, language difficulties appear to be unrelated to autism severity.

430.032 (Poster) From Noun Bias to Verb Bias: Similar Word Learning Processes Among Mandarin-Exposed Children with and without ASD
Y. E. Su and L. R. Naigles, (1)Child Language Lab, School of Foreign Languages, Central South University, Changsha, Hunan, China, (2)Psychological Sciences, University of Connecticut, Storrs, CT

Background: Novel word-learning studies revealed that English-exposed preschoolers with autism spectrum disorder (ASD) observe the universal noun bias principle, i.e., by mapping a novel word onto the novel object, when novel actions and objects are presented together (Swensen et al., 2007). Mandarin Chinese, a verb-friendly language, differs from English by allowing pervasive drops of noun arguments. Conflicting findings exist about whether Mandarin-exposed typically-developing (TD) toddlers adopt a noun bias or verb bias in word learning (Tardif 1996; Waxman et al., 2013), while few studies have investigated how children with ASD learn novel words in a verb-friendly language.

Objectives: To investigate whether word learning processes in Mandarin-exposed children with and without ASD are guided by universal principles of human language or/and by specific features of the target language.

Methods: Utilizing the Intermodal Preferential Looking paradigm (Naigles & Tovar, 2012), we investigated word learning processes in 39 20-29-month-old TD toddlers and 46 36-69-month-old preschoolers with ASD exposed to Mandarin. To evaluate possible developmental trend, the participants were divided into subgroups by a median split of age (Table 1). The two ASD subgroups had more autistic behaviors than the two TD groups (ps < .001), while the two TD groups had higher expressive language levels than the two ASD groups (ps < .001 between the TD/older and the ASD subgroups). Novel actions and objects were presented in side-by-side videos, and the child was tested whether she would map a novel word onto an object or an action.

Results: ANOVAs yielded significant trial x age interactions for three percent looking to match measures, Testtotal: F (1, 81) = 16.41, p < .001, Test1×half: F (1, 81) = 9.12, p = .003, Test2×half: F (1, 81) = 15.92, p < .001. For both children with and without ASD, the younger groups looked longer at the match (i.e., objects) during the test than the control trials, whereas the older group looked more at the nonmatch (i.e., actions) during the test than the control trials. Specifically, the TD/younger group looked longer at the objects during the total, t(17) = 2.54, p = .01, and the 2×half, t(17) = 2.29, p = .02, of the test than the control trials, and the ASD/younger group showed such pattern during the 2×half of the test than the control trials, t(23) = 1.86, p = .04. Contrastively, the TD/older group looked longer at the actions during the total, t (20) = 2.12, p = .02, and the 1×half of the test, t (20) = 2.23, p = .02, than the control trials, while the ASD/older group exhibited such pattern during the 2×half of the test than the control trials, t(21) = 2.34, p = .02.

Conclusions: Similar as TD toddlers, Mandarin-exposed preschoolers with ASD alter from noun bias to verb bias in word learning as they grow. Regardless of the diagnoses, children’s word learning processes may be initially guided by universal principles of human language and later shaped by specific features of the target language.
Background: Despite having normal hearing, a considerable number of children with autism reported classroom noises as explicitly agonizing sensory experiences (Cooperative Research Centre for Living with Autism, 2018) and exhibited varying degrees of speech-in-noise perception (SPIN) issues. Growing evidence suggests that hearing assistive technology (HAT) is a viable solution to the SPIN issue in children with autism spectrum disorder (ASD). However, very little is known about its efficacy in tonal language speakers.

Objectives: This study compared sentence-level SPIN performance between Chinese children with ASD and neurotypical (NT) controls and evaluated HAT use in improving the ASD group’s SPIN performance and ease of SPIN difficulty.

Methods: Children with ASD (n=26) and NT children (n=19) aged 6-12 performed two adaptive tests in steady-state noise and three fixed-level tests in quiet and steady-state noise with and without using HAT. Speech recognition thresholds (SRT) and accuracy rates were assessed using adaptive and fixed-level tests, respectively. Parents or teachers of the ASD group completed a questionnaire regarding children’s listening difficulty under six circumstances before and after a ten-day trial period of HAT use.

Results: No significant difference in SRT was found between the two groups. However, the ASD group showed a significantly lower accuracy rate than the NT group in noise, and the ASD group’s accuracy rate decreased significantly with background noise, but the NT group did not. There was a general improvement in listening difficulty ratings across all conditions after the device trial.

Conclusions: The findings indicated inadequate SPIN in the ASD group and provided an opportunity to adopt a relatively more sensitive measure to gauge SPIN performance among children. In response, the ASD group’s markedly increased accuracy rate in noise during HAT-on sessions confirmed the feasibility of HAT for improving Mandarin speakers’ SPIN performance in controlled laboratory settings, and the ASD group’s reduced post-use ratings of listening difficulty provided evidence for the benefits of HAT use in daily scenarios.

Background: Language delay (LD) is suggested to be one of the earliest manifestations in children with autism although not all autistic individuals are diagnosed with LD. Previous studies have shown that autism and LD both have a strong genetic predisposition; however, few studies have tested the degree to which the same genetic influences underlie autism and LD. Objectives: We aimed to use the classical twin design to assess the degree to which the genetic influences on autism also associates with LD. Methods: Data were collected from participants in the Child and Adolescent Twin Study in Sweden (CATSS). CATSS is an ongoing population-based study of twins born in Sweden since 1992. The families are contacted when the twins are 9 or 12 years of age to complete a structured association of participants in the Child and Adolescent Twin Study in Sweden (CATSS). Current age information of autism diagnosis was collected from NPR. We used the classical twin design to first estimate the degree to which autism and LD associates with LD. Methods: Data were collected from participants in the Child and Adolescent Twin Study in Sweden (CATSS). CATSS is an ongoing population-based study of twins born in Sweden since 1992. The families are contacted when the twins are 9 or 12 years of age to complete a structured association of participants in the Child and Adolescent Twin Study in Sweden (CATSS). Current age information of autism diagnosis was collected from NPR. We used the classical twin design to first estimate the degree to which autism and LD associates with LD.

Methods: Children with ASD (n=26) and NT children (n=19) aged 6-12 performed two adaptive tests in steady-state noise and three fixed-level tests in quiet and steady-state noise with and without using HAT. Speech recognition thresholds (SRT) and accuracy rates were assessed using adaptive and fixed-level tests, respectively. There was a general improvement in listening difficulty ratings across all conditions after the device trial.

Conclusions: The findings indicated inadequate SPIN in the ASD group and provided an opportunity to adopt a relatively more sensitive measure to gauge SPIN performance among children. In response, the ASD group’s markedly increased accuracy rate in noise during HAT-on sessions confirmed the feasibility of HAT for improving Mandarin speakers’ SPIN performance in controlled laboratory settings, and the ASD group’s reduced post-use ratings of listening difficulty provided evidence for the benefits of HAT use in daily scenarios.
Background: While socioeconomic disadvantage has been associated with poor health outcomes and access to care there is little research on how this may affect outcomes of social communication in autistic populations. Socioeconomic status has been noted to predict receptive language (Brignell et al., 2018) and correlate with symptomatology (Chandler et al., 2015) in autistic children, as well as contribute to the worsening of attention problems (Santiago et al., 2011). Research also suggests that ADHD symptoms can exacerbate social impairment in autistic children (Factor et al., 2017). Despite this, there are gaps in the research regarding characteristics of individuals with socioeconomic disadvantage that may influence these effects. The Area Deprivation Index uses census data to operationalize socioeconomic disadvantage based on geolocation (Hu et al., 2018) and can be utilized to better understand how socioeconomic disadvantage may influence autistic populations. This study addresses gaps in the literature to contextualize influences of socioeconomic disadvantage on communication.

Objectives: The present study aimed to examine factors that influence communication in autistic children (9-15 years). This study examined: a) the relationship between socioeconomic disadvantage and communication skills in autistic children; b) whether attention problems mediate the relationship between area deprivation and communication in autistic children; and c) whether race, support needs, and who the child lives with influence the strength of the relationship between these factors.

Methods: The sample comprised 375 children with an autism diagnosis collected through the Simons Powering Autism Research for Knowledge (SPARK) Research Initiative. Multiple regression and mediation analyses were used to examine the relationships between socioeconomic disadvantage (Area Deprivation Index), communication level (Vineland-3 Communication Domain Standard Score), and parent-reported attention problems (via CBCL), with additional predictors of age, sex, race, and number of parents in the household.

Results: The sample represents a diverse population and wide range socioeconomic need (See Table 1 for descriptive statistics). Attention problems were evaluated as a mediator of the effect socioeconomic disadvantage has on communication level in autistic children using hierarchical regression and mediation analyses. Attention problems did not significantly mediate the association between socioeconomic disadvantage and communication level (95% CI: -1.394 to .088). However, higher levels of socioeconomic disadvantage were significantly associated with lower communication levels, B=-2.38, SE=1.01, t(374)=-2.34, p<.05 and accounted for 1.4% of the variance in communication level, R2= 0.014. Additionally, higher levels of attention problems were significantly associated with lower communication levels, B=-.64, SE=.08, t(374)=-7.57, p<.001 and accounted for an additional 13.2% of the variance in communication level beyond that explained by socioeconomic disadvantage, sr2 = .132. The other paths tested were insignificant. Additional planned analyses further examine potential mediators, moderators, and covariates that influence communication levels.

Conclusions: Results indicated a small but significant association between socioeconomic disadvantage and communication level across a broad range of socioeconomic need, but not when controlling for attention problems. Additionally, attention problems were associated with communication level. This study will improve understanding of the relationships between socioeconomic disadvantage and outcomes that extend beyond what has been previously researched.

Background: Autism spectrum disorders (ASD) research has increased over the past 30 years, advancing knowledge of ASD in preschool-aged and higher-functioning individuals. However, few studies have been conducted on non-verbal (NV) and/or minimally verbal (MV) children with ASD. The few studies that have addressed this topic have reported varying levels of prevalence. Older studies suggested that 50% of ASD children were non-verbal (NV) or minimally verbal (MV), while more recent reports offer impairment estimates in the 25% - 35% range. Most of the published studies have reported findings were based on convenience or clinical samples, a significant limitation.

Objectives: Objectives of this cross-sectional study were twofold. The first objective was to determine the proportion of children with ASD that are NV and/or MV. The second objective was to describe the distribution of verbal capacity in ASD children according to demographic factors, including age, sex, race/ethnicity, and socioeconomic status (SES).

Methods: Data were collected from an active ASD surveillance system representing children born in 2008 and residing in New Jersey in 2016. Retrospective information on demographic factors and diagnosis, functional status and language capacity was collected for each child from medical and special education records. Language capacity at and after age 48-months was defined by a tripartite classification: verbal - the child can answer and speak in sentences; minimally verbal - the child can speak in 1 or 2-word phrases; and, non-verbal - the
child produces sounds but not intelligible words. Pearson Chi-square test was used to compare differences between verbal and NV/MV cases. Data were stratified by sex, race, and median household income - a proxy of socioeconomic status (SES).

Results: 1055 8-year-old children were identified with ASD through active surveillance (32 per 1,000). Fifty-six children had insufficient information to determine language capacity and were excluded from consideration, leading to analysis of data from 999 children. We identified 188 ASD children as NV/MV by age 8-years, representing 18.8% of the total ASD population and yielding an NV/MV prevalence estimate of 5.7 per 1,000. A majority of the ASD population had verbal language capacity, consistent with an estimated prevalence of 24.6 per 1,000. Among the 380 children who satisfied the case definition for NV/MV at age 4-years, 206 (54.2%) showed verbal capacity by 8-years (p<0.0001).

While there were no sex differences, we identified variations by race/ethnicity and SES. 8.4% of Non-Hispanic White children were NV/MV, compared to 31.0% of Non-Hispanic Black and 24.6% of Hispanic children. Similarly, ASD children in High-SES areas had higher odds of having verbal capacity compared to children from Low-SES areas (AOR: 3.0; 95% CI: 1.8-5.3).

Conclusions: In the large diverse population, we found that nearly 1-in-5 ASD children showed minimal verbal language capacity at 8 years, a lower proportion than indicated by previous estimates. Approximately half of NV/MV children at age-4 showed verbal language at 8-years, a significant change. The findings reveal disparities in verbal language capacity across demographic groups, thereby highlighting the need for more effective screening and intervention programs, especially ones targeting under-served populations.

430.037 (Poster) Joint Engagement and Communication Skills in Pre-Schoolers with Autism Spectrum Disorder: An Exploratory Study Using Naturalistic Play Context
C. Pinto and S. Tiwari, (1)Department of Speech and Hearing, Manipal College of Health Professions, Manipal, India, (2)Department of speech and hearing, Manipal academy of higher education, Manipal, India

Background:
Joint engagement is a behavioural state where the child and their social partner are actively engaged with the same object or event. Supported joint engagement requires child and caregiver involved with the same object or event, without actively acknowledging the caregiver’s participation. While, in coordinated joint engagement, both child and caregiver are not only actively involved with the same object or event, but needs child to actively and repeatedly acknowledging the caregiver’s participation. Joint engagement is a precursor to communication development, which needs detailed assessment, particularly in children with Autism Spectrum Disorder (ASD).

Objectives:
The objective of the study was to explore the joint engagement and communication skills of pre-schoolers with ASD using naturalistic play context.

Methods:
The present study was conducted in the speech pathology outpatient units of two private hospitals in a South Indian town. The sample included ten parent-child dyads, of children with ASD in the age group of 3 to 5 years (mean age: 3.7 years). All children received a diagnosis of mild to severe ASD by qualified psychiatrists based on DSM 5 criteria, and were attending communication intervention. Written informed consent was obtained from the respective parents before the assessment. The Communication Play Protocol (CPP) was then administered (with authors’ permission) to measure child’s joint engagement and communication skills during a video-recorded play session with their respective parents.

CPP is a semi-structured observation context that is designed to display how a young child communicates with an adult in a naturalistic environment. In this study, we assessed three communicative functions, namely, requesting, social interaction, and commenting, using two five-minute scenes, for each communicative function. Each parent-child dyad session was videotaped, and each session comprised of 6 scenes and lasted for around 15 minutes. The video recordings were then independently coded by the researcher and another clinician (who was blinded to the study). Both coders received training on identifying the specific variables of child’s joint engagement and communication skills as per CPP manual. The inter-rater reliability between the two examiners was computed using Cohen’s Kappa test.

Results:
The results of this study indicate early joint engagement and communication skill deficits in children with ASD during an uninterrupted play session with a parent. Table 1 shows the responses for joint engagement and communication skills across ten pre-schoolers with ASD. The CPP allows observing the parent and the child in various communicative contexts and time. Children in this study spent most of their time in object engagement and rarely participated in supported or coordinated joint engagement. Most of the participants in the current
study preferred playing with toys and rarely responded or initiated communication with their parents. Inter-rater reliability between the raters revealed a substantial agreement, Cohen’s Kappa, $k=0.6$ ($p<0.001$).

Conclusions:

The findings from this study revealed that a naturalistic play method can be used to assess joint engagement and communication skills in preschoolers with ASD. Additionally, this play method can be used in children with varying severity levels of ASD.

430.038  (Poster)  Language Impairment in Autism Studies Underreport Participant Sociodemographics: A Systematic Review

Background: Racially and ethnically minoritized autistic individuals face disparities in diagnosis and service delivery, as well as in research representation. Clinicians and researchers commonly use age-referenced assessments, as well as the research literature, to qualify school-aged individuals for services and to characterize their language profiles. However, the representation of minoritized autistic individuals in research using such assessments is not well understood, with important implications for the generalizability of findings. To address this gap, this systematic review examines reporting practices for participant sociodemographics in studies using age-referenced assessments to evaluate language impairment in autistic school-age individuals.

Objectives: This review asked two primary research questions: 1) What are the reporting practices for participant sociodemographics in terms of race and ethnicity, gender and sex, and SES in studies on LI in autistic school-age individuals? 2) What are the sociodemographics in the literature to date?

Methods: The authors preregistered this systematic review with PROSPERO (CRD42021260394) and followed the Preferred Reporting Items for Systematic Reviews and Meta-Analyses protocol. Database searches took place on August 11, 2021, with an updated search on September 20, 2022, and included Linguistics and Language Behavior Abstracts, PsycINFO, PubMed, and the Directory of Open Access Journals from 1980 to 2022. Search terms included three essential concepts: autism, language, and age. Two coders independently screened and evaluated articles, discussing any disagreements until they reached consensus.

Results: A total of 60 studies qualified for this review addressing linguistic dimensions relevant to language impairment. Of these studies, just 17 (28%) reported any information on participant race and ethnicity. When reported, white participants comprised the majority of participants. Just 17% of studies reported any information on socioeconomic status; more studies reported at least some information on gender or sex (52%). No reporting was intersectional (e.g., reporting race by ethnicity by gender), even in studies with sufficiently large sample sizes.

Conclusions: A systematic review of studies of LI in autism, focusing on ages 3-21, indicates insufficient reporting of participant race and ethnicity and a systematic exclusion of minoritized individuals, who despite being a global majority, continue to be persistently underrepresented in research on language in autism. Replicable reporting presents a simple and necessary step; however, in addition, systemic action is necessary to mitigate inequity in this area of research.

430.039  (Poster)  Language Skill Difference Further Distinguish Social Sub-Types in Children with Autism
Q. Li, W. Zhao, X. Zhang, X. Song, S. Zhu, X. Shou, F. Meng, X. Xu, R. Zhang and K. M. Kendrick, (1)Chengdu University of Traditional Chinese Medicine, Chengdu, China, (2)University of Electronic Science and Technology of China, Chengdu, China, (3)Peking University, Beijing, China

Background:

Language skills are a key aspect of heterogeneity in Autism Spectrum Disorder (ASD). Given that language delay has been associated with a greater incidence of autism (Eigsti et al., 2011; Howlin, 2003), a more in depth and systematic focus on language development (i.e. atypicality inverbal performance) could help with diagnosis and early intervention for children with autism.

However, no studies to date have assessed language skills in the three autism social subtypes compared with typically developing (TD) individuals. Such a cross-subtype study will help provide a better understanding of the status of language development in autistic children with different social phenotypes and identify which ones might benefit particularly from language training interventions.

Objectives:
This study investigated heterogeneity in language skills of children with autism and their relationship with different autistic social subtypes (aloof, passive, active but odd-ABO).

Methods:

A sample of 120 children aged from 3 to 6 years participated in the study, 90 diagnosed with ASD (10 girls (11%), mean age = 4.62 years, SD = 0.58) and 30 age-matched TD children (6 girls (20%), mean age = 4.68 years, SD = 0.45.

Measures included Autism Diagnostic Observation Schedule (ADOS) the Autism Behavior Checklist (ABC), 1988), Childhood Autism Rating Scale (CARS), and Gesell Developmental Schedules (GDS), which all contain a language subscales, and the Beijing Autism Subtyping Questionnaire (BASQ). Language proficiency and skills (performance) were evaluated using a validated Chinese vocabulary test for young children for concrete and abstract words. The TD group were only administered GDS and the vocabulary test.

Results:

We found negative correlations between autism symptom severity (via ABC, CARS, ADOS) but positive correlations between GDS and expressive language skill. The BASQ identified social subtypes exhibited different levels of impaired expressive skills (aloof > passive > active but odd). Using a categorical approach, for concrete items the aloof and passive subtypes exhibited worse performance compared to the TD group but not the active but odd subtype. For abstract items all three subtypes were impaired relative to the TD group. Furthermore, with a dimensional approach, there was a strong negative association between dimension scores and language expressive performance across subjects on the aloof dimension. Linear regression models indicated that the aloof dimension contributed most compared to the other two dimensions in terms of language performance. A ROC analysis showed that language skill performance for both concrete and abstract words could effectively discriminate between the different ASD subtypes.

Conclusions:

Overall, results demonstrate that the different social subtypes in autism are associated with different levels of language skill and can also be accurately identified using this metric. Importantly, our findings also suggest that use of patterns of individual scores on the dimensions of the three subtypes may be informative for predicting language problems with scores on the aloof dimension being positively associated with them. In addition, considering that different social subtypes exhibited different levels of expressive language skills future language interventions should be considered, particularly for individuals scoring high on the aloof dimension.

Background: Although language deficit is not a defining criterion in Autism Spectrum Disorder (ASD) (DSM–V, APA 2013), lexico-semantic knowledge, among other language skills, is an area of difficulty for some children with ASD (Kwok et al., 2015). The linguistic situation of Arabic is characterized by diglossia, which involves the use of two language varieties within the same speech community for a complementary set of functions (Ferguson, 1959; Al Birini, 2016): Spoken Arabic (SpA) for everyday speech and Standard Arabic (StA) for formal speech and writing. The lexicon composition of Palestinian-Arabic-speaking preschoolers disperses over three categories (Saiegh-Haddad & Spolsky, 2014): (1) identical words in StA and SpA (21.2%), (2) cognate words which show partial overlaps in phonological forms (40.6%) (3) unique-SpA words which are not used in StA (38.2%). School aged children make use of (4) unique StA words (Asli-Badarneh, et al., 2022). Surprisingly, a recent multiple-case study showed that Tunisian-Arabic-speaking children with ASD favored StA in their everyday conversations (Kissine et al., 2019).

Objectives: The present study investigated, for the first time, lexico-semantic skills of Palestinian-Arabic-speaking children with and without ASD in the context of diglossia. Research on language skills in Arabic-speaking children with ASD is scarce although Arabic is the fifth most spoken language globally (Simons & Fennig, 2018).

Methods: 77 Palestinian-Arabic-speaking children aged 4-11 were recruited in 3 groups matched for age, all scoring within non-verbal IQ: Children with TLD (n=39), children with ASD with intact (ASD+NL: n=19) and with impaired structural language (ASD+LI: n=19). Two tasks were administered: (i) an Arabic noun and verb production tasks (Armon-Lotem et al., 2020) containing 30 nouns and 30 verbs; (ii) a narrative production task (Gagarina et al., 2015). The coding schemata took into consideration lexico-phonological distance between StA and SpA (Identical, Cognate, Unique-SpA, Unique-StA).

Results: Using mixed-effects modelling, for noun production, effects of Group (TLD>ASD+LI, TLD=ASD+NL, ASD+NL=ASD+LI), Distance (Unique-SpA>Cog>Identical) emerged, yet no Group*Distance interaction. For verb production, there were effects of Group,
Narration (storytelling) is an essential social-communication skill that is often impacted in ASD, where differences in social attention may influence aspects of narrative ability, such as connecting narrated events within overarching psychologically- and socially-salient themes. Narrative differences have been reported cross-culturally in ASD, and subtle narrative differences have also been observed among parents, suggesting that narration is a key skill impacted in ASD across language and cultural environments, and even among clinically unaffected relatives who are at increased genetic liability. This study builds on prior work through comprehensive among parents, suggesting that narration is a key skill impacted in ASD across language and cultural environments, and even among clinically unaffected relatives who are at increased genetic liability. This study builds on prior work through comprehensive

Conclusions: The current study investigated lexico-semantic production patterns of children with ASD in Arabic diglossia compared to their peers with TLD. At a group level, children with ASD, similarly to their peers with TLD, rely more on lexical items from their spoken variety (SpA). Nevertheless, a small number of children with ASD+NL use words from StA, the formal variety, even in an oral storytelling task. Note that children are used to stories being read in StA, which might also be a factor. We will discuss this inter-individual variability in terms background factors (e.g., Age, ASD severity).

430.041 (Poster) Linguistic Correlates of Atypical Brain Lateralization for Speech Processing in Children with Autism Spectrum Disorder: An fNIRS Study

B. Lai, A. Yi, F. Zhang, S. Wang, J. Xin, S. Li and L. Yu, (1)Autism Research Center, South China Normal University, Guangzhou, China, (2)Department of Child Rehabilitation, Foshan Chancheng Central Hospital, Foshan, China, (3)CFO - The Institute of Photonic Sciences, Barcelona, Spain, (4)South China Normal University, Guangzhou, China, (5)Center for Autism Research, School of Education, Guangzhou University, Guangzhou, MN, China

Background: Atypical speech and language development are prevalent in individuals with autism spectrum disorder (ASD). One candidate mechanism to explain the atypical language profiles of ASD is reduced neural specialization for the processing of linguistic structures. It is well-documented that autistic individuals tend to display reduced or absent leftward hemispheric lateralization in response to speech and vocal sounds. However, it is still unclear that what specific linguistic and phonological component is driving the altered brain lateralization.

Objectives: 1) to explore the feasibility of using functional near-infrared spectroscopy (fNIRS) to measure the brain function of speech-impaired children with autism; 2) to verify whether atypical hemispheric lateralization for language applies to individuals with ASD who speak Mandarin Chinese as their native language; 3) to explore the linguistic and phonological components of the vocal stimuli that may drive the atypical lateralization in autism.

Methods: The participant sample included 20 children with autism (age M =5.8 years, SD = 2.2 years) and 20 age-matched neurotypical (NT) children (age M =6.5 years, SD =1.7 years). The participants wore a 3×11 fNIRS cap covering the bilateral temporal and frontal lobes and were instructed to watch a self-chosen muted cartoon while ignore any sounds. The auditory stimuli were presented in a block-design via headphones. Four stimulus conditions were constructed with parametrically decreasing linguistic content: naturally spoken paragraph in native language (linguistic integrity preserved), native speech with scrambled word order (phonological integrity preserved), nonnative speech (speechness preserved) and music (nonspeech). Neural responses were mainly represented by estimates of changes in oxyhemoglobin (HbO) concentration.

Results: Both the autism group and the NT group displayed significant response to native speech and nonnative speech in the left temporal lobe. The autism group showed significant bilateral responses to scrambled native speech, but we did not observe such changes in the NT group. In the NT group but not the autism group, leftward lateralization of the temporal activities systematically decreased with decreasing linguistic content. Lateralization was absent for the scrambled native speech condition driven by enhanced response in the right hemisphere in the autism group only.

Conclusions: Our results replicated previous findings of atypical hemispheric specialization for speech processing in autism in the context of Mandarin Chinese. By using auditory stimuli with parametrically varying linguistic content, we demonstrated that linguistic status drives the hemispheric lateralization in the NT children but not in the ASD children. Instead, hemispheric lateralization for speech was absent at the phonological level, which was associated with abnormally heightened right-hemisphere activities. The findings provide further evidence for understanding insufficient language-specific neural specialization in autism.

430.042 (Poster) Narrative As a Critical Pragmatic Language Skill: A Cross-Contextual and Cross-Linguistic Study of Narrative Ability in ASD and First-Degree Relatives

E. J. Landau, K. Nayar, J. Xing, G. E. Martin, C. J. Stevens, X. Kang, J. Guilfoyle, J. C. Lau, P. Wong and M. Losh, (1)Communication Sciences and Disorders, Northwestern University, Evanston, IL, (2)Communication Sciences and Disorders, St. John's University, Staten Island, NY, (3)University of Kansas, Lawrence, KS, (4)The Chinese University of Hong Kong, Ma Liu Shui, Hong Kong, (5)Communication Sciences and Disorders, Neurodevelopmental Disabilities Lab, Northwestern University, Evanston, IL

Background: Narration (storytelling) is an essential social-communication skill that is often impacted in ASD, where differences in social attention may influence aspects of narrative ability, such as connecting narrated events within overarching psychologically- and socially-salient themes. Narrative differences have been reported cross-culturally in ASD, and subtle narrative differences have also been observed among parents, suggesting that narration is a key skill impacted in ASD across language and cultural environments, and even among clinically unaffected relatives who are at increased genetic liability. This study builds on prior work through comprehensive
characterization of narrative ability across multiple contexts and two typologically-distinct languages, and examination of associated visual attention patterns in ASD and first-degree relatives, with the goal of informing potential genetic and cultural/linguistic influences on narrative in ASD.

**Objectives:** To comprehensively characterize narrative ability across multiple contexts (high, low structure) and languages (English, Cantonese), and assess its relationship with visual attention in ASD and first-degree relatives (parents, siblings).

**Methods:** Participants included 369 English-speaking individuals from the United States (US), comprised of 56 autistic individuals (US-ASD), 42 siblings of autistic individuals (US-ASD-Sib), 161 parents of autistic individuals (US-ASD-Par), 49 typically-developing controls (US-TD), and 61 parent controls (US-TD-Par). For cross-cultural comparisons with the ASD and control groups, 71 Cantonese-speaking individuals from Hong Kong (HK) were included, with 22 HK-ASD and 49 HK-TD participants. Participants narrated a wordless storybook presented on an eye tracker (First Telling; high structure) and retold their narrative after a delay without visual cues (Retell; low structure). Key aspects of narrative quality were coded (e.g., thoughts/emotions, causal attributions). Percent of fixations towards the storybook’s social elements were analyzed in relationship to narratives within groups.

**Results:** Neither the US-ASD nor US-ASD-Sib groups showed expected context differences (i.e., benefit from viewing the illustration in First Telling), with comparable narratives across contexts. Other groups showed stronger narrative performance in the First Telling. Within contexts, group differences emerged only in US groups—ASD, sibling, and parent groups produced narratives with fewer descriptions and causal attributions of characters’ thoughts/emotions relative to controls groups. Culture effects emerged between US and HK groups for descriptions of thoughts/emotions (fewer descriptions in HK), but there were no diagnostic effects. More visual attention to social stimuli was associated with higher-quality First Telling narration in the US-ASD-Par and both HK groups.

**Conclusions:** Context differences suggest that autistic individuals and their siblings from the US did not benefit from visual support/organization the same way as control and HK groups. Results support previous findings of narrative difficulty in usage of cognitive/emotional terms. Similar patterns in relatives provide evidence of a potential genetic link, but evidence of cultural effects was also strong. Variable gaze-narrative associations across groups may implicate differential strategies for integrating visual attention and language simultaneously (First Telling) and asynchronously (Retell). Additional analyses will further detail visual attention patterns associated with ASD and cultural groups. In sum, findings implicate key features of narrative ability impacted in ASD, first-degree relatives and across cultures, and others that are malleable to environmental (cultural) and linguistic influences.

**430.043 (Poster) Narrative Production Abilities of Hebrew Speaking Children with ASD**

**T. Naman** and **N. Sukenik**, (1)Education, Bar Ilan University, Ramat Gan, Israel, (2)School of education, Bar Ilan University, Ramat Gan, Israel

**Background:**

Narrative production is a social-communicative ability that children improve as they get older. In order to produce a coherent narrative, the child must master and integrate linguistic skills at both the micro-level (semantics, syntax, phonology and pragmatics) and the macro-level (narrative structure, coherence, reference to characters). Children with ASD were previously found to struggle with different aspects of narrative production, a fact that has a profound effect on their social functioning. Previous studies that tested the narrative production skills of children with ASD found that compared to typically developing children, children with ASD had low syntactic scores (Capps & Losh, 2003) and low production scores of emotional terms (Rumph et al., 2012). Most previous studies focused on English speaking children with ASD and tested a specific type of narrative.

**Objectives:**

The aim of the current study was to test the narrative production of Hebrew-speaking children with ASD on five different narratives and compare their productions on a micro and micro level to age-matched TD children.

**Methods:**

Participants included 64 children (32 ASD: mage = 6:5; SD = 94.5; 32 TD: mage 6:52; SD 96.93). Children with ASD all had normal-range-IQ scores. Background variables included a linguistic score, ToM abilities and Nonverbal IQ. Narrative production was tested by elicitation of five different narratives (a personal narrative, a narrative from everyday life—elicitation and retelling; and an imaginary narrative—elicitation retelling). Data analysis was conducted at the micro level and macro level. Between groups comparisons were made on all variables tested and between the different narratives. In-group analysis was made in order to compare the productions between narratives.

**Results:**
Micro-level results found that the ASD group produced more verbs and pronouns on the imaginary retelling narrative and the everyday telling narrative than the TD group. The TD group was found to produce more clauses in all narrative types (except for the personal narrative) and produced more prepositions in both imaginary narratives (told and retold). Furthermore, the TD group was found to produce more mental verbs and conjunctions. No group differences were found on any of the Micro level variables regarding the personal narrative.

Macro-level results showed that the ASD group had higher scores on the goal and reaction variables in both the imaginary narratives while the TD group had higher scores of the attempt and outcome variables in both imaginary narratives and in the everyday telling narrative. Macro level scores indicate that for many children with ASD the comprehension of the narrative was better than its production.

Conclusions:

Results in the ASD group were heterogeneous; some had difficulty constructing the narrative according to the sequence of events while others showed a limited vocabulary alongside syntactic deficits.

This study highlights the fact that the type of narrative has an effect on the production abilities of children with ASD, something that future studies should keep in mind when planning research protocols. The individual differences found in this study show how important it is to systematically evaluate each child before starting an intervention program.

430.044 (Poster) Narrowing the Gap: Acoustic Differences in Autistic Children’s Speech May Shrink with Time and Familiarity

Background: Voice conveys rich information about speakers, including physical health and neurodevelopment. Previous studies have shown that autistic children’s voices differ from neurotypical peers in a variety of ways: for example, autistic children have been found to produce speech with greater jitter and shimmer, lower harmonic-to-noise ratio (HNR), and wider pitch ranges compared to neurotypical children (Fusaroli et al. 2017). However, these findings are often measured in lab-based settings and are rarely assessed over time, leaving questions about feature stability and reliability unanswered.

Objectives: Examine whether acoustic features known to differentiate autistic children from neurotypical peers are stable during a longitudinal home-based telephonic voice collection protocol, and query whether participants’ daily condition affects acoustic characteristics.

Methods: Autistic (n=18, 13 boys, mean age=9.3±2.5 years, mean IQ=115.5±14.6) and neurotypical (n=17, 6 boys, mean age=9.9±2.8 years, mean IQ=118.7±13.8) children participated in a longitudinal telephonic study (results from the final sample of 48 will be reported in May 2023). Participants performed several sessions for seven weeks (one session per week), including a picture description task. We analyzed picture descriptions from the first three sessions. Using openSMILE, we extracted jitter, shimmer, HNR, pitch, and mean, standard deviation, skewness, kurtosis of spectral moments, and calculated durational measures using an in-house speech activity detector. At each session, caregivers reported on children’s sleep, eating, mood, stress, and attention. We built linear mixed-effects regression models to examine longitudinal changes in acoustic variables, covarying for sex and including individuals as a random effect.

Results: Autistic children’s median jitter (β=-0.0001, p<0.001) and shimmer (β=-0.007, p<0.001) values decreased over time, whereas their median HNR (β=0.52, p=0.006) and total pause duration (β=4.89, p=0.042) increased, resulting in smaller group differences in later sessions (jitter: β=-0.001, p=0.005, shimmer: β=-0.01, p=0.001, HNR: β=-0.56, p=0.036, total pause: β=-10.38, p=0.003, Fig.1A-D). Autistic children’s median spectral skewness values (β=-0.78, p=0.017) and pause rate per minute (β=4.26, p=0.047) were higher than those of neurotypical children at the first session, and the group differences did not change over time (skewness: p=0.092, pause rate: p=0.19), suggesting that these might be stable voice markers that differentiate diagnostic groups. Children with less stress produced lower median jitter values (β=-0.001, p=0.014) and those with good attention produced shorter total and mean pause durations (total: β=-8.5, p=0.02, mean: β=-0.27, p=0.014) and higher pause rates (β=1.9, p=0.029) compared to those with more stress or average attention levels, regardless of group or sex (Fig.2A-D).

Conclusions: Results revealed key acoustic features that differentiate autistic children from neurotypical children cross-sectionally, but some were found to change over time and/or be affected by children’s daily stress or attention levels. These results can be used to inform the selection of voice-based biomarkers to monitor intervention response or identify diagnostic group differences, with the goal of finding markers that are stable over time and across changing internal and external conditions.
Background: The discourse marker “um” can be used to serve various discourse functions, including turn-taking (Fischer, 2000). Research finds autistic individuals use “um” less often than non-autistic (NonAu) individuals in discourse contexts where they answer questions during diagnostic testing (Gorman et al., 2016), describe how to play a sport (McGregor & Hadden, 2020), and describe pictures (Irvine et al., 2016). These authors argue that paucity of “um” use is due to autistic individuals’ general pragmatic challenges (e.g., inappropriate turn-taking). However, a recent study reported no difference in “um” usage between NonAu and autistic children during conversation (Boo et al., 2022). This suggests that differences in “um” use may not persist across all contexts.

Objectives: To compare “um” use by NonAu and autistic speakers in other discourse contexts, such as a dialogic exchange versus monologic storytelling.

Methods: Data came from two separate discourse tasks: 12 Autistic and 16 NonAu teenagers were selected from a longitudinal study of early language (Naigles & Fein, 2017). Dialogic language samples were derived via conversation with a researcher, who first shared a personal narrative and then prompted the teenager to talk about a similar experience (e.g., “The other day I lost my keys...Have you ever lost anything?”). While the teenager narrated their own experiences, the adult provided backchanneling responses and comments (e.g., “uh-huh”, “tell me more”). In a monologic discourse task, 20 Autistic and 20 NonAu teenagers were asked to develop and narrate a fictional story to a panel of judges (on a video call) who did not backchannel or comment (i.e., Trier Social Stress Test; Kirschbaum et al., 1993). The four groups did not significantly differ in chronological age, but they did differ in CELF-5 scores, with the Autistic group who completed the dialogic task having the lowest CELF-5 scores among the four groups (Table 1). In both language samples, all instances of “um” tokens were tallied.

Results: “Um” tokens did not differ between Autistic and NonAu teenagers in the dialogic task. In the monologic task, NonAu children produced more “um” tokens than autistic children, \( t(38) = -2.097, p = .043 \). Significant cross-task differences also emerged (\( F(3, 64) = 6.974, p < .001, \eta^2 = .246 \)): the NonAu autistic group from the dialogic task produced significantly more “um” tokens than both the NonAu and autistic groups from the monologic task (Figure 1). This finding remained significant even after statistically controlling for chronological age and CELF-5 scores.

Conclusions: Findings suggest that “um” use differs depending on the nature of the discourse context (i.e., monologic vs. dialogic), not depending on the group. In dialogic exchanges, autistic teenagers use “um” similarly to NonAu peers, suggesting they recognize this marker’s usefulness as a turn-taking device. In monologic contexts, this function of “um” is unnecessary and, thus, used less. Therefore, researchers should carefully consider the nature of the discourse context when they are interpreting between-group differences of “um”; our findings suggest that autistic children’s relatively infrequent use of “um” cannot be due to diagnosis-related differences in turn management.
Results: Changes to the Q-SoCIAL based on participant feedback fell into three main areas: (1) changes in instructions and response options, (2) addition of new questions, and (3) rewording or addition of examples to clarify existing questions. Participants stated that they typically did not read all the instructions in the measure and identified several parts of the instructions as redundant or unnecessary, leading us to consolidate the instructions and emphasize areas of importance. A total of 46 new/restructured questions were added based on participant feedback. For example, there was repeated mention of children feeling exhausted after social interaction, prompting the addition of the item, “My child seems emotionally exhausted after long periods of social interaction.” This item reflects many concerns about autism ‘camouflaging’ and social burnout stated by the autistic community (Lai et al., 2021). The wording of 80 items underwent minor changes based upon participant feedback. Participants provided a great deal of positive feedback on items, endorsing the context dependent-individualized nature of the questionnaire. The Q-SoCIAL consisted of 173 measure items after cognitive interview refinement.

Conclusions: Parents and teachers of autistic children provided important feedback in order to refine the Q-SoCIAL. This feedback resulted in changes to item wording, addition of examples, clarification to instructions, and input on items that should be included. The validation of existing items was reinforced, with strong parent and teacher enthusiasm about the strengths-based, inclusionary approach to understanding their child or student’s social communication. This study has demonstrated that stakeholder perspectives are crucial in measurement development and in capturing individual differences in social communication.

430.047 (Poster) Phonetic Alignment in Semi Naturalistic Conversations

M. Belenger, C. Dumont and M. Kissine, (1)ACTE, Université libre de Bruxelles, Brussels, Belgium, (2)ACTE-ULB, Bruxelles, Belgium, (3)ACTE — Center of research in Linguistics — ULB Neuroscience, Université libre de Bruxelles, Brussels, Belgium

Background:

Phonetic convergence is a natural phenomenon whereby interlocutors unconsciously alter their verbal and non-verbal behaviors to align with those of their conversation partner (Pardo, 2006). Convergence comes along with associated benefits such as conversational fluidity, better cooperation and greater empathy, rapport, and closeness. Accordingly, it also has an impact on the first impression individuals make on other, and influences the quality of the subsequent interactions and the relationships (Soliz & Giles, 2014). Pitch, measured as voice signal fundamental frequency (F0), is the prosodic indexes that has been the most extensively studied in the context of phonetic convergence. A few previous studies suggest autistic individuals tend to converge less than non-autistic individuals (e.g. Lehnert-Lehouilliert et al., 2020). However, these studies involved controlled experimental paradigms, in which participants are asked to read the same list of words before and after a cooperative task. In such context, it appears easier to converge than in a naturalistic conversation.

Objectives:

Studying phonetic convergence in more naturalistic contexts seems crucial to understand the impact it can have on everyday interactions of autistic individuals. This study aims to study phonetic convergence in semi naturalistic conversations by investigation variation in F0.

Methods:

In this study, 30 participants (15 autistic and 15 non-autistic) from 9 to 16 years old (M = 11.2) engaged in a three minute get-to-know talk with the investigator. They were then asked to tell a story based on a wordless picture book. The experimenter always began the task by describing the first page of the book. We analysed mean F0 per sentence, and speech rate form this first segment by the experimenter, as well as at three time points from the child’s speech: when the child starts the story telling, in the middle of it and at the end. We expected greater phonetic convergence (less mean absolute difference) at time point 1 and a progressive shift (greater mean absolute difference) from time 2. We expected non autistic participants to have a greater difference in mean absolute F0 between time point 1 and time point 3, indicating greater phonetic convergence.

Results:

Contrary to our expectation, linear regressions did not show difference in F0 mean absolute and speech rate difference across time. These results seem to indicate that participants, regardless of the group diagnosis, do not converge in a more naturalistic setting.

Conclusions:

This yields interesting questions concerning the methodological choices, as phonetic convergence has found to be weaker in challenging task (Abel, 2015). Narrative tasks could be too difficult for participants to engage in convergence. Furthermore, as raised by Hogstrom et al. (2022), the age difference between experimenter and children could be an explanation to our results, as anatomic development has an obvious impact on F0 and may limit the degree of convergence. Finally, a strong limitation to this study is the small sample size; our method should then be replicated with a larger sample size.

430.048 (Poster) Predictive Validity of Parent-Reported Language Skills in Children with and without ASD
S. Ramos-Cabo, Neurosciences, University of California San Diego, San Diego, CA, Spain; Lindy Lab, University of the Basque Country, Vitoria-Gasteiz, Spain

Background:

Parent reports are widely used to assess early language skills. Evidence shows that these are useful and reliable measures of typically developing (TD) children's language abilities (Dale, 1991; Dale, Bates, Reznick, & Morisset, 1989). However, little is known about their validity in Autism Spectrum Disorder (ASD).

Objectives:

The present study aimed at answering the following research question: Do the language reports of parents of children with and without ASD reliably predict their children's language abilities?

Methods:

A total of 47 parents and their children (31 boys and 16 girls) participated in the study. The sample followed a one-to-one caregiver-child correspondence (i.e., only the primary caregiver filled out the parent questionnaire) and comprised three groups. The ASD group consisted of 16 caregivers and their 16 children (2 females) with a diagnosis of ASD; the HR group consisted of 13 caregivers and their 13 children (7 females) at High Risk for ASD (by virtue of having an older biological sibling with ASD), and 18 caregivers and their 18 children (7 females) conform the TD group.

The Merrill Palmer-Revised Expressive Language Parent Form (MPR Parent Form) and the Merill Palmer-Revised Expressive Language Evaluator Form (MPR Evaluator Form) were used as measures. Caregivers filled out the MPR Parent Form and a clinical psychologist assessed children’s language abilities with the MPR Evaluator Form a year later. The use of the same standardized developmental battery allowed the comparison between the scores provided by parents and clinicians on the same measure (i.e., expressive language skills).

Linear regression was employed to determine whether the scores in parent reports reliably predict children’s expressive language abilities as measured by a clinical psychologist a year later.

Results:

Results show that scores of the MPR Parent Form reliably predict the scores of MPR Evaluator Form (R² = .41, F (3, 43) = 10, p = < .001) (see Figure 1). Results also revealed statistically significant group differences between the ASD and TD groups (t= 3.45, p = .001) but not between the HR and the ASD groups (t= .60, p = .54).

Conclusions:

Our findings suggest that parent reports are a reliable measure of expressive language abilities in ASD as well as in TD.

430.049 (Poster) Profiles of Acoustic Diversity during Autistic Children's Natural Conversations

Background: Autism is a heterogenous collection of behaviors that has been historically pathologized, with limited attention paid to the unique profiles of subgroups within this population. Even after attempting to manufacture homogeneity by restricting variables such as age and IQ within study samples, autistic youth still behave very differently across settings (e.g., language skill as measured by a standardized vocabulary test versus a lunchtime conversation with peers). Autistic prosody, a core component of verbal communication, is especially understudied in naturalistic contexts. This study uses a latent class modeling approach to parse acoustic heterogeneity in the spontaneous conversations of autistic youth, with the goal of identifying acoustic profiles that can be used to develop personalized, evidence-based supports to improve social communication outcomes.

Objectives: This study utilizes an exploratory data-driven, latent class approach to identify homogeneous patterns of speech acoustics that characterize subgroups of autistic youth over the course of a short, naturalistic conversation.
Results: A 3-class model provided the best fit for the data and revealed evidence of homogeneous subgroups with (1) Steady (N=31), (2) Increasing (N=6), and (3) Decreasing (N=13) numbers of speech utterances classified as ‘autistic’ over the course of the conversation (Figure). Group intercepts differed significantly, with the Decreasing subgroup producing significantly fewer utterances classified as ‘autistic’ at the start of the conversation (coefficient=-1.42, Wald test=-3.94, p<.0001). Members of the Increasing subgroup produced growing numbers of utterances classified ‘autistic’ over time (coefficient=.45, Wald test=2.77, p<.01), while the relationship between time and ‘autistic’ utterances was not significant for the Steady or Decreasing subgroups. Class members did not differ on age, sex ratio, IQ estimates, ADOS-2 calibrated severity scores, or SCQ scores, but did differ on word count (Increasing > Steady > Decreasing; est: -58.05, t= -2.40, p=.02), conversational turns (Increasing > Steady > Decreasing; est: -4.74, t=-2.36 , p=.02), and acoustic metrics (Table).

Conclusions: Machine-learning classification of speech utterances renders it possible to parse heterogeneous samples into more homogeneous subgroups that represent how behavior can change dynamically over the course of a conversation, even for demographically matched subgroups. In this exploratory study, we found three subgroups of youth that sound more or less ‘autistic’ over time, with the most talkative group sounding increasingly ‘autistic’ over 5 minutes. This profiling approach holds promise for identifying subgroups that benefit from specific interventions and stands to advance the goal of personalized medicine.

430.050 (Poster) Profiles of Autistic Adults with a Significant Early Interest in Reading
J. Crutcher, D. Saltzman, B. Hernandez, C. Heffner, J. S. Magnuson and J. M. Eigsti. (1)Psychological Sciences, University of Connecticut, Storrs, CT, (2)Educational Psychology, University of Connecticut, Storrs, CT, (3)Department of Communicative Disorders and Sciences, University at Buffalo, Buffalo, NY

Background: Autism spectrum disorder (ASD) is sometimes characterized by a strong interest in skills related to print materials and reading, sometimes called “hyperlexia,” shown by ~20-35% of autistic individuals (Klin et al., 2007; Meilleur et al., 2015). While research suggests that special interests and skills are maintained into adulthood (Collis et al., 2022), little work has examined how early reading manifests in adulthood.

Objectives: The current study examines adult outcomes of early print/reading interests, and how this interest in reading is associated with adult autistic symptomatology and with language-related interests and skills.

Methods: A total of 193 adults participated in an online (Prolific) survey (Table 1): (1) autistic individuals with a self-reported early interest in print or reading (autistic+reading; n=50); (2) autistic individuals with no interest in print (autistic-only; n=93); and (3) non-autistic (NA; n=50) individuals. Participants completed a series of questionnaires regarding sociodemographic characteristics, childhood and current reading habits, the Author Recognition test (a measure of reading frequency), restrictive and repetitive behaviors, other-language proficiency, and the Autism Spectrum Quotient Questionnaire (AQ).

Results: Of 143 autistic individuals, 50 (35%) endorsed a strong or unusual interest in letters or reading at an early age; compared to the NA sample (30%; 15 of 50), the difference was not significant, p=.52. On average, the autistic+reading group reported reading words by 3.8 years old, which was numerically but not significantly younger than the NA group (4.5 years old), F(1,63)=3.1, p=.08. A large portion (42%; 21/50) of the autistic+reading group reported learning to read without explicit instruction, compared to only 20% (3 of 15) in NA, though the difference was not significant, p=0.12. Both the autistic+reading group and autistic-only groups reported stronger circumscribed interests in adulthood than the NA group; Table 1. The autistic+reading group and NA group spent significantly more time reading than the autistic-only group; they also reported reading more complex materials and enjoying reading more. The autistic+reading group was familiar with significantly more authors than the autistic-only group. Interestingly, an association between time spent reading, and ASD symptoms was significant in the autistic-only group and missed significance in the ASD+reading group; Table 2. The early-reading autistic group showed no increased language-learning proficiency.

Conclusions: Autistic individuals with a strong early history in print materials learned to read at an early age (3.8 years), often without explicit instruction, and continued to show an interest in reading as adults, engaging with more complex reading materials, and enjoying reading significantly more than autistic peers without this history. A negative correlation between autistic symptomatology and time spent reading hours, observed in the autistic-only but not the autistic+reading group, may suggest that reading serves a different purpose in this group and provides more pleasure. An early interest in print may have long-term positive effects in autism, by providing an enjoyable and cognitively-stimulating outlet for leisure or work.
430.051 (Poster) The Relationship between Form and Function Processing of Prosody in Autism Spectrum Disorder – Evidence from Mandarin and English Speakers

L. Wang¹, S. Xiao¹, C. Jiang¹, Q. Hou¹, A. H. D. Chan¹, P. Wong¹, A. Yeic¹, T. Williams¹ and F. Liu¹, (1)Shenzhen Research Institute, Chinese University of Hong Kong, Shenzhen, (2)School of Psychology & Clinical Language Sciences, University of Reading, Reading, United Kingdom, (3)School of Public Administration, Nanchang University, Nanchang, China, (4)Music College, Shanghai Normal University, Shanghai, China, (5)Department of Music and Dance, Nanjing Normal University of Special Education, Nanjing, China, (6)School of Humanities, Nanyang Technological University, Singapore, Singapore, (7)The Chinese University of Hong Kong, Ma Liu Shui, Hong Kong

Background:

Studies on how the form versus function aspect of prosody is processed by autistic individuals have mainly focused on speakers of non-tonal languages (e.g., English), and have produced equivocal results. While the samples’ heterogeneous cognitive abilities may be possible contributing factors, the phenotype of prosodic processing in autism may also vary with one’s language background.

Objectives: N/A

Methods:

To explore this possibility, in Experiment 1, we investigated prosodic processing at the form and function levels in 38 autistic and 32 non-autistic speakers of Mandarin, a tone language, while controlling for their musical training experience and cognitive abilities. Participants completed a lexical tone task and an intonation perception task, each containing a function condition and a form condition. In Experiment 2, as a comparison, we examined form processing of prosody in 27 autistic and 52 non-autistic English speakers using the same set of Mandarin tasks.

Results:

The main results from Experiment 1 suggested that the abilities to discriminate lexical tone and intonation were not impaired at either the form or function level in autistic Mandarin speakers, and that these abilities were positively associated with one another in both autistic and non-autistic groups. Additionally, the more severe the ASD symptoms, the worse the form- and function-level of prosodic processing, and musical training experience and cognitive abilities were significantly correlated with prosodic performance for the autistic group mainly. Furthermore, while enhanced prosodic processing has been found in a subgroup of autistic participants, it may not be a general characteristic of the autistic population even for those with long-term tone language experience, as evidenced by the comparable performance between autistic and non-autistic groups. Results from Experiment 2 corroborated the finding of unimpaired form processing of prosody in English-speaking autistic participants across all tasks.

Conclusions:

The present findings reveal typical prosodic processing at both the form and function levels in autism across Mandarin and English speakers and provide evidence for associated pitch processing abilities across levels.

430.053 (Poster) Spatial Language and Cognition in Young Autistic Children

K. E. Prescott¹, K. Crespo² and S. Ellis-Weismer³, (1)University of Wisconsin - Madison, Madison, WI, (2)Boston University, Boston, MA, (3)University of Wisconsin-Madison, Madison, WI

Background: The development of spatial language – the lexical domain describing the features, locations, and relations of and between objects in space – has garnered considerable interest in the neurotypical (NT) literature as an intersection point between linguistic and nonverbal visuospatial skills. Autism spectrum disorder (ASD) is associated with relative strengths in the visuospatial domain but varying abilities in the linguistic domain. This uneven profile has motivated a small number of recent studies to begin investigating spatial language and its relationship to nonverbal spatial cognition in ASD. These previous findings suggest parallels between spatial language and spatial cognition in older autistic individuals, but no research to date has examined this relationship in young autistic children, who on average experience language delays in early childhood. Predictors of spatial language production identified in previous work with older autistic individuals and NT preschoolers include ASD symptom severity and parent spatial language input, though it is not yet known if these factors are relevant to early spatial language development in ASD.

Objectives: The purpose of the present study was to investigate the connection between children’s spatial language production and nonverbal spatial cognition over time during the preschool years. We also examined two potential predictors of spatial language observed in previous literature, ASD symptom severity and parent spatial language input.
Methods: In past work investigating spatial language in NT children of the same age, parent-child interactions have been a primary context for study. Therefore, in the present study, we analyzed transcripts of dyadic naturalistic play interactions between 129 autistic children and their parents over three time points from age 30 to 66 months and administered standardized cognitive and ASD diagnostic assessments at each visit. Transcripts were coded for total spatial word production of children and their parents and “other” (non-spatial) word production. Mullen Scales of Early Learning Visual Reception T-Scores were used as our measure of nonverbal spatial cognition. ASD Symptom Severity was measured by Autism Diagnostic Observation Schedule (ADOS) Calibrated Severity Scores (CSS). Linear mixed-effects models were fit to answer each research question, including “other” (non-spatial) child and parent language as a covariate.

Results: Children’s spatial language production was related to their nonverbal spatial cognition abilities even when accounting for overall language production (Figure 1). Parent spatial input (but not ASD severity) significantly predicted children’s spatial language production over and above the effect of overall language production (Figure 2).

Conclusions: Spatial language is associated with spatial cognition in young autistic children and appears to reflect the interaction of overall linguistic skills and nonverbal spatial cognitive ability regardless of autism severity. Results suggest parent-mediated interventions may be a promising context for increasing spatial language in autistic preschoolers. Targeting spatial language in intervention could also translate to improved academic achievement by bringing children’s attention to spatial features and concepts foundational to learning in science, technology, engineering, and mathematics (STEM), so it will be critical to examine whether parent training can increase spatial language abilities in autistic children in future research.

430.054 (Poster) Speech Timing Is Linked with Language Difficulties in Autistic and Non-Autistic Children

T. Liu, J. Zuk, H. Tager-Flusberg, A. Kershbaum, J. O. Gabrielli and I. Madsen Hardy; (1)Boston University, Sargent College, Boston, MA, (2)Boston University, Boston, MA, (3)Department of Psychological and Brain Sciences, Boston University, Boston, MA, (4)Harvard University, Cambridge, MA, (5)McGovern Institute, Massachusetts Institute of Technology, Cambridge, MA

Background: Prosody, otherwise known as suprasegmental features of speech, includes the intonation, rhythm, and timing of spoken communication. As prosody is an important aspect of pragmatics and social communication, prosodic differences in autistic individuals compared to typically developing (TD) peers are commonly observed. However, these differences have not been clearly quantified, resulting in a lack of understanding of not only how certain prosodic features may differ in autism, but also which particular prosodic features differ (i.e., pitch versus timing). Evidence that timing impairments are vulnerabilities across neurodevelopmental disorders, including autism and developmental language disorder (DLD), suggests timing features of prosody may be particularly sensitive to language ability. However, studies of prosodic differences in autism have not examined prosody’s relationship to language abilities.

Objectives: Characterize prosodic differences among autistic children with and without language difficulty, children with DLD, and TD children, and examine for any sex differences in the prosodic profiles.

Methods: This retrospective analysis included 38 TD children (24 male, \(M=10.3\) years, \(SD=2.27\)), 25 autistic children without language difficulty (ASD; 23 male, \(M=11.2\) years, \(SD=3.35\)), 7 male autistic children with co-occurring language difficulties (ASD_DLD; \(M=11.3\) years, \(SD=2.36\)), and 20 children with DLD (15 male, \(M=11.3\) years, \(SD=2.75\)). Language sample recordings were elicited and transcribed from the ADOS-2’s “Telling a Story from a Book” task. Children’s utterance durations and /f0 (pitch) measures (mean, range and standard deviation) were extracted using Praat. Speech rate (syllables per second) was separately derived for each child. Clinical Evaluation of Language Fundamentals (CELF) and Kaufman Brief Intelligence Test (KBIT) scores were obtained to assess children’s language skills and nonverbal intelligence.

Results: One-way ANOVAs revealed a significant main effect of diagnostic group on children’s speech rate, \(F(3,86)=4.24, p<0.01\). Post-hoc analyses revealed that TD children’s speech rate was significantly faster than the ASD_DLD and DLD groups, \(p’s<0.05\) (see figure). There were no significant main effects of diagnostic group on /f0 metrics. These results were stable with ANCOVAs controlling for sex. These ANCOVAs additionally revealed a main effect of sex on /f0 variation, \(F(1,85)=4.24, p=0.05\), where male children’s pitch varied more than female children’s. Partial correlations controlling for age, sex, and nonverbal intelligence revealed significant relationships between speech rate and children’s CELF Core Language Scores (CLS) in children without language difficulty (TD/AOD collapsed) and children without autism (TD/DLD collapsed), as well as significant relationships between /f0 variation and CELF CLS in children with language difficulty (DLD/ASD_DLD collapsed).

Conclusions: Results suggest timing aspects of prosody, such as speech rate, may be sensitive to detecting language differences among autistic and non-autistic children. The sex difference in pitch variation warrants further examination of sex differences in the prosodic profiles of these populations. Given the heterogeneity in both autism and DLD, better understanding of the relationship between language skills and prosody in these populations will help to better characterize and quantify prosody in autism. Future directions include investigating relationships between prosody and social communication skills and additional timing features of prosody, such as speech rhythm and pause counts/durations.
Background: Attenuated communication is a common and central symptom of autism spectrum disorder (ASD). One of the most common diagnostic methods, the Autism Diagnostic Observation Schedule (ADOS®, Lord et al., 2000), highlights that both changes in prosody and speech rate may indicate ASD. Previous studies have found higher and more varied pitch in autistic people (Fusaroli et al., 2017) and a decrease in the variation of intensity (Ochi et al., 2019). Recently, Lahiri and colleagues (2022) used interpersonal synchrony of spectral, prosodic and lexical features to distinguish between autistic and non-autistic children.

Objectives:

In the current study, we quantify differences in communication between autistic and non-autistic adults on the individual and the dyadic level (Bone et al., 2015). These differences could provide a marker for autism in adults, similarly to findings in children (Lahiri et al., 2022).

Methods:

We analysed the data of 40 dyads of which 14 were control dyads and 26 were heterogeneous and included an autistic participant (autistic: 6 women, age \(M = 32.11, SD = 11.04\); non-autistic: 33 women, age \(M = 30.93, SD = 10.44\)). All dyads engaged in two 10-minute naturalistic conversations, one where they discussed their hobbies and one where they collaboratively planned a meal requiring more back-and-forth between participants (Georgescu et al., 2020). We used praat (Boersma et al., 2021) and the “uhm-o-meter” (De Jong et al., 2021) to extract speech (pitch and intensity) and turn-taking (turn-taking gap, pause-to-turn-ratio, number of turns) features. We used the speech features to calculate each participant’s tendency to adjust their pitch and intensity to the previous turn (turn-based synchronisation). We will use a Support Vector Machine (SVM) with stratified nested k-fold cross-validation to classify dyads based on these features.

Results:

Control and heterogeneous dyads differed in the length of their turn-taking gaps in the mealplanning condition with control dyads reacting faster. Additionally, control dyads had a decreased pause-to-turn ratio, meaning that they took fewer pauses than heterogeneous dyads. There was no difference between dyads in the average number of turns, however, both types of dyad exhibited significantly more turns in the mealplanning condition. Last, we investigated whether there were differences between non-autistic and autistic participants in their tendency to adjust their pitch and intensity to the previous turn. This turn-based synchronisation of pitch was significantly higher in non-autistic participants, but there was no difference between groups for turn-based synchronisation of intensity.

Conclusions:

The people communicating with each other heavily influence dyadic communication. In this study, we have compared two naturalistic conversations between either two non-autistic or one non-autistic and one autistic participant. Our results show a difference of both individual and dyadic features of communication. Turn-based features, especially turn-taking gap and pause-to-turn ratio, also showed a difference mainly in the mealplanning condition. This indicates that differences are more prominent if the conversational setting requires the participants to work collaboratively. Lastly, non-autistic participants showed increased turn-based synchronisation of pitch compared to autistic participants. This mirrors results on other aspects of interpersonal synchrony, for instance motion synchrony.
Objective: To support efforts to design research studies driven by SLPs’ real-world service priority this study aimed to better understand community SLPs’ perspectives on where they believed researchers should focus their efforts. This knowledge can be used to establish research priorities, inform future research strategy, and signal opportunities for collaborative research, thereby advancing SLPs’ practice with autistic children.

Methods: We used an online survey to collect qualitative data from SLPs providing services to preschool children with suspected or diagnosed autism in Ontario, Canada. Participants provided demographic information then responded to the following open-ended questions: What specific research aims should we try to achieve? What clinical problems should we try to solve? What possible solutions should we pilot test? What should be the focus of our research? An inductive, reflexive thematic analysis approach was used to identify patterns of meaning across SLPs’ responses. This method is well suited to answering questions related to people’s experiences (Braun & Clarke, 2012; 2020). To promote credibility and trustworthiness of findings, our research team worked reflexively to control how prior knowledge influenced interpretation of the data.

Results: 131 participants from across the province, with varying degrees of clinical experience working with autistic clients responded to the survey questions. Responses were categorized into three main categories: partnerships, service delivery, and clinical effectiveness. Within each category, we identified 3-4 themes. For each theme, we report on aims to achieve and problems to solve, solutions that should be tested, and research questions to investigate.

Conclusions: This study provides an initial exploration of SLPs’ perspectives on the aims, solutions, and research questions that researchers should pursue to improve real-world SLP service delivery for autistic preschoolers. Participants’ views were complex and wide-ranging yet told a highly patterned story of the overarching aims they believe researchers should focus their efforts on. These included, testing and implementing systems/processes designed to promote collaboration across health professionals (and communities), and generating evidence based clinical decision-making processes and tools, that support efforts to provide equitable, needs-based services.

430.057  (Poster) Stability and Change in Lexical Features: A Longitudinal Telephone-Based Study of Autistic Children

Background: Prior research highlights numerous aspects of linguistic behavior that distinguish autistic and neurotypical children. For example, autistic children tend to use fewer epistemic verbs (e.g., “think”, Tager-Flusberg, 1993) and psychological state terms (e.g., “happy”, Weismer et al., 2011) compared to neurotypical peers. Autistic children also use more nouns during storytelling, suggesting object-focused language production (Boorse et al., 2019). However, longitudinal studies are necessary to determine whether language differences in autistic and neurotypical children are stable over time and across elicitation contexts.

Objectives: Determine whether lexical differences in autistic and neurotypical speech are stable over time, and whether they vary by elicitation context.

Methods: A preliminary sample of autistic (n=17, 12 boys, Mean age=9.33±2.3 years) and neurotypical (n=15, 6 boys, Mean age=10.46±2.7 years) children matched on IQ participated in a home-based longitudinal study over the telephone once a week for seven weeks (results from the final sample of 48 participants will be reported in May, 2023). Using Linguistic and Word Count (LIWC) text analysis software, matching game and picture description samples from the first three sessions were analyzed for the following variables: word count; and the LIWC features: “Big” (i.e., words > 6 letters long); “Analytic”; “Authentic”; “Cognition”; “Affect”; and “Social” words. These categories were chosen based on prior literature suggesting potential group differences in mentalizing language. We constructed linear mixed-effects regression models to track longitudinal changes across sessions by task, with individual participants and age included as random effects. Since groups were not matched on sex ratio, we included sex as a covariate. Finally, we compared children’s word frequency during the picture description task using the weighted log-odds-ratio informative dirichlet prior algorithm (Monroe et al., 2009).

Results: In the matching game (Fig.1), autistic children produced fewer total words (β=-93.20, p=.009) and “Big Words” (β=-2.08, p=.032) than neurotypical peers, and had lower “Analytic” scores (β=-16.17, p=.037) and higher “Authentic” scores (β=20.15, p=.021). Total words and “Big Words” increased in later sessions for both groups (β=69.74, p=.041 and β=11.59, p=.042, respectively), while “Authentic” scores decreased (β=20.15, p=.021). Autistic children also increased their “Social” word production over time, while neurotypical children decreased (β=-2.06, p=.021). There were no group differences in “Cognition” or “Affect” words. For the picture description task (Fig.1), only “Authentic” talk differed by group; again, autistic children had higher “Authentic” scores than neurotypical children (β=15.24, p=.036). Analyses of word frequency (Table 1) revealed that autistic children produced “then” as the most frequent word relative to neurotypical children; more than half (68.85%) occurred as part of a coordinating conjunction or discourse marker (“and then”). On the other hand, neurotypical children produced “like” as the most frequent word, used overwhelmingly as a discourse marker (85.04%).
Conclusions: This study showed that lexical differences in autistic and neurotypical children vary over time and are sensitive to task demands. Analyzing word frequency sheds light on children’s underlying thought processes during natural speech. In the future, frequent at-home language samples could serve as a useful tool for monitoring subtle changes in autistic children’s social communication.

430.058 (Poster) Studies Pertaining to Language Impairment in School-Age Autistic Individuals: A Systematic Review

Background: Language in autism is widely heterogeneous, with significant variation in receptive-expressive language profiles. In addition, diagnosis of autism spectrum disorder (ASD) no longer requires a language delay, such that autistic individual can have co-occurring language impairment. Oftentimes, clinicians and scientists commonly use age-referenced assessments and research findings to qualify school-aged individuals for services and to characterize their language profiles. However, how studies assess the dimensions of language pertaining to language impairment and defines to language impairment hinders our understanding of language phenotypes. To address this gap, this systematic review examines reporting practices for language skills using age-referenced assessments in autistic individuals.

Objectives: This review asked two primary research questions: What are the reporting patterns of LI in ASD prior to and after publication of the DSM-5? How does the literature characterize the language abilities of autistic individuals with respect to LI using age-referenced assessments?

Methods: The authors preregistered this systematic review with PROSPERO (CRD42021260394) and followed the Preferred Reporting Items for Systematic Reviews and Meta-Analyses protocol. Database searches took place on August 11, 2021, with an updated search on September 20, 2022, and included Linguistics and Language Behavior Abstracts, PsycINFO, PubMed, and the Directory of Open Access Journals from 1980 to 2022. Search terms included three essential concepts: autism, language, and age. Two coders independently screened and evaluated articles, discussing any disagreements until they reached consensus.

Results: Searches yielded 60 qualifying studies, with 25 studies (42%) directly addressing LI in ASD. Studies varied in how they operationalized and determined LI status, with no discernible differences by DSM version. Findings indicated variable language profiles in autistic individuals with and without LI.

Conclusions: A systematic review of studies of LI in autism, focusing on ages 3-21, indicates inconsistent operationalization of LI and age-referenced assessments used to characterize the language abilities of autistic individuals. Interpreting research on LI in autism requires careful attention to diagnostic and grouping criteria. Better understanding the variability in the language skills of autistic individuals with LI may enhance understanding of phenotypic variability and contribute toward development of efficacious supports.

430.059 (Poster) Testing the Labeling Effect in Autistic Children

A. Vicente, E. Rodríguez-Armendariz, J. V. Hernández-Conde, S. Parrillas and E. Castroviejo, (1)Ikerbasque, Vitoria-Gasteiz, Spain, (2)University of the Basque Country, Vitoria, Spain, (3)Valladolid University, Valladolid, Spain, (4)University of the Basque Country, Vitoria-Gasteiz, Spain

Background:

Children presented with two or more objects that receive the same label expect that such objects share the same non-obvious properties (e.g., a sound that one of the objects makes). Such expectation is reversed when objects receive distinct labels: children expect differently named objects to have different non-obvious properties. Linguistic labels thus induce children to generate concepts aligned with linguistic categories.

The labeling effect has been robustly tested using different paradigms in neurotypical children of different ages, from 10 months (Dewar & Xu, 2010) to 11 years (Sloutsky & Lo, 1999), but there has been little discussion about its relation to cognitive, social or linguistic abilities, although Pickering et al. (2018) relate labeling to cooperation.

The effect has not been tested on autistic children, who might not generate concepts on the basis of labeling alone, given difficulties in generalization and communication. This entails that their concepts might not get aligned with those of their linguistic community.

Objectives:
We replicate an experiment by Graham et al. (2013) with TD children. Children are invited to manipulate an object after a presentation of another one that makes a determinate sound. This kind of action-oriented paradigm seems appropriate for autistic children with low verbal abilities.

Methods:

30 autistic children are divided into two groups: same label (SL) and distinct label (DL). Children in the SL group are presented with pairs of unknown objects in three conditions: (i) [Predicted]: the experimenter labels one of the objects with a name, shows how to extract a sound from it, and gives the child the other object while making it clear that it has the same name as the first one. The second object makes the same sound as the first object; (ii) [Unpredicted]: same as [Predicted], except that the second object does not make the expected sound; (iii) [Baseline]: the experimenter labels the first object without acting upon it and gives the child the chance to explore the second object.

Children in the DL group receive objects in the same three conditions as in SL, but the experimenter insists that the second object has a different name.

Number of actions on the second object are counted, and two conditions are compared: (i) [Unpredicted SL], where expectations are violated because the second object is disabled, and [Predicted DL], where expectations are not violated because the second object (with a distinct label) is disabled.

Results:

We fitted a mixed effects model with number of actions on the test object as a dependent variable, group (SL / DL), condition (Baseline / Predicted / Unpredicted) and an interaction between group and condition as explanatory variables, and participant and label as random effects, which yielded a main effect of group (p = 0.009). In pairwise comparisons, we also encountered a significant difference between unpredicted SL and predicted DL (p = 0.004), which replicates the results by Graham et al. (Figure 1).

Conclusions:

Results of the study suggest that autistic children are sensitive to the cognitive effects of acts of labeling.

430.060 (Poster) The Acquisition of Mental Stat Verbs in Children with Autism Spectrum Disorder
I. Eilon and R. Novogrodsky, (1)University of Haifa, Israel, Haifa, Israel, (2)University of Haifa, Haifa, Israel

Background: Mental state verbs (MSV) are part of the primary language instruments people use to describe the knowledge, thoughts, feelings and desires of themselves and others and are divided into six semantic categories: desires, emotional, cognitive, physiological, perception and moral verbs (Bretherton & Beeghly, 1982; Shatz et al., 1983). These verbs begin to appear in children's language at 18 months, and they develop in production and comprehension in terms of frequency, diversity and pragmatic use through childhood and into primary school age (Bartsch & Wellman, 1995; Pascual et al., 2008). As compared to typically developing children (TD), children with Autism Spectrum Disorder (ASD) tend to use less MSV (e.g., in various narrative tasks, Brown et al., 2012; Rumpf et al., 2012; Siller et al., 2014).

Objectives: The current study aims to describe the developmental process of MSV from different semantic categories in children with ASD compared to TD children.

Methods: For this purpose, we developed a MSV parental questionnaire measuring the diversity of MSV in children's lexicon from the age of 1.5 to ten years old. The questionnaire contains 80 MSV from five categories (desires, emotional, cognitive, physiological, and perception. Moral verbs are included in the Hebrew version in the other categories), and a sixth category of 10 physical verbs as a control (Eilon & Novogrodsky, 2022). Using an online questionnaire, 29 parents of children with ASD aged 3-10;07 years participated in the study and filed the MSV questionnaire about their child. In addition, 95 parents of TD children aged 3-10;01 filed the questionnaire. Both groups were divided to preschool children (aged 3-6) and school-age children (aged 6-10).

Results: Across the six types of verbs, results showed main effects of age (F(1,1)=50.33, p<0.0001) and group (F(1,1)=28.22, p<0.0001), meaning that older children used more different verbs than younger children and TD children used more diverse verbs than ASD children. No significant effect of interaction was shown. The effect of age maintained significance in all semantic categories, showing the growth in the diversity of verbs in each MSV category with age (see figure 1 below). The group effect reached significance only in the cognitive, emotional, desires and physiological verbs, showing that TD children scored significantly higher than ASD children. The effect of group in the physiological verbs was surprising, as both groups scored high in this category, and it might be explained by ceiling performance of the TD group in both age groups.
Conclusions: The finding highlights the difficulty of children with ASD in cognitive, emotional, and desires verbs. Previous studies have argued that MSV use and the sequence of verb acquisition (from the desire category to the knowledge and belief-cognitive category) in TD children reflect the Theory of Mind (TOM) of the developing child (Tardif & Wellman, 2000). Furthermore, children with ASD tend to have difficulty in the understanding of TOM (Baron-Cohen et al., 1986). Our findings support and tie these two claims, showing the specific deficit children with ASD have in verbs that reflect the understanding of the mind.

430.061 (Poster) The Emotional Valences of Passive Sentences in Japanese Perceived By Adults with ASD: An Interim Report

Background: Lartseva et al. (2015) point out that "...individuals with ASD are able to correctly identify words, sentences or stories as emotionally positive or negative". However, it is not yet clear whether individuals with ASD can accurately classify them into positive or negative in a Japanese cultural context.

The Japanese language has two types of passive voice sentences: 1)direct passive sentences which clearly convey either a positive or negative meaning; 2)indirect passive sentences which are more difficult to interpret requiring the listener to infer the speaker’s emotions, which are often times negative, coupled with the difficulty caused by occasional ellipsis of the subject. In addition, there is another type of passive sentences with inanimate subjects which are neutral in meaning.

Objectives: The purpose of this study is to clarify the emotional values that adults with ASD feel about four types of passive sentences including direct passive sentences with positive, negative, or neutral meanings, and indirect passive sentences, in order to explore possible difficulties they experience in daily communication. The experimental group had 11 ASD adults(age range:17-52) and the control group had 106 university students.

Methods: Following Yorozuya et al.(2020), we measured the emotional values of four types of passive sentences. The participants marked the strength of their feelings concerning each sentence on a straight line ranging from negative to positive meanings (the visual analog scale: VAS). Emotional values were measured by the distance from the center point (neutral) to the mark the participants made. The mark distance values were converted by 2-centimeter intervals into a five-point scale ranging from 1 to 5.

Results: Among the four types, only the indirect sentences showed difference between the ASD group and the control group(medians: 2 and 3), whereas the other three types showed no difference. A further analysis of U test showed a significant group difference for the indirect passive sentences(U(176,1696)= 133809.5, p =0.016). Also a U test of each of the 16 sentences revealed two sentences showed significant differences(U(11,106)= 377.5, p=0.022 U(11,106)=349, p=0.018)(Table 1). On the other hand, in terms of average ranks, the ASD group was higher than the control group for 11 sentences, and lower for 3 sentences. In terms of median, the ASD group was higher for 3 sentences and lower for 2 sentences, whereas the two groups’ medians were equal for the other 11 sentences(Table 1).

Conclusions:

Among the four types of Japanese passive voice sentences, indirect passive sentences showed a significant difference between the ASD group and the control group, which contradicts with what Lartseva et al.(2015) pointed out does not apply to Japanese indirect passive sentences.

A U test and a comparison of medians revealed that overall the ASD adults felt the indirect passive sentences were “less negative” than the control group did. Lastly it is noteworthy that further research is needed since in terms of average rank and median the ASD adults felt the opposite feelings to the overall trends about some sentences.

430.062 (Poster) The Low Verbal Investigatory Survey for Autism (LVIS): Psychometric Properties from a Large and Diverse Sample of Autistic Participants
I. M. Eigsti, E. Tenenbaum and A. Naples, (1)Psychological Sciences, University of Connecticut, Storrs, CT, (2)2424 Erwin Rd., Durham, NC, (3)Child Study Center, Yale University, Child Study Center, New Haven, CT

Background: Approximately 30% of autistic children are minimally verbal. Improved methods are needed to determine which children are at greatest risk for MLV outcomes to optimize interventions and assess response to treatment. However, the field lacks measures of communicative capacity among minimally or low verbal (MLV) autistic children. We recently demonstrated promising psychometric properties for the Low Verbal Investigatory Survey (LVIS), a brief parent-report measure evaluating communicative capacity among MLV autistic children, in a sample of 147 participants (Naples et al., in press). We found that two latent factors, Verbal Communication (e.g.,
regular use of words and phrases) and Atypical Communication (e.g., echolalia, reduced prosody), were associated with communicative performance on standardized measures.

Objectives: To assess the psychometric properties of the LVIS in a large diverse sample of autistic individuals to test whether: (1) the latent factor structure replicates in a larger, more diverse sample; (2) the measure yields convergent and divergent validity; and (3) scores on the LVIS differ as a function of sociodemographic factors.

Methods: A sample of 826 English-proficient parents were recruited via the Simons Foundation Autism Research Initiative (SPARK Consortium, 2018) and completed an online survey. Parents completed the LVIS, along with questionnaires probing sociodemographics and adaptive functioning (Vineland Adaptive Behavior Scales, Third Edition; VABS-III). IQ was collected from record review. Principal components analysis (PCA) assessed LVIS factor structure; convergent and divergent validity were assessed for all derived factors.

Results: In addition to the two factors reported previously, a third factor was retained in PCA based on Eigenvalues (range for Factors 1 to 3: 1.99 – 4.81, Factors 4 and above <1.4) and scree plot. Loadings on factors 1 and 2 (Verbal Communication and Atypical Communication) were comparable to previous findings; Factor 3, Nonverbal Communication, reflected variability in pointing behaviors. As predicted (OSF pre-registration), Verbal Communication was more strongly associated with VIQ, \( r = .71, p < .001 \), than NVIQ, \( r = .50, p < .01 \). Neither Atypical Communication nor Nonverbal Communication were associated with IQ (\( p 's > .1 \)). Similarly, VABS-III scores were correlated with Verbal Communication, \( r = .67, p < .001 \), but not Atypical Communication or Nonverbal Communication (\( r > .1 \)). Verbal Communication differed as a function of parent-reported verbal status (“would you describe your child as minimally verbal,” \( p < .001 \). Neither Atypical Communication (\( p = .81 \)) nor Nonverbal Communication (\( p = .11 \)) differed by verbal status; Figure 1. None of the three LVIS factor scores differed as a function of sex, \( p 's > .30 \). Preliminary analyses suggest that Verbal and Nonverbal Communication (but not Atypical Communication) differ as a function of race and ethnicity; this will be further explored in future analyses.

Conclusions: These findings provide strong validation of a tool designed to capture multiple dimensions of communicative capacity in autistic children with minimal or low verbal skills. Discussion will address factors beyond communication abilities that may influence racial and ethnic disparities in scores, including item-wise bias. The LVIS has the potential to provide information that has immediate relevance both clinically and for research.

430.063 (Poster) The Q-Social: A New Questionnaire Measure of Social Communication in Young Autistic Children

K. M. Walton, A. R. Boroway, C. Taylor and L. Lecavalier, (1)Nisonger Center, The Ohio State University, Columbus, OH, (2)Psychology, University of South Carolina, Columbia, SC, (3)The Ohio State University, Columbus, OH

Background: Social communication is a major target for early interventions provided to autistic children. Social communication is among the most frequently measured endpoints in early intervention trials, yet existing social communication outcome measures have major limitations (Anagnostou et al., 2015). These limitations include limited construct coverage, few items tapping skills in children with limited language, high burden of administration, and limited sensitivity to short-term or incremental change. Moreover, many of the tools currently in use for measuring social communication either (1) explicitly measure autism “symptoms,” without regard to which or these are most important as treatment targets, or (2) were not designed for an autistic population, meaning that autism-typical behaviors and concerns may not be well-represented. Thus, there is a pressing need for a social communication outcome measure that is efficient to administer, sensitive to change, and tailored to the unique needs of young autistic children.

Objectives: This presentation describes the development and initial validation of a new questionnaire measure of social communication, the Questionnaire for Social Communication in Young Autistic Learners (Q-SoCIAL).

Methods: The Q-SoCIAL was developed using qualitative and quantitative methods consistent with best practices in the development of patient-reported outcome measures (FDA, 2009; NIH, 2012). Initial item content was derived through a combination of information from (1) focus groups with parents, teacher, and expert clinicians, (2) review of more than 4,500 items from 93 questionnaire or interview measures tapping social-communication related constructs, and (3) review by a panel of research and clinician experts. The initial draft measure then underwent cognitive interviewing with parents (n=30) and teachers (n=29) serving young autistic children to inform addition revisions to questionnaire instructions and items. An online survey was used to collect responses to the new measure from parents (n=500) and teachers (n=250) of typically developing (TD) children to inform developmental ordering and utility of the items.

Results: The Q-SoCIAL is a new measure of social communication in young autistic children that covers expressive, receptive, and pragmatic communication skills; social engagement and interaction with peers and adults; play and imitation; and autism-specific social concerns. The Q-SoCIAL includes 149 developmentally ordered, competency-based items (rated on a 6-point scale from “Never” to “Outgrown”) and 24 “strengths and challenges” items (rated on a scale from “Never” to “Always”) that represent unique social communication challenges impacting autistic children. Initial data collection in TD children indicated that competency-based items followed a clear developmental progression, and also identified some items that may show floor or ceiling effects in the targeted age range. Autism-specific problems items showed low endorsement in the TD sample.
Objectives: The study assessed predictors of adaptive functioning by (1) examining whether cognitive ability predicts adaptive functioning in children with and without ASD, and (2) exploring whether an ASD diagnosis moderates the effects of receptive and expressive language on adaptive behavior.

Methods: This study included 196 participants who were evaluated for ASD at the UAB Civitan-Sparks Clinics, a tertiary care clinic. Data from these assessments, such as adaptive measures, were collected. Adaptive behavior was assessed using the Adaptive Behavior Composite from the Vineland Adaptive Behavior Scales-Second/Third Editions (Vineland-II/3). Receptive and expressive language were measured using the Clinical Evaluation of Language Fundamentals (CELF-P2/4/5) or the Preschool Language Scale, Third, Fourth, and Fifth Editions (PLS-3/4/5). Two hierarchical multiple regressions were conducted: Step 1: covariates; Step 2: ASD diagnosis, cognitive ability, and language ability; Step 3: the interaction between ASD diagnosis and language. Due to the multicollinearity between receptive and expressive language, they were assessed in separate regression models.

Results: In this sample, 89 participants (45%) were diagnosed with ASD, 53 (27%) were female, and the average age was 6.63 years old (SD= 3.08). After controlling for motor abilities and maternal education, cognitive ability and autism diagnosis significantly predicted adaptive functioning (p<.05). Neither receptive language nor expressive language were significant predictors of adaptive functioning (t=-.10, p=.92; t=1.41, p=.17, respectively). Both the final model with receptive language significantly predicted adaptive functioning (F(6, 185)= 12.02, p<.001, R^2=.30) and the model with expressive language significantly predicted adaptive functioning (F(6,185)= 12.29, p<.001, R^2=.30).

Conclusions: Autistic participants had significantly poorer adaptive functioning compared to those without ASD, which affirms previous research (Bal et al, 2015; Di Rezze, et al., 2019). Additionally, participants with higher cognitive ability had greater adaptive behavior. Contrary to what was expected, receptive and expressive language abilities did not predict adaptive functioning in ASD or non-ASD participants. While it has been previously demonstrated that poorer receptive language is associated with worse daily living skills (Bal et al., 2015), the current study’s findings suggest language deficits in autistic individuals may not impact adaptive behavior as a whole.

Background: Autism spectrum disorder (ASD) is a developmental disorder characterized by social impairments, communication difficulties, and restricted, repetitive behaviors. Communication deficits are a hallmark characteristic of ASD (American Psychiatric Association, 2013). Many autistic children develop language at a slower rate than typically developing children (Mitchell et al., 2006), yet there has been limited research connecting receptive and expressive language abilities to overall adaptive functioning. Language is one factor that may contribute to adaptive skills in autistic children.

Objectives: The major objective of the study was to translate, adapt and validate the Communication Matrix parent version to Sinhala. Pretesting the Sinhala translated tool was done after evaluating the validity of the tool. The primary purpose of the study was to translate, adapt and validate the Communication Matrix parent version to Sinhala. Under the validation procedure, the aim was to evaluate face and content validity. Pretesting the Sinhala translated tool was done after evaluating the validity of the tool.
General objective – To translate, adapt and, validate Communication Matrix parent printable version from English to the Sinhala language.

Specific objectives

- To cross-culturally adapt and translate Communication Matrix parent version into the Sinhala language.
- To evaluate the face and content validity of the Sinhala version of the Communication Matrix parent version.
- To pre-test the translated tool with parents of children who have complex communication needs.

Methods:

The Sinhala translated version of the Communication Matrix was developed through a forward-backwards translation procedure. An expert panel of six participants including four SLTs and two linguists contributed to validate the translated tool in two rounds using an open-ended questionnaire and a four-point rating scale. Modified Delphi technique was used for this procedure. A group of ten parents contributed to pretest the translated tool by answering an open-ended questionnaire.

Results:

Suggestions were given in the expert panel round one to modify the translated tool. The face and the content validity index of the modified Sinhala translated Communication Matrix parent version was evaluated. The face validation was qualitatively done based on the answers to the open-ended questionnaire given to the expert panel. Under the content validity, the item content validity index (I-CVI) and the scale validity index (S-CVI) were measured using the four-point rating scale. Both I-CVI and S-CVI s were 1 while the total agreement of the tool was 24. Pre-testing the translated tool was also successful as the parents provided mostly positive answers to the questions.

Conclusions:

The Sinhala translated Matrix parent version is an appropriate self-administrative and objective AAC assessment that can be used in local clinical settings. Moreover, this can be used to increase the participation of parents in decision-making procedure with professionals despite their educational background to the most suitable AAC for their children. However, it is recommended to pre-test the Sinhala translated Matrix assessment with a larger number of parent group to gain more comprehensive result related to the user-friendliness of the tool.

430.066 (Poster) The Relationship between Social and Contextual Inferencing and Narrative Language in Autistic and Control Boys

L. Mäkinen, A. Kotila, H. E. Ebeling and S. Loukusa; (1)Research Unit of Logopedics, University of Oulu, Oulu, Finland, (2)Research Unit of Clinical Medicine, Child Psychiatry, Oulu University Hospital and University of Oulu, Oulu, Finland, (3)Research Unit of Logopedics, University of Oulu, Oulu, FINLAND

Background:

Previous research has shown that social communication is an area of vulnerability in autistic individuals. The challenges in narrative and social-pragmatic language, including inferencing, might hinder the successful communication in social situations as they both require processing of various linguistic domains, mindreading and the simultaneous utilization of contextual language. However, the relationship between narrative and social and contextual inferencing is not fully understood and needs to be studied further.

Objectives:

The aim of this study is to examine the performance of the autistic and control children in tasks measuring narrative and social and contextual inferencing and explore their connections.

Methods:

The participants were 15 autistic (aged 5;1–10;7 years) and 15 control boys (aged 5;2–10;0 years). All children were monolingual and Finnish speaking. Children’s narratives were elicited by a Cat Story which is a Finnish narrative assessment method, based on a pictorial story generation. The content of the children’s narratives was analyzed by information scores that is a combined measure of the relevant story content and the accuracy of the referential cohesion. The social and contextual inferencing was assessed by a Pragma test, which requires understanding implied meanings of utterances in a given context. Questions are presented along with short verbal scenarios and pictures or objects. There are five subcategories in the Pragma test, but only contextual inferience with Theory of Mind (ConToM) and understanding of false beliefs (FB) were included in this study. Group differences were assessed by Mann Whitney U-test and Spearman’s rho correlation was used to assess connection between narrative and social-pragmatic language measures in groups.
Results:

The control children outperformed the autistic children in ConToM ($U = 192, p = .001$) and in FB ($U = 187, p = .021$), but there was not statistically significant difference in narrative language ($U = 152.0, p = .106$). In the autistic group, there was a significant correlation between ConToM and the Cat Story ($r = .570, p = .027$) and between FB and the Cat Story ($r = .653, p = .008$). In the control group, only the connection between the Cat Story and ConTom was significant ($r = .556, p = .031$).

Conclusions:

The social-pragmatic language comprehension (i.e., ConToM and FB) was challenging for autistic children, but there was no statistically significant difference in the content of the narratives between the groups. Narrative language and social and contextual inferencing with ToM seemed to be connected in both groups. Since successful picture-based narration requires the utilization of a given context and the ability to acknowledge the story characters’ and the listener’s different perspectives and mental states, this connection seems plausible. Moreover, autistic children showed significant connections between false belief reasoning and narration. Thus, it seems that in autistic individuals mindreading skills might also support the expression of relevant story content in a coherent way. These findings might be utilized in supporting the social communication of autistic individuals, since by focusing on social-pragmatic language we might also improve narrative language or vice versa.
Background: Language requires generalization. Words differ in meaning depending on their context, and the same word can often apply in a variety of related but distinct contexts. In fact, up to 84% of English words have multiple semantically related meanings [1]. While an ability to extend known word meanings in new ways is critical to successful communication, there is reason to believe that this ability is especially challenging for autistic individuals.

Objectives: Do verbal autistic adults and neurotypical adults with similar levels of education extend word meanings to a similar extent (n = 280, preregistered)?

Methods: A Flexible Meaning Extension (FME) task required participants to extend familiar words to label semantically related objects. A Label Learning (LL) task required applying labels to objects without meaning extension. Both tasks used a 4AFC design.

Results: 80 verbal autistic adults performed above chance but significantly below 60 neurotypical peers on the FME task, while simultaneously matching neurotypical participants on the LL task. The second study replicates the same pattern in a separate group of 80 autistic adults with masters’ degrees and 60 new comparably educated neurotypical adults. The predicted interaction between group and trial type was significant at both education levels, with random intercepts for subjects and items. In both studies, autistic participants were significantly less accurate than neurotypicals on the FME task: study 1 (b = -.10, t = -4.47, p < .0001); study 2 (b = -.045, t = -5.75, p < .0001), but did not differ on the LL task.

Conclusions: These findings demonstrate that autistic adults do not extend word labels in the same ways as their neurotypical peers, providing evidence that these differences in generalizing extend to the language domain.

testing (p<0.05, 1000 permutations). Each PC was qualitatively named to aid interpretation based on the pattern of loadings on symptom measures (Figure 1).

Second, using PrimeNet, we test whether symptom axes across PCs map onto distinct FC patterns that allow prediction of behavior at the individual-subject level. Specifically, the analysis runs 1,500 iterations of a multi-level model to select FC edges (pairwise correlations) for each iteration that are associated with PC scores. The edge-features selected in each iteration are used to train single-feature support vector regression (SVR) models using leave-one-out cross-validation. In turn, we apply the trained models to held-out data across the 1,500 iterations (Figure 2). Preliminary analyses with 75 subjects show that FC parcels selected by the training model as being associated with PC1 scores (i.e., social communication skills) are located primarily within Language and Cingulo-Opercular networks. Ongoing analyses test whether these parcels are predictive of behavioral scores. Furthermore, whole-brain FC maps seeded to a language network parcel show higher cortical and subcortical FC in the ASD group.

Conclusions: Collectively, the results indicate that heterogeneous language and social communication deficits can be reduced into a low-rank symptom solution that is cross-diagnostic. These derived symptom axes are expected to map onto distinct neural patterns, which are predictive at the individual-subject level. Ongoing analyses will also assess the extent to which these neural patterns vary as a function of diagnostic group.

430.071 (Poster) Collaborating with a Level 3 Autistic Author in Order to Elucidate Hyperlexia and Relationship to Language in Non-Speaking Autistic Individuals

F. Cazalis¹, H. Nicolas¹, V. Truffert¹, A. Ena¹, K. Buttin¹ and P. Ancet¹, (1)CNRS, UMR8557, Paris, France, (2)free lance, Medreac, France, (3)CNRS UMR5319 Passages, Bayonne, France, (4)Ecole des Hautes Études en Sciences Sociales, Paris, France, (5)Université de Bourgogne, LIR3S (UMR CNRS-uB 7366), Dijon, France

Background:

Hélène Nicolas is a young French woman diagnosed with level 3 autism and severe handicap. Although she cannot speak and has never been taught how to read, she exhibits exceptional literary talents. Using cardboard letters, she has written five books published under the nom de plume Babouillec. This phenomenon raises three important questions: (1) What cognitive mechanisms allowed her to learn how to read and write by herself? (2) Once identified, could such learning processes be applied in order to elicit reading and writing in other level 3 autistic individuals? (3) Could her texts provide clues towards a better understanding of the relationship that non-speaking autistic people have with verbal language?

Objectives:

This ongoing study aims at investigating the works and thoughts of Hélène Nicolas in order to identify markers of hyperlexia in autism, as well as characterizing her worldview in order to better comprehend highly atypical forms of intelligence such as those often observed on the spectrum.

Methods:

Participative research prevailed as the only acceptable format for this study. Dialogues between Hélène Nicolas and the rest of the research team (including autistic and non-autistic persons), focusing on philosophy, cognitive science and psychological introspection, have been documented in detail. Excerpts from these conversations will be presented to other level 3 autistic persons and their reactions and feedbacks will be collected as a mean of fostering fruitful reflexivity within the research team, and also as a way to gather heuristic insights about the functioning of the autistic mind.

Results:

We have so far collected more than 20 hours of recorded conversations. For example, this dialog took place with Fabienne Cazalis:

F – researchers think that autistic persons may not experience the same emotions as non-autistic people. What is your favorite emotion?

H- Make my adrenalin burst.

F- What is the emotion that you hate the most?

H- The dark trail of adrenalin.
F- What’s your opinion about oxytocin?

H- To this, the brain answers yummy.

F- And what about testosterone?

H – Good. The world is weeping, cradled by Jupiter.

Conclusions:

This research is still going on and results are being analyzed. Temporary conclusion is that current collected conversations confirm Hélène Nicolas not only as a wordsmith but also as someone with a very astute and profound understanding of the world.

430.072 (Poster) Screening for Language Difficulties in Autism and ADHD
V. P. Mohanakumar Sindhu, A. Brignell, K. Kallady, M. A. Bellgrove and B. P. Johnson, Monash University, Clayton, VIC, Australia

Background: Children with autism spectrum disorder (autism) and attention deficit hyperactivity disorder (ADHD) have an increased likelihood of speech and language difficulties compared to their typically developing peers. The diversity of clinical presentation of autism and ADHD means there is a pressing need to identify appropriate screening tools for language difficulties in these populations. The Clinical Evaluation of Language Fundamentals 5th Edition Screening Tool (CELF-5 Screener) and expressive and receptive language subscales from the Vineland Adaptive Behaviour Scales (Vineland-3) are two instruments that are widely used and may assist in identifying these concerns.

Objectives: We examined how accurately the CELF-5 Screener and parent-rated Vineland-3 expressive and receptive language subscales can detect receptive and expressive language difficulties compared with the clinician-administered CELF-5, a comprehensive and widely used clinical tool evaluating language skills.

Methods: Our sample consisted of 112 children aged 6-14 (n=25 typically developing; n=15 autism, n=27 ADHD, and n=45 autism +ADHD). Diagnosis of all participants was confirmed by the best clinical estimate: a registered psychologist or paediatrician, and speech pathologist, collated information gathered during participation in the study, in addition to any previous clinical reports, to confirm the diagnosis (informed by comprehensive best practice assessment tools, including but not limited to the ADOS, Conners rating scale). Outcomes from the CELF-5 Screener and Vineland-3 (adaptive receptive and expressive language scores) were compared to the clinician-administered CELF-5 (receptive and expressive composite scores) using sensitivity and specificity analysis. The current data is based on a pilot study, however, recruitment, and data collection are ongoing to establish a larger sample size.

Results: Children who scored below cut off on either expressive or receptive language composite scores on the CELF-5, 67.9% had scored at or above criteria on the CELF-5 Screener (i.e., had passed), indicating poor sensitivity of the CELF-5 Screener at identifying speech and language difficulties among children with autism and/or ADHD. By contrast, the Vineland-3 missed 30.8% and 17.6% of children with expressive or receptive language difficulties, respectively. The Vineland-3 incorrectly identified expressive or receptive language difficulties in 65.1% and 41.0% of children who did not have expressive or receptive language difficulties, respectively.

Conclusions: While the use of a language screening tool is at least a first step in ruling out possible language difficulties, the administrators should be aware of the strengths, limitations, biases, and errors of the tool, especially while assessing neurodiverse children whose language development might not follow a normative trajectory. The results of screening tools and parent reports should be carefully considered, and children may require a comprehensive evaluation (clinician-administered and parent-rated measures, detailed assessment of structural, pragmatic and functional skills) of their language skills to avoid overlooking more elusive deficits.

430.073 (Poster) The Relationship between Language and Behaviours of Concern in Autistic Children
A. Farrugia1, M. McInerney2 and A. Brignell1, (1)Speech Pathology, Australian Catholic University, Fitzroy, VIC, Australia, (2)Australian Catholic University, North Sydney, NSW, Australia

Background: Language impairment and behaviours of concern (BoC), such as self-injurious behaviours and aggression, are commonly seen in autistic children. It is often assumed these two domains are associated, however the evidence to date has been inconclusive for autistic children. Furthermore, it remains unclear whether distinct components of language (i.e., receptive and expressive) may be differentially associated with BoC outcomes.

Objectives: This study investigates the longitudinal association between receptive and expressive language ability and BoC for autistic children using data from a large population-based sample.
Methods: Participants were drawn from the Longitudinal Study of Australian Children (LSAC), which follows two cohorts of children, the Birth, and the Kinder cohort. Receptive and expressive measures of language were collected at age 4 years old, including the Peabody Picture Vocabulary Test, and LSAC parent questionnaires that asked about the child's language development. The BoC outcome measure, Strengths, and Difficulties Questionnaire – Conduct Problems subscale, was collected at ages 8 years. Correlation and regression analyses were conducted, with the following covariates included in analyses: socio-economic status, non-verbal IQ, age, gender, pro-sociality (e.g., peer socialisation) and peer problems.

Results: In total, n=145 children (79% male) were reported by their parents to be autistic in the Birth cohort and n=92 (80% male) in the Kinder cohort. No significant association was found between receptive or expressive language ability at 4 years (for all language measures) and BoC at 8 years for both cohorts of autistic children (P=0.05 for all analyses). Two covariates, non-verbal IQ (β=−0.284, P=0.004) and pro-sociality (β=−0.257, P=0.008), were significantly associated with BoC for the Birth cohort, contributing to 14% of the variance in BoC outcomes.

Conclusions: BoC can have a significant impact on an autistic child and their family’s quality of life and their participation in community, education, and employment. An understanding of the factors that may contribute to BoC outcomes is critical for prevention and prognostic counselling. Our findings highlight factors other than language may contribute to BoC outcomes for autistic children. Variables such as peer socialisation and non-verbal IQ may be important considerations for screening, assessment, and intervention targets. Findings from this population-representative sample provide an important counterpart to those of existing studies that have utilised selected and clinically ascertained samples.

430.520 (Poster) Sex-Differentiated Linguistic Predictors of Conversation Quality in Autistic Children

Background: Social challenges manifest differently in autistic girls compared to boys. However, the field has been slow to pinpoint sex differences in objective markers of social communication, such as conversational speech patterns in naturalistic settings. Prior research has shown that young adults rate autistic girls higher than autistic boys on a brief measure of conversation quality (Cola et al., 2020), and autistic girls differ from boys on several speech dimensions, such as speech rate and response time (Cho et al., in prep). The identification of linguistic drivers of conversation quality in autistic girls vs. boys could lead to the development of personalized supports that improve conversational outcomes and enhance social success for all children.

Objectives: Identify drivers of conversation quality in seventy-three female and male youth with or without autism, using computational linguistics and cross-validated machine learning approaches.

Methods: Seventy-three participants who were verbally fluent (Table 1) engaged in a 5-minute “get-to-know-you” conversation with a young adult confederate. After the conversation, the adult confederate completed a modified version of the Conversation Rating Scale (CRS; Ratto et al., 2011). Statements such as, “the other person was interested in what I had to say” were rated on a scale of 1 to 7. Audio samples were systematically diarized, time-aligned, and orthographically transcribed. We extracted two different sets of features: dialogue (lexical) features based on experts’ knowledge and acoustic features used in previous studies (Cho et al., 2019). Cross-validated support vector regression (SVR) and multi-layer perceptron (MLP) predicted CRS scores with high accuracy, and the top predictive features for girls and boys were identified by interpretable machine learning methods.

Results: For autistic boys, features like average sentence length and percent of silence were top predictors of conversation quality (Figure 1). In contrast, acoustic features (e.g. loudness) accounted for more variance in CRS scores in girls. We also observed that our predictor performed better when predicting the interaction quality of girls than that of boys, regardless of the children's diagnostic status.

Conclusions: Natural conversations provide an ecologically valid opportunity to characterize speech-language markers of social communication challenges that manifest differently in autistic girls vs. boys. In this study, we found that CRS scores are driven by linguistic patterns that differ by sex. Specifically, acoustic features predicted conversation ratings for autistic girls, whereas dialogic features were more predictive for autistic boys. These findings can be used to inform personalized supports for enhancing conversational success in autistic youth and provide a first glimpse into potential drivers of conversation quality in boys vs. girls that could improve our long-term understanding of behavioral heterogeneity in autism. Ultimately, improved understanding of sex differences in autism will help to lower the age of diagnosis for girls and improve access to early intervention services for this understudied subgroup.
Background: Prediction deficit theories of autism spectrum disorders (ASD) propose that autism characteristics can be attributed to domain-general differences in prediction relative to neurotypical (NT) peers. According to these theories, autistic individuals assign disproportionate weight to prediction errors (i.e., mismatches between expected input and actual input), leading to higher perceived novelty and “hyperplasticity” of learning (overweighting current exposure while underweighting aggregated prior learning). As these prediction differences are posited to be domain-general, hyperplasticity of learning should be observable in language learning and processing for autistic individuals. However, no studies to date have examined this theoretical account in a linguistic context. Prediction differences could have cascading consequences for language development in ASD, warranting examination in young children in the early stages of language acquisition.

Objectives: The purpose of this study was to determine whether 2- to 3-year-old autistic children demonstrate prediction differences indicative of hyperplasticity during a linguistic sequence-learning task compared to NT peers matched on nonverbal cognition.

Methods: Participants included 33 autistic children (M=31.30 months, SD=3.36) and 33 NT children (M=20.04 months, SD=1.68) matched on nonverbal cognition (as measured by Developmental Assessment of Young Children (DAYC-2) raw scores). Participants in the ASD group were older to facilitate matching. Diagnoses were confirmed via psychologist administration of autism diagnostic measures. Children in both groups participated in an eye-tracking task designed to elicit anticipatory eye movements (AEMs) to target words based on their predictive relationship with a cue word. In block 1 of the experiment, “happy” consistently predicted “kitty” while “silly” consistently predicted “birdy” such that the cue-target probabilistic relationship increased over time. The contingency was then switched for two trials so “happy” preceded “birdy” while “silly” preceded “kitty”. In block 2, the contingencies reverted to the original pairings. If children make predictions based on cumulative probability, then AEMs to target images should be similar between block 1 and block 2. However, if autistic children overweight recent observations at the expense of cumulative probability (thus demonstrating hyperplasticity of learning), then AEMs to target images should be disrupted in block 2 compared to block 1. Proportion of looks to target during the anticipatory window (2200-2700 ms after trial onset) was the dependent variable regressed on the three-way interaction of diagnostic group, block, and linear time.

Results: Results revealed a significant group by block interaction, indicating that autistic children demonstrated a larger discrepancy in AEMs to target between block 1 and 2 than NT children (Figure 1). Linear time and the three-way interaction between group, block, and linear time were also significant, indicating that AEMs to target and group differences between blocks increased over the course of the trial.

Conclusions: Results of this study provide support for theories proposing prediction differences underlying autism characteristics. Findings suggest autistic toddlers’ predictions during language processing are more driven by recent exposures than aggregated experience, possibly contributing to early language difficulties. Ongoing work by our research group will examine whether early prediction differences demonstrated in this study are related to non-linguistic processing and to language abilities one year later.

Diagnostic, Behavioral & Intellectual Assessment

209 - Breaking Down Barriers to Research for Children with Genetic Disorders, Intellectual Disability, or Communication Challenges

Panel Chair: Carol Wilkinson, Department of Developmental Medicine, Boston Children's Hospital / Harvard Medical, Boston, MA

Discussant: Alycia Halladay, Autism Science Foundation, Scarsdale, NY

Collecting neuroimaging and behavioral data in children with genetic disorders associated with autism can be challenging for a variety of reasons. Increased frequency of intellectual disability, communication challenges, and behavioral dysregulation can limit the types of assessments used as well as the amount and quality of the data collected. Many standardized assessments of cognitive, language, and behavior do not capture meaningful functional differences across individuals who fall below normative averages. Further, travel to study sites can be challenging, both financially and logistically, and create additional barriers to participation. Innovative and effective methods in data collection to support research in these often underserved and understudied populations is crucial to improving our understanding of common challenges within these disorders and advancing effective therapeutics. Here we will discuss data collection practices covering the following themes: (1) collecting meaningful and accurate behavioral assessments, (2) methods for successful acquisition of lab-based EEG, (3) methods for successful in-home based EEG acquisition, and (4) using virtual visits for speech and language assessments. The panel will include cross disciplinary discussion and exchange of ideas on how to overcome challenges related to data acquisition in autistic children with intellectual, communication, behavioral, or logistical barriers to participation.

(Panel Discussion) Standardized Assessment of Individuals with Neurogenetic Syndromes: Challenges and Recommendations
Background: Many individuals with neurodevelopmental disorders, particularly those with an associated genetic diagnosis, have significant cognitive and language impairments. The variety and extent of impairments in these individuals impacts their ability to complete valid behavioral assessments. Duplication of 15q11.2-q13.1 (dup15q syndrome) is one of the most common copy number variations associated with autism spectrum disorders (ASD) and intellectual disability (ID). As with many neurogenetic syndromes, accurate behavioral assessment is challenging, frustrating efforts to clearly characterize the phenotype and lay the groundwork for upcoming clinical trials. The dup15q population represents a wide range of abilities, from near normal IQ to profound intellectual disability, presenting an excellent opportunity to examine the strengths and limitations of standardized measures.

Objectives: Using the dup15q population as an example, we will present guidelines for collecting assessment data in heterogeneous NGS populations and examine the utility of common standardized assessment.

Methods: Participants included 62 children with dup15q syndrome (30 months to 18 years). Participants were assessed at either a university 15q specialty clinic, or at a Dup15q Alliance Family Conference. The assessment battery included a variety of measures to assess cognition, language, adaptive behavior, motor skills, challenging behaviors and social communication characteristics (Table 1).

Results: A comprehensive evaluation of individuals with an NGS should evaluate cognitive and language functioning, adaptive behavior, motor skills, and co-morbid psychiatric concerns (e.g. autism, anxiety). Verbal and nonverbal cognitive were evaluated using a flexible set of assessments with “drop-down rules”, such that participants first attempted an age-appropriate standardized assessment, and then moved to an out-of-norm assessment if valid scores cannot be obtained. In our dup15q sample, cognitive and language development were assessed with either the DAS-II or the MSEL. The MSEL was used to assess participants who were under 68 months of age, and participants who were older but unable to achieve a basal score on the DAS-II. Ratio scores were used to account for the scores of children who performed outside of the standardized norms for their chronological age. This provided a wide range of cognitive and language scores, from the average to severely impaired range. Adaptive behavior standard scores, as assessed with the VABS, showed a normal distribution without evidence of a floor effect, suggesting that the VABS is an appropriate measure for evaluating the full range of participant abilities. Parent report of autism symptoms (SRS) was moderately correlated with verbal and nonverbal cognition ($r=-0.55$, $p<.001$; $r=-0.64$, $p<.001$), while ADOS-2 scores were associated with verbal cognition only ($r=-0.37$, $p=0.03$). Parent report of challenging behavior, as evaluated with the ABC, was largely unrelated to cognitive ability.

Conclusions:

Studies of individuals with neurogenetic syndrome should employ a flexible set of assessments, that allow each participant to receive the assessment that reflect his/her developmental abilities and provides a range of scores that facilitates stratification. Although measures of ASD symptoms (such as the ADOS and SRS) are likely relevant to clinical trials, they are strongly correlated with cognitive ability in children with NGS and should be interpreted with caution.

209.002 (Panel Discussion) Lab Based EEG Collection in Young Children with Fragile X Syndrome

C. L. Wilkinson, Department of Developmental Medicine, Boston Children's Hospital / Harvard Medical, Boston, MA

Background: Collecting high quality EEG data in young children requires successful netting and placement of EEG sensors, sustained attention to selected stimuli, and behavioral regulation. Autistic children with significant behavioral, communication, and cognitive challenges are often not included in neuroimaging research studies due to these barriers with data collection. This creates a large gap in our understanding of the neurobiology underpinning severe deficits in communication or cognition that greatly impact functioning for some individuals with autism. Here we present our experience in collecting data from young children (2-7 years old) with Fragile X syndrome (FXS). FXS is the most common inherited form of intellectual disability and virtually all males will have some autistic traits with 30-50% meeting formal diagnostic criteria. Individuals with FXS also often have sensory hypersensitivity, hyperactivity, and inattention making EEG data collection especially challenging.

Objectives: To discuss trials, tribulations, and triumphs in collecting EEG in children with Fragile X Syndrome.

Methods: EEG netting was attempted in a total of 16 children with full mutation FXS (15 male, 1 female). Prior to study visits an extensive interview was performed with parents to obtain information about each child’s language ability, preferred interests, motivators, and behavioral characteristics. Families were provided a social story reviewing the lab visit, including details of EEG netting. Once netted, four EEG paradigms were attempted (baseline, 2 passive auditory tasks, and visual evoked potential). Percentage of successful netting and task completion was assessed and a quality review of reasons why netting was unsuccessful was performed.
Results: 14/16 (87%) of FXS children were successfully netted and 10/16 (62%) completed portions of all four tasks. Visual tasks were more challenging that passive auditory tasks. Data quality analysis showed that compared to age-matched typically developing comparison groups, FXS participants had significantly lower number of trials completed during both visual and auditory tasks (p<0.05, p<0.005). Children unable to complete all four tasks were older in age (66m vs. 46m; p = 0.01), and had better language ability based on the Preschool Language Scale Total Raw score (79.6 v 49.9, p <0.01).

Conclusions: With preparation and supports in place EEG data can be successfully collected in children with behavior and communication challenges. Specific behavioral strategies and task designs will be shared as part of this presentation.

209.003 (Panel Discussion) Experiences from the Road: Mobile EEG Success for Minimally Verbal and Minimally Ambulatory Populations
C. M. Hudac. Department of Psychology; Carolina Autism and Neurodevelopment (CAN) Research Center, University of South Carolina, Columbia, SC

Background: Several subgroups of autism linked to known genetic variants are rapidly advancing towards personalized treatments (Freitag, Persico, & Vorstman, 2022). However, brain-based biomarker development in these subgroups is often lacking due to study enrollment criteria that excludes based upon verbal or cognitive abilities. For instance, many people with SCN2A (96%) or GRIN2B (~70%) mutations have a diagnosis of intellectual disability (ID), even in the absence of epilepsy (Carvill et al., 2021). Amongst other avenues to improve inclusion of minimally verbal and minimally ambulatory subgroups (e.g., paradigm modifications, behavioral training ahead), there is a current push towards mobile, off-site research testing provide an opportunity.

Objectives: Here, we describe the process for conducting a 3-month road trip for research in monogenic groups associated with ASD (SCN2A, GRIN2B) and report on the success of data collection in participants.

Methods: At the start of the road trip, 12 families of a child with an SCN2A or GRIN2B mutation had confirmed research testing date for the BioGENE Study. The EEG experimental battery consisted of a resting state task (6 minutes), a classic auditory oddball attention task (Hudac et al., 2018; 8 minutes), and a new speech-discrimination oddball attention task (8 minutes). Parents reported on demographics, autistic and social behaviors (SRS), behavioral features (CBCL), sensory features (Sensory Profile), and repetitive behaviors (RBS-R).

Results: The 92-day long solo road trip involved driving over 15,000 miles (over 24,000 km) across the United States. The trip was only partially structured so that additional families were able to enroll in the study flexibly. By the end, we completed testing with 55 participants aged 1-25 years (30 female, 25 male; 1 additional parent carrier). Forty-eight participants (87%) had an ID diagnosis. Thirty-six participants (65%) were nonverbal and an additional 4 participants only used a few verbal phrases. Sixteen participants (29%) were non-ambulatory or required assistance to walk. We will share specific planning features, behavioral strategies for the participants, and education strategies we used to aid the helpers that joined the research session (e.g., parents, siblings, ABA therapists).

Almost all participants 54/55 (98%) successfully provided data for at least 1 experimental EEG task; the one child without data did not want to wear the EEG net. Participants who were walking and talking did retain more ERP trials after data cleaning, F(1, 48)< 4.76, p < .034, but trial retention was not related to diagnostic status (ASD and/or ID), F(1, 48)> 1.68, p < .20.

Conclusions: This study “fuels” the momentum towards improving inclusivity of EEG biomarkers for subgroups of autism that are minimally verbal or minimally ambulatory, as well as improving access for rural families.

209.004 (Panel Discussion) Remote Assessment of Speech/Language and Motor Skills in Children with Neurodevelopmental Conditions
K. V. Chenausky1, S. V. Gill1, L. Keegan1 and M. Ayoub2, (1)Communication Sciences and Disorders, MGH Institute of Health Professions / Harvard Medical School, Boston, MA, (2)Boston University, Boston, MA

Background:
Communication and motor delays are common across neurodevelopmental conditions (NDCs) – for example, spoken language is delayed or even absent in up to 78% of NDCs. Assessment of spoken language and motor skill is challenging in this population for many reasons: families are geographically remote, children may be dysregulated in unfamiliar locations, and many standardized instruments do not accurately characterize their skills. Yet careful, accurate characterization of spoken language and motor skills is vitally important not just for treatment planning, but also for monitoring progress, capturing phenotypic variations, and understanding phenotypic similarities across conditions.

Objectives: We report data capture rates and descriptive statistics for a remote assessment protocol to capture spoken language and motor performance in moderately and profoundly affected children with one particular NDC, autism spectrum disorder (ASD).
Results:

Mean Vineland Adaptive Behavior Composite for the group was 58.2 (SD 13.8), range 13-84. Mean Vineland Receptive Language V-score was 6.8 (SD 4.2); that for Expressive Language was 3.9 (SD 4.4). On average, children produced 38.6 different words during the language sample (SD 49.8, range 0-233). Using a cutoff of 20 Number of Different Words (NDW) from the language sample, 48 participants were classified as minimally verbal. 42 participants were able to produce at least three repetitions of most of the syllables in the syllable repetition task. Speech repetition data was sufficient to determine that 52 participants met criteria for childhood apraxia of speech, while 17 did not meet criteria and 21 did not produce sufficient speech to classify. Acoustic analysis of syllables was possible for 38 participants, and kinematic analysis for 19.

Of the 85 participants with available motor data, 57 displayed 70% or more “successful” walking trials (i.e., produced either quantitative or behavioral data). Although only 27 participants were able to attempt heel-to-toe walking, 74 were able to balance on one foot (either independently or with extra support). Only 19 participants had majority “unsuccessful” trials (i.e., expressed behaviors coded as “other”) across all tasks, typically due to factors such as fatigue, lack of motivation, or environmental noise. 5 participants could not be processed due to poor video quality.

Conclusions: Remote assessment of spoken language and motor skills is feasible for children with NDCs and yields rich phenotypic data.

---

**PANEL DISCUSSION — DIAGNOSTIC, BEHAVIORAL & INTELLECTUAL ASSESSMENT**

**227 - Divergent Trajectories Associated with Genetic Liability for ASD and Other Neurodevelopmental Disorders**

**Panel Chair:** Catherine Burrows, Department of Pediatrics, University of Minnesota, Minneapolis, MN

**Discussant:** Lonnie Zwaigenbaum, Autism Research Centre, University of Alberta, Edmonton, AB, Canada

Children at varying genetic liability for ASD provide unique opportunity to study the progression of ASD-relevant features across development. These study designs enable examination of trait and symptom emergence prior to the consolidation of the disorder in unbiased, prospectively ascertained samples. Diverse risk samples may also share early precursors that complicate clinical decision-making and lead to both diverging and shared pathways of liability over time. We present 4 talks studying children at increased likelihood for ASD and other neurodevelopmental conditions based on familial likelihood (i.e., having an older sibling with ASD or ADHD) or genetic liability (i.e., Fragile-X), studied longitudinally. We examine a variety of predictors (biological sex, Burrows; later group membership; Piergies) and outcomes, including ASD diagnostic outcomes (Grzadzinski, Caravella), and attention shifting (Piergies). Results highlight shared genetic predisposition for a variety of concerns over time, including attention shifting difficulties and psychopathology (e.g., anxiety and attentional concerns) in later childhood. Patterns of symptom emergence appear to be time-varying and differing by sex. These findings highlight the importance of continued longitudinal investigation of children at likelihood of developing ASD and other neurodevelopmental concerns.

**227.001 (Panel Discussion) ASD Diagnostic (In)Stability in a High-Familial Likelihood Sample from 24 Months to School-Age: Qualitative and Quantitative Impressions from Case Reviews**

Background: Autism spectrum disorder (ASD) is historically considered to be a lifelong, pervasive neurodevelopmental disorder. However, recent works highlight a subset of individuals who go on to have “optimal outcomes” or no longer meet criteria for ASD later in life. Trajectories of late onset (after 24-36 months) are less frequently reported in research, even though the average age of diagnosis in the community is over 48 months. Studies that follow siblings at elevated likelihood for ASD longitudinally from early life provide a novel opportunity to evaluate diagnostic trajectories in a genetically enriched sample.

Objectives: To establish quantitative and qualitative descriptions of behavioral profiles in individuals with variable ASD diagnoses from 24 months of age to school-age, with the goal of guiding clinical care in diagnostic practices.

Methods: A group of clinical researchers with expertise in ASD conducted extensive review of current and historical information in cases with changing diagnoses seen through the Infant Brain Imaging Study (IBIS). The workgroup met virtually for at least 1 hour per case to review clinical information obtained at 6/12 months (pre-diagnosis), 24-37+ months (initial diagnoses), and 7-11 years (school-age diagnoses).

Results: A total of 31 cases shifted diagnoses from toddlerhood to school-age; 18 cases (58%) had diagnoses of ASD in early life but transitioned to non-ASD by school-age (ASD→non-ASD) while the remaining 13 (42%) received a first diagnosis of ASD at school-age (non-ASD→ASD). See Table 1 for further characterization. Six ASD/non-ASD cases (33%) were female while 7 (54%) non-ASD→ASD cases were female. At 24 months, clinicians were “very confident” (on a 3-point scale from “not confident” to “very confident”) in their diagnostic accuracy for 5 (28%) ASD→non-ASD cases and 6 (46%) non-ASD→ASD cases. Many children in the ASD→non-ASD group showed persistent but subthreshold ASD symptoms at school age. Most children in the non-ASD→ASD group showed few symptoms at 24 months (apart from 38% demonstrating language delays), but significant symptoms at school age. At school-age both groups showed mild elevations on the Child Behavior Checklist (CBCL) on Attention Problems, ADHD problems, and Depressive Problems. Following in-depth case review, “late onset of symptoms” was a predominant clinician descriptor of the non-ASD→ASD (80%). For all cases, reviewing clinicians agreed with diagnoses (ASD or non-ASD) at each time point, highlighting the accuracy with diagnoses given based on available information.

Conclusions: Overall, a “deep dive” into clinical cases with changing diagnostic trajectories from toddlerhood to school-age revealed findings with immediate clinical implications. Groups differed in terms of symptom trajectories, with many ASD→non-ASD children demonstrating persistent symptoms at school age, while the non-ASD→ASD group showed symptom onset after the 24-month visit. Children in both groups demonstrated consistent patterns (per clinician review and CBCL) of non-ASD psychopathology at school-age, mostly anxiety and ADHD, possibly highlighting the shared genetic predisposition across psychiatric conditions as well as overlapping early phenotypes. A useful descriptor for longitudinal studies to consider may be “ever” ASD (did the individual ever meet criteria for ASD?), which clinical researchers agreed was an accurate conceptualization of all the cases reviewed.

227.002 (Panel Discussion) Longitudinal Stability of Autism Spectrum Disorder Diagnoses in 2–7-Year-Old Males with Fragile X Syndrome
K. E. Caravella, K. Donovan, K. Hills, and J. Roberts, (1) Carolina Institute for Developmental Disabilities, University of North Carolina, Chapel Hill, NC, (2) Gillings School of Global Public Health, University of North Carolina, Chapel Hill, NC, (3) University of South Carolina, Columbia, SC, (4) Department of Psychology, University of South Carolina, Columbia, SC

Background: Fragile X syndrome (FXS) has the highest penetrance of ASD of any single gene disorder. Concerns exist within the field about the ability to accurately diagnose ASD in FXS males in toddlerhood when global developmental delays are present, and diagnostic accuracy may be reduced. To date, no study has utilized a clinical best estimate (CBE) diagnostic procedure to examine the stability of autism diagnoses in young males with FXS, and how symptom trajectories differ between individuals with stable and unstable diagnoses.

Objectives: The present study has two aims; first, to report the stability of clinical best estimate diagnoses of ASD in 2-7-year-old males with FXS. Second, to compare trajectories of autism symptomatology across diagnostic stability groups to examine change over time.

Methods: Thirty-one males with FXS were evaluated longitudinally between 2-7 years old (range: 2-4 assessments each, 101 total). CBEs were determined at each visit. A stable diagnosis was defined as meeting or not meeting CBE criteria for ASD at all time points: Stable-ASD or Stable-noASD. A non-stable diagnosis was defined as changing between an ASD and non-ASD diagnoses; Unstable-noASD (i.e., ASD to No ASD) and Unstable-ASD (i.e., non-ASD to ASD). To examine symptom trajectories, video clips from each assessment were used to code the Brief Observation of Social Communication Change (BOSCC). Mixed-effects models were used to examine trajectories of BOSCC scores (Social and RRB) across the four stability groups.

Results: Across participants, 54% (n=17) fell in the Stable-ASD group, 22.5% (n=7) fell in the Stable-NoASD group, 9% (n=3) fell in the Unstable-NoASD group, and 13% (n=4) fell in the Unstable-ASD group (Figure 1). Thus, 77% demonstrated a stable diagnostic trajectory, and 23% demonstrated an unstable diagnostic trajectory.
Visual Attention Shifting in Infants Developing Autism and ADHD Concerns

**A. Piergies**, G. S. Young, S. M. Rivera, J. Morales-Martinez, M. M. Soller, K. G. Tenar, J. P. Sandler, and M. Miller, (1)MIND Institute and Psychiatry & Behavioral Sciences, University of California, Davis, Sacramento, CA, (2)Psychiatry and Behavioral Sciences, MIND Institute, University of California, Davis, Sacramento, CA, (3)Department of Psychology, University of California, Davis, CA, (4)UC Davis, Sacramento, CA, (5)Psychiatry & Behavioral Sciences, UC Davis MIND Institute, Sacramento, CA

**Background:** Autism and ADHD have distinct diagnostic criteria yet frequently co-occur (Lai et al., 2019) with some symptom overlap (Ronald et al., 2014). Evidence of shared heritability in families (Miller et al., 2019) suggests potential for common developmental pathways and early markers, including differences in attention regulation (Hatch et al., in prep; Miller et al., 2020). Substantial evidence supports differences in visual attention shifting among infants with family histories of autism (Elshabagh et al., 2013), but this has not been examined in infants with family histories of ADHD.

**Objectives:** We aim to compare visual attention shifting among infants developing autism and ADHD concerns.

**Methods:** Data were drawn from a prospective longitudinal study of infants with family histories of autism (n=39) or ADHD (n=31), or no history (n=24). At 12 and 18 months, visual attention shifting was measured using a gap-overlap task, requiring attention to be redirected from a central to peripheral stimulus under two conditions: gap (central stimulus disappears before peripheral stimulus appears) and overlap (central stimulus remains visible). A gap effect was calculated by subtracting average gap from overlap latencies to fixate on the peripheral stimulus. Preliminary ANOVAs and post-hoc comparisons examined differences in latencies across trial types and whether there were gap effects at each age by 24- or, when possible, 36-month outcome group: Autism (meeting DSM-5 criteria), ADHD Concerns (elevated symptoms), and Comparison. Associations between latencies and concurrent measures of autism-relevant and ADHD-relevant behaviors were also examined.

**Results:** Results are summarized in Figure/Table 1. There were no group differences at 12 months. At 18 months, there was a main effect of group for overlap latencies. Relative to the Comparison group, the Autism group exhibited significantly longer latencies (p=0.027; Cohen’s d=0.62); the ADHD Concerns group exhibited marginally longer latencies (p=0.069, Cohen’s d=0.47). There was also a main effect of group for the gap effect at 18 months. The Autism group exhibited a marginally larger gap effect (p=0.080, Cohen’s d=0.47) than the Comparison group; the ADHD Concerns group exhibited a significantly larger gap effect (p=0.042, Cohen’s d=0.54).

Controlling for group, associations with examiner-rated social engagement were non-significant (12-month ps>0.185, 18-month ps>0.226). However, the association between examiner-rated attention, activity, and impulsivity composite and the gap effect was significant at 12 months (r=0.28, p=0.037). Associations between ADHD-related behaviors and gap (r=0.39, p=0.001) and overlap (r=0.30, p=0.01) latencies were significant at 18 months.

**Conclusions:** Results suggest overlapping difficulties in visual attention shifting at 18, but not 12, months among infants developing autism or ADHD concerns, replicating findings that infants later diagnosed with autism exhibit longer overlap latencies (Kawakubo et al., 2007) and larger gap effects than comparison infants during the second year (Elshabagh et al., 2013). No prior studies have examined this in early ADHD. Studies involving older children with ADHD have found no differences or longer latencies and smaller gap effects (Matsuo et al., 2015; Kleberg et al., 2020). Early-life attention shifting may relate to ADHD-relevant, but not autism-relevant, behaviors. Findings may have implications for understanding neuropsychological mechanisms and developing interventions.
Background: The study of ASD in females has been confounded by male-biased diagnostic inclusion criteria. Since the classic paper by Wing and Gould (1979), describing females with ASD as being “active-but-odd”, seeking interaction in ways that distinguished them from Kanner’s descriptions of social isolation, there has been a recognition of sex-specific differences in ASD-related impairment. However, virtually all studies aiming to characterize females were conducted with subjects ascertained on the basis of having first met clinical (DSM) criteria and are biased towards males. Studies utilizing prospective recruitment of children at increased likelihood of developing ASD and repeated assessments of ASD symptomatology provide a unique avenue to explore sex differences in the timing of onset of symptoms.

Objectives: 1) Examine rates of “late diagnosed ASD” (i.e., first ASD diagnosis in school age despite early ASD diagnostic evaluations) by sex in a high-familial likelihood (HL) for ASD sample. 2) Characterize differences in early development between early-diagnosed and late-diagnosed ASD in an HL sample.

Methods: Participants enrolled in the Infant Brain Imaging Study (IBIS) who received an ASD diagnosis (N=115; 31 females) based on clinical best estimate at any visit were classified as “early diagnosed” (Early-ASD; first diagnosed at the 24+ or 36-month time point; N=101) or “late diagnosed” (Late-ASD; first diagnosed at school age; 7-11 years; N=14). We present sex differences in group composition. We then examined differences in early language skills (24-month Mullen Expressive Language T-Score) between Early-ASD and Late-ASD groups using univariate ANOVA.

Results: Early-ASD participants were more likely to be male (77% or 78 males of 101 Early-ASD participants), whereas Late-ASD participants were more likely to be female (57% or 8 females of 14 Early-ASD participants; chi-square=7.38, p=0.007). 26% of females (8 of 31) versus 7% of males (6 of 84) were not diagnosed until school-age. Early-ASD participants demonstrated lower Mullen Expressive Language skills (M=39.60, SD=1.44) compared to Late-ASD participants (M=48.98, SD=3.26), F(1,108)=6.93, p=0.01. The main effect of sex and sex by group interaction was not statistically significant. However, when examining proportions of children demonstrating average or higher 24-month expressive language skills, 88% of Late-ASD females (7 of 8) had average or better skills, compared to 17% of males (1 of 6). Overall, 23% (7 of 31) of ASD-ever females versus 1% (1 of 84) of ASD-ever males were diagnosed late and had average or better language, revealing a striking contrast of high clinical relevance.

Conclusions: These findings are the first from a prospective sample unbiased by ASD diagnostic inclusion criteria and who have received identical assessments, that demonstrate that females are diagnosed later than males. This difference is at least partially explained by better language skills in late diagnosed females. Findings are consistent with reports in community ASD samples showing both pragmatic/linguistic deficits and advantages, specific to ASD females, elicited in semi-structured interactions. These findings provide support for the need to fully explicate the longitudinal features of the ASD phenotype in females and highlight the utility of samples that are not biased with respect to ascertainment strategy.
Objectives:

The objective was to pilot the content and validate the digital ICF core set rating scales for ASD. Particularly, we sought to examine whether self-reported autistic functioning profiles in terms of the ICF domains of body functions, activities and participation, and environmental factors would mimic current research evidence on strengths and challenges of autistic people, and environmental barriers and facilitators they encounter.

Methods:

The digital ICF core set rating scales for ASD were piloted in a group of 48 adolescents and adults (17-65 y, M=38.9, SD=12.3; 35 female) diagnosed with ASD and 203 (17-82 y, M=43.4, SD=15.2; 110 female) general population controls. ICF profiles per group (ASD vs. controls) were analyzed and compared per ICF domain and items.

Results:

Autistic participants reported strengths for several body functions (e.g., creativity, curiousness, sensory accuracy, logical thinking) and in the activities/participation domain (e.g., processing of symbols, avoiding health and economic risks), although these were not statistically superior to the control participants. They also reported a range of challenges, such as poor sleep, rumination, low control over activity levels and unusual motor movements, and distractibility, problems with change in routines, handling tasks and stress, and a range of social behaviors and relations as well as community exclusion. All of these were significantly more challenging than in controls. Perceived reported environmental facilitators were some forms of medication (melatonin), cognitive aids and communication and media services. Perceived barriers were other medications (e.g., neuroleptics), lack of support from authorities, insurances, clinical, employment and forensic services, as well as the education system. Most of the environmental barriers were perceived as significantly more hindering by autistic people than by control participants.

Conclusions:

Results indicate that the digital ICF core sets rating scales generate valid information on functioning profiles in ASD regarding both individual strengths and challenges and environmental facilitators and barriers. These results give a balanced and holistic picture of functioning in ASD beyond clinical diagnosis and serve support planning, environmental adaptations to needs, and strengths-based approaches. Larger scale data collections on the ICF core sets platform and formal comprehensive psychometric evaluation including young and school-aged children are required to make more firm conclusions about its usefulness and scientific properties - the studies are currently in progress.

303.002 (Oral) Development of a Tool to Facilitate Community-Based Identification and Engagement with Care of Children with Developmental Disabilities in Ethiopia and Kenya

Background:

Most children with autism and other developmental disabilities (DD) in sub-Saharan Africa remain unidentified and undiagnosed due to a lack of awareness and scarcity of qualified human resources. A community informant method is a task-sharing approach whereby trusted community members with the necessary training undertake household visits to improve identification and encourage care engagement.

Objectives:

To co-develop a community case detection tool (CCDT) and associated training package aiming to increase community-based detection of children with DD and promote care engagement in Ethiopia and Kenya.
Methods:

The study took place across four sites: Addis Ababa and rural Gurage zone in Ethiopia, and Nairobi and rural Kilifi in Kenya.

Eight consultation workshops (two in each site) were conducted to understand the needs and priorities of the local community. Stakeholder groups included caregivers of children with DD, community health workers, teachers, policymakers, and professionals from the health and education sectors. Participants were asked to reflect on current community understanding of DD and which cadre of community members can support identification of children with DD. Stakeholders were presented with sample tools using vignettes and illustrations describing signs of DD and a developmental milestone chart. They were also consulted on the training needs of prospective community informants and the need for awareness-raising in the wider community. All workshops were audio-recorded, transcribed verbatim and data analyzed using thematic approach. These findings informed the development of a draft CCDT and associated training package.

Results:

Stakeholders shared there is a high level of stigma and low awareness about DDs in the community. It was reported that among community members, DDs were often attributed to supernatural causes, spirit possession and wrongdoing by parents, resulting in stigma and discrimination against children with DDs and their caregivers.

When reviewing the sample tools, participants proposed using a combination tool with vignettes, illustrative images, and referral guidance. Participants suggested that vignettes should include positive characteristics to avoid reinforcing negative beliefs and should instil hope to promote help-seeking. The resulting draft tool includes two vignettes describing children with intellectual disabilities including autism, supplemented by illustrations. The tool includes a simple decision tree to encourage referrals for professional assessments and supportive care.

Community health volunteers and teachers were identified as suitable community informants in both countries, in addition to women’s development groups in Ethiopia. Parents of children with DDs were also suggested due to their shared lived experiences.

Alongside the community case detection, awareness-raising for the larger community was suggested to promote community engagement and address negative beliefs. The involvement of parents of children with DD in raising awareness was encouraged, in line with the principles of social contact to address stigma towards children with DD and their families in the community.

Conclusions: The acceptability and feasibility of the draft case detection tool will be tested in a pilot study followed by a large-scale evaluation across all four project sites. The findings of this project can inform initiatives to facilitate early detection and care engagement across low-income contexts.

Background: SPARK is an online research study that collects phenotypic and genetic data on individuals with autism and their families. The online research environment creates a unique ability to engage hundreds of thousands of participants; however, this scale does not allow for traditional clinical examinations and requires mostly self-and parent-report surveys. Due to differences in diagnostic practices and differences in parent recall, it can be challenging to assess accurate informant-report of diagnostic history, assessment results, and reporting of individuals with intellectual disability.

Objectives: Leveraging the data collected in SPARK, the objective of the current study was to create an algorithm for estimating cognitive impairment in children and dependent adults in the absence of clinical IQ scores and evaluate its accuracy.

Methods: The algorithm of the derived cognitive impairment variable (DCI) assesses 14 parent-reported variables and assigns a dichotomous value of likely cognitive impairment (0/1). The variables seeding the DCI include reported intellectual disability diagnosis, language level, cognitive delay relative to age, mental age equivalent, language disorder diagnosis, language regression, minimally verbal status, Vineland-3 Communication standard score, and parent reported cognitive test scores. It is calculated for children over the age of 2 years and dependent adults with a reported professional diagnosis of ASD. DCI results were compared against nonverbal (NVIQ) and full scale (FSIQ) IQ scores from medical record review, where NVIQ or FSIQ < 80 was defined as cognitive impairment (inclusive of borderline intellectual impairment). Accuracy of the DCI classification was evaluated using the Receiver Operating Characteristic (ROC) curve and associated statistics completed in SPSS.

Results: 3,845 individuals were included (mean age 8.3 years; 21% female). This sample is representative in race/ethnicity and sex at birth of the full SPARK cohort of children and dependent adults. The full SPARK cohort of children and dependent adults is older than the
sample in this study (mean age 9.1 years). The area under the receiver operating characteristic curve (AUC) was 0.812. The sensitivity of the DCI was 80% and the specificity was 72%. The positive predictive value was 0.72 and the negative predictive value was 0.78.

Conclusions: The DCI has good accuracy in comparison to actual IQ based on the AUC. Selecting a cutoff of FSIQ/NVIQ<80 was shown to have the best performance for this set of variables in SPARK. The higher sensitivity and relatively lower specificity of the DCI are desirable for the intended application of this algorithm, which is to maximize the ability for researchers, particularly those in genetics, to identify individuals with subaverage intellectual ability when clinical IQ scores are not available. With this derivation, we were able to provide an estimate of cognitive status in over 99,000 individuals in SPARK with missing data. The algorithm serves as a model of a useful proxy for ID diagnosis in large scale studies. Future analyses should assess which variables in combination best predict actual IQ and extend the algorithm to an adult sample.

303.004 (Oral) Echo Autism in East Africa: Understanding Barriers to Care, Professional Development Needs to Improve Access to Autism Best-Practices
B. Pujol, Kipepeo Therapies, Nairobi, Kenya

Background: Limited access to health and education professionals with autism expertise in Kenya and across Africa creates significant disparities. Consistent screening, identification, diagnosis, and longitudinal care for autistic children is severely lacking leading to less optimal supports and services for children and their families. The Project Extension for Community Healthcare Outcomes (ECHO) framework represents an innovative solution for building capacity for best-practice healthcare for autistic people. ECHO Autism is a technology-enabled collaborative learning model developed to train community-based clinicians through mentoring, case-based learning, and guided practice. The model demonstrates effectiveness in increasing clinician self-efficacy related to autism in North America (Mazurek et al, 2017, Mazurek et al, 2020)

Objectives:
- Test the ECHO Autism model in Kenya to determine feasibility and acceptability.
- Assess participant changes in self-efficacy related to autism following participation in ECHO Autism.
- To increase collaboration across disciplines, primarily doctors and therapists, teachers, and direct providers.

Methods: A hub of content experts including developmental behavioral pediatrician, mental health clinician, resource specialist, and parent of a child with autism conducted twelve, 90-minute ECHO Autism sessions over six months. Content experts were predominantly from Kenya with one based in the US. The original ECHO Autism curriculum was modified for cultural and linguistic considerations specific to Kenya and similar African locations. Pre- and post-surveys were administered to participants evaluating barriers to care, self-efficacy related core topics in autism, participant demographics, and practice patterns.

Results:
Forty-two unique professionals participated from seven African countries, as well as the United States and Australia. Forty-five percent of participants identified as school professionals and 55% of participants identified as healthcare professionals. Average session attendance was 19.

Participants reported positive impacts on their ability to care for children with autism. Specifically, 99% of individuals agreed or strongly agreed with the statement “participation will improve my ability to care for children with autism in my practice.” 98% felt the “recommendation of the specialists will improve my ability to provide care for children with autism in my practice.”

Ninety-six percent reported learning new information about autism best-practices, and 95% agreed or strongly agreed that they connected with peers and would ask for professional advice and recommendations.

As a result of participating in ECHO Autism in Kenya 100% of participants had access to screening tools and the ability to utilize those tools for any child, as well as resources to share with families. This was a marked change from pre-program rates of 34%, 0% and 38% respectively. Participants reported high program satisfaction and interest in continuing learning through ECHO Autism.

Conclusions: The ECHO Autism program in Kenya is a feasible, acceptable, and satisfactory approach to increasing access to professionals with improved self-efficacy related to autism best-practices. The ECHO Autism program in Kenya demonstrates the adaptability of the model to reduce disparities across cultures and professional disciplines. The unique blend of participants from education and healthcare offers additional advantages for low- and middle-income countries where preventative healthcare may be less common, therefore necessitating multivariate approaches to autism screening, identification, diagnosis, and longitudinal supports.
**321.001** (Oral) Essential Characteristics of Autism: How Can We Provide Greater Access to High-Quality Assessments for Autism Spectrum Disorder?

**I. Kamp-Becker, A. Langmann, M. Fleige, S. Roepke, M. Schulte-Ruther, V. Roessner, H. Scheuermann, S. Stroth, N. Wolff and L. Poustka**, (1)Department of Child and Adolescent Psychiatry, Psychosomatics and Psychotherapy, Philipps University Marburg, Marburg, GERMANY, (2)Department of Child and Adolescent Psychiatry, Psychosomatics and Psychotherapy, Medical Clinic, Philipps-University Marburg, Marburg, IA, Germany, (3)Department of Psychiatry, Charité Berlin, Berlin, Germany, (4)Department of Psychiatry, Charite Berlin, Berlin, Germany, (5)Department of Child and Adolescent Psychiatry and Psychotherapy, University Medical Center Göttingen, Göttingen, GERMANY, (6)Department of Child and Adolescent Psychiatry, University Hospital Carl Gustav Carus, Technische Universität Dresden, Dresden, Germany, (7)Department of Child and Adolescent Psychiatry, Psychosomatics and Psychotherapy, Philipps University Marburg, Marburg, Germany, (8)Department of Child and Adolescent Psychiatry, University Hospital Carl Gustav Carus Dresden, Dresden, Germany, (9)Department of Child and Adolescent Psychiatry and Psychotherapy, University Medical Center Göttingen, Göttingen, Germany

**Background:**

Due to increasing numbers of referrals seeking an assessment for ASD there are extremely long waiting lists for diagnostic evaluations, delaying early detection and intervention for ASD. Practitioners are thus under increasing pressure to provide quicker or abbreviated evaluations to decide whether a person needs a full diagnostic assessment for ASD or rather other examinations.

**Objectives:**

By carving out a subset of items from the ADOS-2 and ADI-R which optimally discriminated between ASD and other developmental or mental disorders, we laid the foundation for the development of a training tool designed to support health care professionals in referring (or not) a given person to a specialized center for ASD. Our tool is a web-based training program for practitioners not specialized in ASD that teaches a reduced but essential set of behavioral aspects characteristic of ASD by employing different didactic methods, e.g. video clips, case examples and quizzes.

**Methods:**

We used data from a well-characterized clinical population (n= 3,648 individuals, 1,884 with ASD, 1,764 with other developmental or mental disorders, initially referred with suspicion of ASD). This cohort contains individuals with a wide age and IQ range (age: 1 - 72 years, mean=13.3 ±11.1; IQ: IQ < 85 to > 115), 18% females. We used approaches such as machine learning or multivariate pattern classification in order to identify symptom profiles and predict individual diagnostic classification based on multiple clinical data. Random Forest Analyses were used to identify diagnostically relevant characteristics from ADOS and ADI-R that differentiate ASD from other mental disorders with gender effects as co-variates.

**Results:**

A reduced subset of diagnostic items from both ADOS-2 and ADI-R was identified that provided the best discrimination between ASD and other conditions across all age groups. For nonverbal children, for example, the subset included GAZE; SSOV; IJA, EYE; REQ EXPO. These models had the same or even better diagnostic accuracy than models with more items. On the basis of the identified behavioral aspects we devised an online-based training-tool to assist clinicians in focusing on the most relevant behavioral characteristics of a certain individual.

**Conclusions:**

Our first data emphasize two important aspects: First, a reduced number of diagnostic items sufficiently differentiates between ASD other conditions; second, practitioners may significantly expand their knowledge on ASD and its characteristic behavioral aspects via a 60 min training tool. Further results will show whether we will be able to significantly improve clinicians' competence to the point where they make fewer false positive or false negative assignments.

**321.002** (Oral) Early Autism Risk Detection from Electronic Health Records: Machine Learning and Early Developmental Milestones
Background: Early autism spectrum disorder (ASD) detection is critical for maximizing the benefits of early intervention. However, community providers are limited in healthcare resources for screening and lack ASD-specific expertise. Previous research shows the value of Machine Learning (ML) methods for subtyping ASD based on a child’s electronic health records (EHR) and for predicting ASD risk from a family’s medical history. ML offers an opportunity to utilize population-based routine surveillance records for predicting an infant’s ASD risk level.

Objectives: (1) Build an ML model to predict ASD diagnosis from an infant’s EHR generated by a national screening program, and test its accuracy. (2) Characterize the early developmental profile associated with ASD.

Methods: Database included EHR of 775,940 children born between 2014-2019, of which 1,163 had a documented ASD diagnosis after age 2 years. EHR consisted of data from routine screening visits: birth parameters, growth measurements, developmental milestone progression, and post-natal variables. 38 developmental milestones entered the model as binary variables. Model was limited to measurements from the first 2 years. Gradient boosting (CatBoost) ML model with a 3-fold cross validation and Yuden Threshold was applied. SHAP tool quantified feature importance.

Results: 93 features entered the initial model, an iterative process led to a final set of 14 consistently important features (fig 1). Model AUC=0.86. Using the model’s prediction we were able to detect a high risk group with a 0.76 incidence rate, a 760 fold increase of the incidence from the entire cohort (0.001). About 43% of the important features, related to developmental milestones. ASD was mostly associated with a higher rate of failing/passing verbal and non-verbal communication milestones checked in the second year of life, however also with higher rates of failing two fine motor milestones (fig 2). ASD was significantly (p<.001) associated with: higher rates of male, parental concern for development and not nursing, older mother age, lower pregnancy week, higher last weight by height percentile, and higher head circumference percentile standard deviation. Chi-square test with Bonferroni adjustment showed that 11.2% of the false positive group had a provider global developmental concern which was similar to the false negative group (11.1%) and significantly lower than the true positive group (27.6%, p<.001).

Conclusions: Findings highlight the utilization of ML methods for advancing personalized ASD screening under the age of 2 years considering interactions between birth, growth, post-natal, and developmental parameters. Future clinical testing of decision support models, can lead to tailoring providers' developmental checkup to detect ASD risk during routine care in the second year of life.

W. Guthrie¹, C. J. Zampella¹ and L. S. Cubit¹, (1)Center for Autism Research, The Children’s Hospital of Philadelphia, Philadelphia, PA, (2)Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA, (3)Center for Autism Research, Children’s Hospital of Philadelphia, Philadelphia, PA

Background: Research suggests that many children later diagnosed with ASD show early developmental deceleration – or slowing of developmental progress – and that this pattern is sometimes evident before clear autism symptoms emerge. Research from our lab has demonstrated that developmental deceleration can also be detected in a low-risk, general population sample using the Survey of Well-being of Young Children, a broadband screening tool recommended by the American Academy of Pediatrics to screen for developmental delays. While we found that a pattern of generalized developmental deceleration indicated a significantly elevated risk for ASD, it is not yet clear whether this pattern is present across all developmental domains or driven by any specific domain(s). 

Objectives: Determine whether early developmental deceleration is (1) observed in specific domains and (2) associated with elevated likelihood of ASD.

Methods: Children from ten Children’s Hospital of Philadelphia (CHOP) primary care sites were administered the Ages and Stages Questionnaire–Third Edition (ASQ-3) at 9, 18, 24, and 30-month well-child visits, according to AAP guidelines. Children with at least one ASQ-3 who received care at CHOP through at least 4 years of age were included (N=8,124). This cohort was racially (68.1% minoritized populations) and social-economically (50.4% public insurance/Medicaid) diverse, and received an average of 1.5 of the 3 recommended developmental screenings. ASD prevalence was 3.1%.

Results: Growth mixture models (GMM) identified distinct developmental trajectories of ASQ-3 scores from 9-30 months, with separate models run for each of the five ASQ-3 domains. GMMs identified four Fine Motor classes, five Communication and Problem-Solving classes, and six Gross Motor and Social classes.

Final models for Communication, Social and Problem-Solving domains each identified one or two classes characterized by decreasing ASQ-3 scores from 9-30 months, which were associated with increased risk for ASD. For example, children with typical and borderline
Communication skills at 9 months and a significant decrease from 9-30 months had an 11.4% and 25.0% risk of ASD respectively (compared to 3.1% rate in the entire cohort). Models also revealed that children with low scores at 9 months that were stable over time also had an elevated ASD risk (Gross Motor: 16.8%, 16.9%, Fine Motor: 19.4%, Social: 34.1%, Problem-Solving: 25.4%).

Conclusions: Children with developmental deceleration in social, communication, and problem-solving skills appear to be at elevated risk for ASD, suggesting that screening for trajectories in these domains may detect more at-risk children than screening at a single timepoint. In addition, deficits in any domain (including fine and gross motor) that emerge early and persist may also indicate ASD risk. Findings from the Social domain were of particular interest, as 34.1% of infants with clear deficits at 9 months were later diagnosed with ASD. While these developmental patterns were not sensitive enough to detect all children on the spectrum, the positive predictive values of developmental deceleration and early, persistent deficits were at or above those of autism-specific screening tools (Guthrie et al., 2019). Thus, repeated screenings with broadband developmental tools may be a fruitful avenue for earlier and more sensitive ASD detection.

Objectives: To develop and assess a framework for generating a culturally-sensitive parental-report autism screening measure that is highly predictive of autism risk.

Methods: We developed and piloted a pictorial screening tool to identify toddlers at risk for social communication challenges or autism. Eleven social communication behaviors associated with autism (e.g., reciprocal play, use of facial expression, imitation) were presented along with photos and brief text illustrating each behavior (See Figure 1 for example). Respondents identified the frequency of each behavior. We then employed Plan-Do-Study-Act (PDSA) cycles to solicit feedback from our target communities and allow us to adjust the behaviors, photographs, and item wording as needed. PDSA employs an iterative process that focuses on the translation of ideas into appropriate action by repeatedly soliciting feedback from end-users throughout development. During each PDSA cycle, we conducted focus groups with CALD caregivers of children aged 16-35 months in collaboration with nonprofit community agencies serving African and Middle Eastern immigrants and refugees and Black Americans. Additionally, caregivers completed a pilot version of the items and a Likert-scale survey assessing the usability and acceptability of the items. Nonprofit providers (i.e., program staff that work directly with target communities) also completed a survey about the items. A second PDSA cycle will occur between November – December 2022.

Results: Eighty-two caregivers completed surveys and participated in one of eight focus groups in a first PDSA cycle; five providers completed surveys (See Table 1 for caregiver characteristics). Mixed-methods analyses revealed that aspects of six of the 11 social communication behaviors required adjustment. Thematic analysis on the focus group transcripts resulted in four themes: increase the diversity of photo representation, improve the representation of “play behavior,” increase forms of imitation presented, and clarify the language of question items (e.g., “point to share interest” and “point to request” were both interpreted as requests).

Conclusions: Using mixed methods within PDSA cycles to systematically assess the cultural sensitivity of screening items from multiple end-users (i.e., providers and caregivers) results in rich feedback that informs essential revisions to the development of screening items. This process may provide a model for the development of culturally sensitive measures.

421.062 (Poster) $283M of Publicly-Funded Research Directed between 2008 and 2018 to Improve the Screening and Diagnosis of ASD in the United States: From Ideas to Instruments to Implementation

P. Doehring, ASD Roadmap, Chadds Ford, PA
Background: Researchers have sought to improve the identification of ASD through basic research (for example, on possible biomarkers) and applied research (for example, on the development of specific clinical tools for screening and diagnosis). We have previously noted patterns of publication and funding that generally favor basic research over applied research, with a negligible proportion targeting implementation involving community-based settings and professionals. Revisions to the Interagency Autism Coordinating Committee’s (IACC) strategic plan in 2016 included new objectives prioritizing applied research, perhaps to address the advocacy community’s desire for research demonstrating a more immediate impact on outcomes.

Objectives: What proportion of publicly funded research has sought to improve screening and identification of ASD in community settings since revisions to the IACC’s strategic plan in 2016? Has this increased over time relative to other areas of research?

Methods: We downloaded data from the Autism Research Database on all grants funded between 2008 and 2018 to address Identification, excluding projects that were privately-funded or that focused on training or infrastructure. We conducted a project-by-project review on the remaining projects to distinguish between those involving basic versus applied research, and within the latter between clinical, implementation, and other applied research.

Results: Between 2008 and 2018, $283M was directed towards 242 basic and applied research projects focused on improving Identification. Funding of applied research increased between 2008 and 2018 (see Figure 1), clearly overtaking basic research by 2017. While funding for applied research on screening and diagnosis remained flat (about $12M/year) between 2015 and 2018, funding for research on the general biology of ASD increased by over 50%, from $94M to $143M.

Most applied research funded between 2008 and 2011 involved clinical research (e.g., testing new tools for screening and diagnosis), but this shifted later (see Figure 2): of the 24 research projects funded between 2015 and 2018, only 6 involved clinical research while 7 involved implementation research and 11 involved other applied research (e.g., secondary data analyses to document related outcomes). An explosion was noted in the funding of implementation research in 2014, suggesting that the 2016 Strategic Plan did not spark changes but certainly reinforced the trend. Such research tested protocols for community-based screening and diagnosis, explored how family navigators can prevent families from being left behind, and tracked how early screening led to early intervention. Nonetheless, the implementation research projects undertaken in 2018 constituted about only 3.5% of all publicly funded research directed towards improving the lives of people living with ASD, a 0.2% increase since 2015.

Conclusions: Our analyses reveal a clear increase in applied research funding in the United States between 2008 and 2018 and focused on screening and diagnosis, with a marked increase in implementation research since 2014. These investments in testing new practices in community settings will likely encourage advocates focused on more immediate, real-world outcomes. It remains to be seen, however, if these new practices can be scaled up to impact early intervention outcomes at a meaningful scale.

421.063 (Poster) A Classification System of Autism Based on Eye Tracking Technology

W. You, Q. Liu, X. He, B. Zhou, L. Shen and X. Gao, (1)School of Medicine, School of Medicine.Tsinghua University, Beijing, China, (2)School of Medicine, Tsinghua University, Beijing, China, (3)School of Medicine, Tsinghua University, Beijing, China

Background:

Early diagnosis of autism is critical for developmental improvement in autism. Due to the shortcomings traditional scale-assisted diagnosis methods, which are highly professional and lack objectivity, in recent years, eye-tracking technology to assist early diagnosis of autism in children has become a research hotspot in the field of autism. However, it is a challenge for researchers to use eye-tracking technology to mine effective eye movement physiological indicators to improve the objective and accuracy of early diagnosis of autism.

Objectives:

Our study therefore proposes and implements an early auxiliary diagnosis system for autism based on pupillary responses and gaze behaviors, which can objectively and efficiently assist autism diagnosis in children age 3-6.

Methods:

Our study designs an eye-tracking experiment based on pupillary responses and gaze behavior. Then two types of eye-tracking features, relative pupillary response features and relative fixation rate features in the area of interest, are extracted from the existing dataset.

The pupillary response experiment used a dataset of 75 subjects (including 25 ASD children and 50 TD children) for model creation and validation. A total of 45 subjects (including 19 ASD children and 19 TD children) participated in establishing and validating the model in the fixation-based behavior-based experiment. We fuse the two models in a joint decision-making way. Finally, an additional 20 ASD children and 13 TD children validated our model.
Results:

The two models have an average classification accuracy of 93.3% and 84.21% and an average AUC of 93.84% and 79.50%, respectively, with the leave-one-out cross-validation method. The experimental results show that the prediction results of the fusion model achieve a classification accuracy of 93.94% and an average AUC of 96.92%.

Conclusions:

By combining two eye-tracking experiments with a machine learning method, this study proposes a classification system that can be used to assist the identification of autism at an early stage of life. The system extracts key features from the data of eye-tracking experiments, selects the most predictive feature subsets, and constructs two independent parallel classifying models. The classification system proposed in this paper can provide clinicians with additional evidence to support the identification of children with autism, with an achieved performance in this study of 95.00% precision, 95.00% recall, 93.94% accuracy and 96.92% AUC.

421.064 (Poster) A Direct Comparison of Three Screening Methods for Siblings at High-Risk of Autism Spectrum Disorder

C. M. Wong, N. Mohd Zambri, H. H. Fan, L. H. S. Lau, L. M. Daniel and H. C. Koh, (1)Department of Child Development, KK Women's and Children's Hospital, Singapore, Singapore, (2)Department of Child Development, KK Women's and Children's Hospital, Singapore, Singapore, (3)Department of Child Development, KK Women's and Children's Hospital, Singapore, SINGAPORE

Background: While universal screening for autism in a low-risk general population is not recommended, targeted screening of children at high-risk for autism is. However, many screening tools have been validated for use mainly in low-risk populations. There are also screening tools that rely predominantly on caregiver report, and others that involve direct observation by trained administrators, with consequent differences in cost implications in their implementation.

Objectives: To compare the accuracy of three autism screening tools as Level Two screeners in a population of siblings at high risk for autism. The tools are the Modified Checklist for Autism in Toddlers, Revised with Follow-up (M-CHAT-R/F), the ASDetect mobile app, and the Social Attention and Communication Surveillance, Revised (SACS-R).

Methods: Siblings, aged 12 to 30 months old, of children with confirmed autism were invited to undergo a structured screening programme at 12, 18 and 30 months old. This involved caregivers completing the M-CHAT-R/F and ASDetect at each visit, while the siblings were directly tested by trained nurses using the SACS-R. Although the M-CHAT-R/F is only validated for children 16 months and older, it was used at 12 months to compare its utility to the other screeners. The siblings then underwent an Autism Diagnostic Observation Schedule – Second Edition (ADOS-2) assessment at 36-48 months old. Sensitivity, specificity, positive predictive and negative predictive values for the three screening methods were computed.

Results: 189 siblings underwent screening (56.1% male; 60.3% Chinese, 29.1% Malay, 5.3% Indian). 76 were screened at 12 months, 117 at 18 months, and 140 at 30 months, with some being screened at more than one time-point. 33 withdrew and 156(82.5%) completed the ADOS-2. 56 met ADOS-2 criteria for autism spectrum, and 32 were confirmed to have autism while 9 did not meet full DSM-5 criteria. 15 of the 56 did not attend clinical evaluations to determine final diagnosis, hence were excluded from further analyses.

Conclusions: Although not validated for use at 12 months old, the M-CHAT-R/F had the best sensitivity for this age group. The ASDetect had the lowest sensitivity at all ages. The sensitivity of the M-CHAT-R/F declined with age, however, while the SACS performed better at 18 and 30 months, indicating differences possibly due to lenient caregiver-reporting versus more objective direct screening. Further evaluations on the highest discriminating items for each tool will be conducted. If targeted screening of high-risk children is to be conducted, the performance of tools developed for low-risk ASD screening should also be examined in higher-risk populations.

421.065 (Poster) A Multi-Modal, Multi-Informant Assessment of Daily Living Skills in Autistic Adolescents

A. Duncan, J. Meinzen-Derr, A. C. Modi, C. Fassler and L. J. Stark, (1)Division of Behavioral Medicine and Clinical Psychology, Cincinnati Children's Hospital Medical Center, Cincinnati, OH, (2)College of Medicine, University of Cincinnati, Cincinnati, OH, (3)Division of Biostatistics and Epidemiology, Cincinnati Children's Hospital Medical Center, Cincinnati, OH

Background: Autistic adolescents without an intellectual disability (ID) often have daily living skills (DLS) that are 6-8 years behind same-aged peers and impact their ability to successfully transition to adulthood. Surviving and Thriving in the Real World (STRW) is the only known DLS intervention for autistic teens that targets hygiene, laundry, cooking, and money management skills. In a recently completed RCT, the STRW intervention led to significant gains in DLS on the Vineland Adaptive Behaviors Scales, 3rd Edition (VABS-3) caregiver report compared to a social skills control group (i.e., PEERS). However, in order to comprehensively understand how interventions may impact DLS in adolescents with autism, multiple assessment methods (e.g., questionnaire, daily phone diary, direct behavioral observation) and informants (e.g., caregiver, self-report) are needed.
**Objectives:** To assess the change in DLS of autistic adolescents who received either the STRW or PEERS interventions using a multi-modal, multi-informant DLS battery: (1) the Adaptive Behavior Assessment System, 3rd Edition (ABAS-3) self-report and caregiver questionnaire; (2) the DLS Direct Behavioral Observation (DLS-DBO); and (3) daily phone diaries (DPDs).

**Methods:** Participants included 48 youth with ASD (ages 14 to 16 years, M=15.3, SD=0.69; 72.9% male; 83.3% White) without an intellectual disability (IQ M=100.9, SD=10.3). Participants completed the DLS battery at baseline, were randomized to and completed STRW or PEERS, and then completed the DLS battery at post-treatment. Adolescent and caregiver participants completed the ABAS-3 which includes the Practical Domain that assesses DLS in the subdomains of Home Living, Community Use, Self-Care, and Health and Safety. At an in-person DLS-DBO, adolescents were assessed on their ability to cook on the stove and microwave, complete a load of laundry, and purchase items at a store using a predefined budget. Items were scored from 0-2 with higher scores indicating that tasks were done correctly and independently. Autistic teens completed DPDs on 3 consecutive days and reported on all activities that they completed over a 24-hour period. Each time a teen reported completing a DLS, they reported on whether it was done independently. The total number of DLS and independent DLS was calculated for each teen across 3 days. Descriptive statistics were calculated for DLS-DBO, DPDs, and the ABAS-3 at baseline and post-treatment. Change scores were computed and independent sample t-tests were used to test the differences between STRW and PEERS from baseline to post-treatment.

**Results:** See Table 1 for results. Participants in STRW made significant gains on the DLS-DBO (Laundry, Total), DPDs (total DLS, independent DLS), ABAS-3 Caregiver (Health and Safety, Community Use), and ABAS-3 Teen (Practical Domain, Home Living, Health and Safety, Self-Care).

**Conclusions:** Autistic adolescents in STRW demonstrated DLS improvements across different assessment methods and informants compared to adolescents in PEERS from baseline to post-treatment. Collectively, both parents and teens are reporting gains in all DLS areas targeted in STRW on the ABAS-3, and teens are demonstrating these gains via direct behavioral observation of laundry skills and self-report of independent DLS completed at home. Implications for assessment of DLS in adolescents will be discussed.

**Background:** Autism spectrum disorder (ASD) is a neurodevelopmental disorder that emphasizes early interventions for a better prognosis. Yet direct observations by trained administrators can often be time-consuming, while questionnaires or caregiver interviews can be subjective to factors such as parental awareness of ASD or human biases. Therefore, to overcome such shortcomings, there has been a high demand for a simple and objective approach to detecting risk signs of ASD in young children.

**Objectives:** The purpose of the study is to explore the effectiveness in detecting and classifying young children with or without ASD using a five-minute video sequence.

**Methods:** Key behaviors were selected from the Behavior Development Screening for Toddlers (BeDevel; Bong et al., 2021), a screening instrument for ASD that has demonstrated high sensitivity and specificity. Eight tasks based on initiation and response to joint attention, response to name, social referencing, eye contact, social smile, imitation, and pointing behaviors were used in the video sequence. The videos were shown on three TV screens with an actress who led each task and induced each key behavior. Cameras installed below the screens recorded the participants’ responses and were independently scored by two researchers. Kappa values (κ) were used to calculate agreement between the video sequence and the in-person BeDevel ratings. Classification and regression trees (CRT) were used to explore the hierarchical representations of interaction between the variables and the final prediction.

**Results:** A total of 110 young children, comprised of 75 participants with ASD (age M=31.37, SD=7.12, 18.7% female) and 35 non-ASD participants (age M=35.68, SD=5.81, 28.6% female), were included for analysis. Response to name, imitation, social smile, and pointing behavior showed fair strength of agreement (κ > .21). Based on the CRT analysis, eye contact, response to joint attention, and pointing behaviors were ranked as important variables in predicting final group classifications. Presenting both pointing behaviors and responses to joint attention in each of the respective tasks best classified young children into the non-ASD group. However, young children who did not show pointing behaviors and maintained satisfactory levels of eye contact in one task without response to joint attention or social smiles were classified into the ASD group. The overall prediction based on our model was 73.6% (Figure 1).

**Conclusions:** This pilot study demonstrates promising results in using a short video sequence to detect and screen for early ASD risk signs in young children.
Background:

Demand for formal diagnostic assessment of autism in adulthood has increased dramatically in the last 10 years in the UK and waiting times for assessment can be more than 2 years (Crane et al., 2018). Referral procedures need to ensure assessments are offered to those most likely to be diagnosed with autism to ensure the best use of limited resources. Information about diagnostic rates, characteristics of the population referred and post diagnostic outcomes can be of value to those seeking autism assessment in adulthood and those planning and managing services.

Objectives:

To answer the following questions through a systematic literature review:

1. What is the diagnostic rate for those entering the autism diagnostic pathway in adulthood in the UK?

2. Do the demographic characteristics of those assessed and diagnosed with autism differ from those not diagnosed with autism?

3. What is the response to the diagnostic outcome for those receiving a diagnostic assessment in adulthood? How does this differ between those diagnosed with autism and those not?

Methods:

Electronic databases Embase, APA PsycNET and Web of Science were searched and evaluated against the inclusion criteria - studies or reports of primary data from UK adult autism diagnostic assessment outcomes published June 2012 to January 2022. Studies reporting on non-primary data or clinician or parent/carer experience were excluded. The PRISMA statement was used for reporting the review. Studies were appraised using the critical appraisal skills programme (CASP).

Results:

14 studies met the inclusion criteria. 11 studies provided information on diagnostic rate. Average diagnostic rate was 53.77%, range <25 to 90%. Four studies provided information on age. Of these, three found a significant difference in age between those diagnosed with autism and those not, with those receiving a diagnosis being younger. Six studies reported on gender and of these only one found a significant difference in gender between those diagnosed and those not, with more males diagnosed than females in this case. Only one study provided information on ethnicity and here only 5% of those assessed were not white British. There was high incidence of psychiatric co-morbidity in both those diagnosed and those not diagnosed with autism. Only one study reported on the service user response to the assessment outcome and only in people diagnosed with autism. Emotional response to diagnosis and impact on life were mainly positive although this did vary. There was no information available on the experience and outcomes in those receiving assessment who were not diagnosed with autism.

Conclusions:

Based on this review nearly half of all adults accessing a diagnostic assessment of autism are not diagnosed with the condition. They are similar in demographic characteristics to the group diagnosed. There is no available information on outcomes for this non-diagnosed group.

This non-diagnosed group is of clinical interest due to their demands for clinical resources assigned to autism diagnostic assessment. The group also has possibly unresolved needs. Further information about this group and their outcomes would help with future service planning.

**421.068 (Poster) Accelerating Diagnosis of Autism Spectrum Disorder Using Asynchronous Telehealth Methodology**

Background: Early identification and treatment of autism spectrum disorder (autism) helps prevent additional problems later in a child’s life. However, long wait lists and long travel distances often make it difficult for parents to obtain timely evaluations. Telehealth technology has the potential to offer a significant advantage over traditional in-person assessments (IPA) for families with limited resources for a diagnostic assessment. Telehealth technology also provides clinicians with the ability to observe a child’s behaviors in natural environment (i.e., a home setting) while providing families with the ability to communicate with a clinician without having to incur the costs associated with long distance travel.

Objectives: The objective of this study was to compare the length of time from referral to the completion of a diagnostic evaluation between two groups of children randomly assigned to telehealth group or IPA assessments. This study was not designed to assess the validity of the telehealth diagnosis as that study was completed and published previously. A secondary objective was to gather information form parents regarding their experiences with telehealth or IPA assessment.

Methods: Three tertiary autism centers participated in this study; centers were located in Southeast, Southwest, and West. Recruited families were from consecutive self-referrals to the centers who were seeking an autism assessment for their child. Fifty-seven families from the surrounding urban and rural communities participated; children ages 18 months – 6 years participated in either an IPA (n=27) or a telehealth (n=30) assessment. Children were randomly assigned to the IPA or a telehealth assessment. IPA consisted of the regular assessment provided at each clinic, while the telehealth assessment was completed using the Naturalistic Observation Diagnostic Assessment (NODA™). NODA assessment included families capturing and uploading four video segments of their child at home, which expert clinicians reviewed and tagged for behaviors associated with autism as well as typical behaviors. The NODA proprietary system organized behavior tags according to the DSM-5 criteria for autism, which clinicians reviewed to determine final autism diagnosis. Parents received a summary report detailing the NODA or IPA assessment results and recommendations. Parent surveys were provided prior to receipt of feedback to gage their satisfaction with the assessment process based a Likert scale 1-5.

Results: Across the 3 sites, the average time from referral to diagnostic completion was 115 for the IPA and 66 days for the telehealth method (p < .001). Post participation satisfaction surveys were received 77% of participating families (IPA=21; NODA=23). Families positively rate the assessment as gathering important information about their child (4.57/5 for IPA and 4.13/5 for telehealth) and that they learned valuable information about their child (4.76/5 for IPA and 4.09/5 for telehealth). Families undergoing the telehealth assessment rated the process less favorably than the IPA (4.43/5 for IPA and 3.87/5 for telehealth).

Conclusions: This study found that video capture smartphone-based technology offered a significant timesaving option for families seeking an autism evaluation. Asynchronous telehealth evaluations are thus a promising method to facilitate autism evaluations and provide feedback to families regarding treatment options.

421.069 (Poster) Parental Concerns Regarding Social Emotional Reciprocity Deficits Correspond with Their Children’s Ultimate Diagnosis of ASD

R. Saban-Bezalel1, E. Ben-Itzchak2, D. A. Zachor3 and E. Avni4, (1)Communication disorders, Ariel University, Ariel, Israel, (2)Bruckner Center for Research in Autism, Communication Disorder, Ariel University, Ariel, Israel, (3)The Autism Center/ALUT, Pediatrics, Ditza Antebi Zachor Prof, Zerifin, Israel, (4)The Autism Center/ALUT, Pediatrics, ALUT-Israeli organization for Children with ASD, Zerifin, Israel

Background:

Social and developmental concerns are a common reason for parents to approach professionals for evaluation of their children. These concerns may suggest a possible autism spectrum disorder (ASD), but this is not always the case of the concerns. Assigning a definitive ultimate ASD diagnosis is challenging, especially at young ages and for the milder variants of the spectrum with preserved cognition. Better understanding of parental concerns and their correspondence to an ultimate diagnosis of ASD among this group is critical.

Objectives:

- To analyze which of the DSM-5 criteria for ASD are reflected in parental first concerns expressed during child evaluation.

- To compare parental concerns corresponding to DSM-5 criteria for ASD between groups of children receiving or not receiving an ultimate ASD diagnosis.

- To explore predictors (adaptive behavior and parental primary concerns) for an ultimate ASD diagnosis.

Methods:

Participants (N = 81, 24 females), aged 44–154 months, IQ>70 (range 72-122), underwent a comprehensive assessment for a possible ASD diagnosis using standardized tests in a tertiary autism center. The participants were divided into two groups based on their ultimate
diagnoses: ASD (n = 40, 8 females) or non-ASD (those not meeting diagnostic criteria for ASD, n = 41, 16 females). The groups were matched by sex, age, and IQ scores.

Parental first concerns were collected from the free description portion of introductory questions of the Autism Diagnostic Interview-revised. Each parental concern was analyzed as to whether it corresponded to one of the seven subdomains of the DSM-5 criteria for ASD.

Results:

Of the DSM-5 criteria for ASD reflected in parental reports of both groups, deficits in developing, maintaining, and understanding relationships was the most common concern (86%), followed by deficits in social-emotional reciprocity (58%), excessive adherence to routines (52%), hyper- or hypo-reactivity to sensory input (35%), stereotyped/repetitive behavior (26%), and highly restricted/fixated interests (21%). The least reported criterion was non-verbal communication deficits (12%).

Examining differences between ASD and non-ASD groups revealed that only the DSM-5 criterion for social-emotional reciprocity (as reported by parents) significantly distinguished between ASD and non-ASD groups, X²(1, N=81)=9.35, p=.002.

A logistic regression was performed to predict the likelihood of an ultimate diagnosis of ASD versus a non-ASD diagnosis based on the children's adaptive behavior and of parental concern regarding social-emotional reciprocity difficulty. The logistic regression model was statistically significant, (X²(2)=10.66, p=.005), and explained 17.0% (Nagelkerke R²) of the variance, with only one significant predictor: parental report of social-emotional reciprocity difficulty (β =.23, p=.001).

Conclusions:

Social difficulty was the most reported first concern expressed by parents seeking professional evaluation for a possible ASD diagnosis for their children, while non-verbal communication was the least. However, the only parental concern that distinguished between groups ultimately receiving ASD/non-ASD diagnoses related to impairment in social emotional reciprocity. These findings have important clinical implications for professionals during the early stages of parental interviews in the context of ASD evaluation and highlight the significance of first concerns regarding deficits in social-emotional reciprocity.

421.070 (Poster) Accuracy of Chinese Version of Autism Spectrum Rating Scale: Short Form (2-5 years) for Detecting Autism Spectrum Disorder in Toddlers

Y. C. Huang and C. C. Wu, (1)psychology, Department of Psychology, Kaohsiung Medical University, Kaohsiung, Taiwan, (2)Department of Psychology, Kaohsiung Medical University, Kaohsiung, Taiwan

Background: Previous studies showed early interventions were helpful to improve prognosis and outcomes of toddlers who suffer from autism spectrum disorder (ASD). There are a lot of screening tools for toddlers with ASD around the world. However, the screening tools for young children with ASD in Taiwan are inadequate. The Chinese version of Autism Spectrum Rating Scale: Short Form (2-5 years) (ASRS-C: SF 2-5 years; Yuan & Lin, 2015) could be one of the better screening tools for toddlers with ASD. It has shown decent sensitivity and specificity for ASD. However, there was only one study discussing ASRS-C: SF (2-5 years) in Taiwan as of today. Another issue is that most studies focused on mothers’ perspective, while few studies specially aimed at the role of fathers. Based on the above reasons, more comprehensive researches are required.

Objectives: The purpose of this study was to examine the accuracy of the ASRS-C: SF (2-5 years), as well as finding out whether different ways of parenting, involvement, or perspective between mother and father would influence the scale rating score.

Methods: This study recruited 132 toddlers with ASD and 73 toddlers with development delays (DD) before 36 months of age, and their parents as participants from the region of Kaohsiung and Chiayi in Taiwan. These toddlers came from both clinical referral and community. All of them are not diagnosed before the recruitment. This study used Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition (DSM-5) to distinguish the diagnose ASD and DD. the ASRS-C: SF (2-5 years) was filled in by parents. Using Receiver Operative Characteristic (ROC) to determine the best cut-off score, and calculated sensitivity, specificity, and screening accuracy in ASD and DD group. Moreover, using t test to find out whether there was a significant difference between mother’s total score and father’s total score.

Results: In the total score of mothers, the cut-off was 31, yielding the sensitivity of .765, and specificity of .725. The area under the ROC curve of the ASRS-C: SF (2-5 years) was .776. In the total score of fathers, the cut-off was 30, yielding the sensitivity of .716, and specificity of .608. The area under the ROC curve of the ASRS-C: SF (2-5 years) was .736. Lastly, t test showed no significant difference between the total score of mothers and fathers.
Conclusions: The results of this study showed that the ASRS-C: SF (2-5 years) is an acceptable screening tool for the level 1. It could be used to help making a distinction between ASD and DD diagnosis in Taiwan. Though there were no significant different between the total score of mothers and fathers, the result presented higher sensitivity and specificity of the score of mothers rather than the score of fathers. This study provides additional evidence of mothers and fathers perspective of the ASRS-C: SF (2-5 years).

421.071 (Poster) Accuracy of the Chinese Version of the Modified Checklist for Autism in Toddlers, Revised with Follow-up: Brief Form
Y. L. Huang and C. C. Wu, (1)Kaohsiung Medical University, Kaohsiung, Taiwan, (2)Department of Psychology, Kaohsiung Medical University, Kaohsiung, Taiwan

Background: Autism spectrum disorder (ASD) is thought as an innate neurodevelopmental disorder and characterized by impaired social communication and social interaction, as well as restricted and repetitive patterns of behavior and interest. After diagnosis of their toddlers, parents could develop better coping strategies and make further adjustments. In addition, toddlers with ASD and parents could receive early intervention and family services. The benefits and effectiveness of early intervention highlighted the importance of earlier identification of toddlers with ASD. Among the numerous screening tools, the Modified Checklist for Autism in Toddlers, revised with follow-up (M-CHAT-R/F) is one of the most widely used and well-studied in early age. In Taiwan, there are rarely related validity studies of the Chinese version of M-CHAT-R/F (C-M-CHAT-R/F).

Objectives: The purpose of this study was to examine the accuracy of C-M-CHAT-R/F. In addition, C-M-CHAT-R/F was used to develop a brief form for detecting toddlers with ASD before 36 months of age in order to increase the utility of screening tools.

Methods: In this study, all participants were 170 toddlers with developmental disabilities aged 18-36 months, including 116 toddlers with ASD and 54 toddlers with developmental delays (DD). These participants were recruited from the Southwestern Taiwan, and all of them are not diagnosed before the recruitment. These caregivers of toddlers with developmental disabilities filled out C-M-CHAT-R/F. Following previous studies, the chi-square test (X² test) was used to find out the better discriminative items of the C-M-CHAT-R/F, which was regarded as C-M-CHAT-R/F: Brief Form (C-M-CHAT-R/F: BF). P < 0.01 were considered statistically significant. Moreover, using the receiver operating characteristic (ROC) to determine the best cutoff score and calculating sensitivity and specificity. Also, this study calculated positive predictive value (PPV) and negative predictive value (NPV).

Results: Using any three failed items of the 20 C-MCHAT-R/F as cutoff, the findings of this study yielding the sensitivity of .73 and specificity of .72. The PPV was .85 while the NPV was .56. The area under the ROC curve of C-MCHAT-R/F was .79. Also, this study found out 13 items with better discriminative power, including 1-item, 3-item, 6-item, 7-item, 8-item, 9-item, 10-item, 11-item, 15-item, 16-item, 17-item, 18-item, 19-item. These 13 items were set as new screening method, which was referred to as Brief 13. Brief 13 used any two failed items as cutoff, yielding the sensitivity of .74 and specificity of .59. The PPV was .59 while the NPV was .59. The area under the ROC curve of C-MCHAT-R/F was .81.

Conclusions: The results of this study suggested that C-M-CHAT-R/F can be used as the screening tool for detecting toddlers with ASD in high-risk group in Taiwan. The preliminary results of both C-M-CHAT and Brief 13 demonstrated an acceptable sensitivity and specificity. However, parents should be enhanced to heighten their awareness and knowledge of ASD early indications in rural area of Taiwan.

421.072 (Poster) Accuracy of the Developmental Behaviour checklist and the Strengths and Difficulties Questionnaire for Screening for ADHD Diagnoses in Autistic Children and Adolescents
M. Palmer, R. Bailey, Z. Fang, V. Carter Leno, S. Chandler and E. Simonoff, (1)King’s College London, Institute of Psychiatry, Psychology & Neuroscience, London, United Kingdom, (2)Institute of Psychiatry, Psychology and Neuroscience, King’s College London, London, UNITED KINGDOM, (3)Institute of Psychiatry, Psychology and Neuroscience, Institute of Psychiatry, London, United Kingdom

Background: ADHD (characterised by inattention and/or hyperactivity/impulsivity problems) co-occurs with autism at high rates. However, questionnaires developed to screen for ADHD are often not validated for use with autistic individuals.

Objectives: We examined the performance of two commonly used measures of child psychopathology (The Developmental Behaviour Checklist [DBC] and the Strengths and Difficulties Questionnaire [SDQ]) to screen for ADHD in autistic children. Longitudinal data from a well-characterised cohort (QUEST) was analysed to examine 1) the accuracy of measures for correctly distinguishing ADHD cases from non-ADHD cases, 2) whether the presence of common co-occurring conditions in this population such as intellectual disability or emotional disorders influenced accuracy, and 3) whether including teacher and parent report together improves accuracy.

Methods: Parents and teachers completed the DBC in early childhood (M=6.8 years), and the SDQ during mid-to-late adolescence (M=13.4 years for teacher report, M=15.4 years for parent report). Concurrent ADHD diagnoses were established using the Preschool Age/Child and Adolescent Psychiatric Assessment (PAPA/CAPA) from parent semi-structured interview (N=101 and 72 respectively). Receiver operating characteristic (ROC) area under the curve (AUC) analyses assessed screener performance for distinguishing cases. Sensitivity, specificity and correct classification statistics were obtained for pre-existing cut-points (where available) and/or Youden’s J identified optimal cut-
Investigating Autistic Symptoms in Sotos Syndrome: A Brief Report from a Case-Control Study

Background: Sotos Syndrome (SoS) is a rare (1:14,000) congenital condition caused in the 90% by abnormalities of NSD1 gene, characterized by facial dysmorphism and multiple organ overgrowth. A heterogeneous neuropsychological phenotype has been described, including variable cognitive impairment and behavioral difficulties. A possible association between SoS and ASD symptoms has recently been highlighted; however, to date, only few data are available and no prior studies investigated ASD symptoms in SoS through the administration of the Autism Diagnostic Observation Schedule–Second Edition -ADOS-2.

Indeed, based on the knowledge that some genetic conditions present ASD symptoms and that, similarly, 10–20 % of ASD is linked to genetic causes, it is therefore important to deeply investigate the presence of ASD symptoms within the SoS population. It could lead not only to a better definition of the SoS neuropsychological profile, but also to determine whether SoS could be implicated in ASD.

Objectives: 1. To investigate the presence of autistic symptoms in individuals with SoS 2. To characterize the socio-communicative profile in SoS, providing a comparison to an idiopathic ASD control group.

Methods: A sample of individuals affected by SoS (age range 2-18 years) was recruited. SoS individuals underwent a standardized evaluation of non-verbal IQ (Leiter-R). The presence of autistic symptoms was investigated through the administration of the ADOS-2, the Social Responsiveness Scale -SRS and the Social Communication Questionnaire-SCQ.

A control group of children with ASD - matched for age, sex and Intelligence Quotient (IQ) - was therefore included.

Results: Around 50% met clinical thresholds for ADHD during early childhood and 40% in adolescence (see Table 1 for cohort characteristics). AUC values for parent reports were acceptable, however, sensitivity for picking up ADHD cases was less than optimal for the specified cut-points on both the DBC and SDQ (see Table 2). Accuracy of teacher reports was not much more than chance and sensitivities were low. There were no statistically significant differences in accuracy of ADHD screeners by co-occurrence of intellectual disability or emotional disorders; this held across informants and timepoints. Adding in teacher reports did not statistically improve prediction of ADHD diagnosis from the parent-reported ADHD screener scores.

Conclusions: Although the DBC was not developed as an ADHD screening tool, both parent-reported ADHD questionnaires appear acceptable in detecting ADHD cases in autistic children in early childhood and mid-to-late adolescence. However, sensitivity was low. Teachers’ reports did not detect ADHD cases from non-ADHD cases with acceptable accuracy, but reports in adolescence were at a different timepoint from ADHD diagnoses. It should also be noted that although the PAPA/CAPA ADHD research diagnoses are based on parent reports, they do consider symptom pervasiveness. Tool accuracy was not influenced by co-occurring intellectual disability or emotional disorders, two common conditions in this population, although the reduced sample size in subgroup analyses may have decreased power to detect effects. Consideration of questionnaire item adaption may improve measurement precision. Comprehensive assessment from a range of informants, including direct observation of ADHD symptoms is required.

Conclusions: Our results highlighted that 72.7% of SoS individuals presented mild to moderate/high level of ASD symptoms as measured by the ADOS-2. Interestingly, an overlapping impairment in the social responsiveness scale emerged within SoS and ASD. Therefore, the
ASD symptoms’ assessment should be regularly performed in SoS children, with subsequent important implications in terms of therapeutic strategies and later outcome.

421.074 (Poster) Implementing Neurodevelopmental Pathways and Understanding Waiting Times for Neurodevelopmental Assessment and Diagnosis through a National Notes Audit in Scotland

D. Maciver, M. Rutherford, L. Johnston, A. Singh Roy, J. Utley, E. Curnow and M. Boilson, (1)National Autism Implementation Team, School of Health Sciences, Queen Margaret University, Edinburgh, United Kingdom, (2)National Autism Implementation Team, School of Health Sciences, Queen Margaret University Drive, Musselburgh, Edinburgh, United Kingdom, (3)NHS Fife, Fife, United Kingdom

Background:

Neurodevelopmental assessment is time consuming, with wide variation in time-to-diagnosis. The Covid-19 pandemic has additionally stalled progress, changed how services are delivered and has led to increases in wait times for neurodevelopmental assessment and diagnosis.

Objectives:

This study presents new information on the development of an evidence-based pathway, as part of a Scottish Government funded project, to develop standards for neurodevelopmental assessment, and investigates duration of diagnostic assessment nationally following the COVID-19 pandemic, through retrospective notes audit. Recommendations for steps to improve provision are made, informed by evidence, professional and lived experience.

Methods:

In phase 1 we drew on the Medical Research Council (MRC) guidance for development of complex interventions to produce a new children’s pathway on neurodevelopmental terminology, assessment, diagnosis, triage, and time standards. The guidance recommended maximums for acceptance of referral to first appointment (84 days), first appointment to last appointment (154 Days), and for full waiting time from referral to diagnosis (252 days). In phase 2, a Scottish Government commissioned project investigated duration of diagnostic processes nationally. As there were no comparable targets for adults, we assessed child and adult pathways using the same standards. We completed a national notes audit, and applied two-stage non-probability sampling methods, with quotas for cases for all Scottish services proving children’s or adults neurodevelopmental assessment. Areas were allocated a quota dependent size and neurodevelopmental disorder referral rate. Cases were within the last 12 months, with a completed assessment, even if the outcome was no diagnosis.

Results:

71% of Scottish health boards agreed to participate, covering a population of c4.8M million (89% of Scottish population). 409 case notes were audited [children’s pathway N=206 cases, 62.62% males, mean age 8.99 years, range 1.42-17.92 years; adult pathway N=202 cases, 49.28% males, mean age 29.96 years, range 15.75-71.08 years]. Diagnoses received by children were: Autism (69.90%), Attention deficit hyperactivity disorder (20.87%), Developmental coordination disorder (2.43%), Developmental language disorder (1.46%), Intellectual disability (8.25%), other neurological or psychiatric diagnosis (8.25%) and no diagnosis (13.59%). For adults, diagnoses received were Autism (38.92%), Attention deficit hyperactivity disorder (45.32%), Developmental language disorder (0.99%), Fetal alcohol spectrum disorder (0.49%), Developmental coordination disorder (0.49%), Intellectual disability (5.42%), other neurological or psychiatric diagnosis (13.30%), and no diagnosis (13.79%). In children’s services, 43.20% of the cases received their first appointment within 84 days, 39.32% of cases completed the assessment process within 154 days, and 19.90% of cases achieved the overall 252 day target. For adults, 45.05% of cases received their first appointment within 84 days, 73.27% of cases completed the assessment process within 154 days, and 47.03% of cases met the overall 252 day target.

Conclusions:

The pathway and recommendations were adopted by the Scottish Government, with national reach. Phase 2 has identified problems in delays for children and adults seeking neurodevelopmental assessment. Our approach allowed for the collection of a rich detailed dataset, whilst also providing a useful method for services to reflect on their capacity. The work is part of an ongoing community of practice which will support change processes nationally.

421.075 (Poster) An Analysis of Sex Differences in Autism Spectrum Disorder Clinical Presentation in a Tertiary Care Clinic

J. J. Cottle, K. C. Guest and S. E. O'Kelley, The University of Alabama at Birmingham, Birmingham, AL

Background: Autism Spectrum Disorder (ASD) is diagnosed at a substantially lower rate in females compared to males (1:3) (Loomes et al., 2017). Recent research suggests that females with ASD may not be accurately diagnosed when evaluated (Ratto, 2020). Furthermore,
much of the research into sex differences in ASD presentation requires an ASD diagnosis for inclusion, omitting females who may be mis- or under-diagnosed by current ASD diagnostic measures (Ratto et al., 2018). Research into sex differences in ASD presentation requires inclusion of those currently falling through the diagnostic cracks to characterize this phenotypically diverse population.

Objectives: To explore sex differences in clinical presentation among children and adolescents referred for an ASD evaluation.

Methods: Participants included children and adolescents referred and clinically evaluated for an ASD diagnosis at a tertiary care clinic between 2006-2020. ASD symptom severity was evaluated using diagnostic algorithm scores from the Autism Diagnostic Interview-Revised (ADI-R), and comparison scores and domain-level calibrated severity scores from the Autism Diagnostic Observation Schedule (ADOS-G, ADOS-2). Sex differences in adaptive, cognitive, and language skills were assessed using measures administered during evaluation. Factorial ANOVAs were conducted to examine interactions and main effects of sex and ASD diagnosis on ASD symptom severity and skills, and Chi-Square tests of independence were conducted to examine likelihood of reaching diagnostic algorithm cutoffs and receiving an ASD diagnosis by sex.

Results: Participants included 1,099 total individuals, with 54.8% of the sample diagnosed with ASD (Table 1). Factorial ANOVA indicated a main effect of sex for ADOS RRB domain scores (Table 2), such that females referred for an ASD evaluation had lower RRB scores than males. Chi-Square tests of independence indicated that females were more likely to reach the ADI-R algorithm cutoff for RRBs compared to males ($\chi(1) = 6.25, p = 0.012$), and that males were more likely to receive an ASD diagnosis compared to females ($\chi(1) = 5.12, p = 0.024$). Factorial ANOVA indicated a significant interaction between sex and ASD diagnosis for expressive language ($F(1, 813) = 4.05, p = 0.044$), such that females diagnosed with ASD had lower expressive language scores ($M = 66.42, SD = 17.69$) than males diagnosed with ASD ($M = 69.42, SD = 18.53$), whereas females not diagnosed with ASD had higher expressive language scores ($M = 71.45, SD = 17.22$) than males not diagnosed with ASD ($M = 68.88, SD = 16.07$).

Conclusions: In a clinical sample of individuals referred for an ASD evaluation, females were more likely to have clinically significant RRBs reported by caregivers than males, although males exhibited greater observed RRB severity than females. Overall, likelihood of ASD diagnosis was higher for males compared to females. An interaction between sex and ASD diagnosis on expressive language aligns with camouflage theory, suggesting that compensatory skills may mask ASD symptoms for females, resulting in lower diagnostic rates. Future research into sex differences should continue considering those missed by diagnostic procedures, as these findings suggest quantifiable sex differences in factors influencing ASD diagnosis among those referred for an ASD evaluation.

Objectives: To compare clinical presentation among school aged children who are minimally verbal across caregiver and therapist contexts.

Methods: All participants received a social communication intervention (Kasari et al., 2021; Smith et al., 2001) as a part of a registered intervention trial (Clinical Trial: NCT01751698). Inclusion criteria were that children must: (1) be between 5-8 years old, (2) use less than 20 spontaneous words on a language sample, and (3) have a non-verbal cognitive ability greater than 12 months. Descriptive information is provided in Table 1. The BOSCC (Grzadzinski et al., 2016) was coded from two contexts, a play interaction between children and their caregivers (CCX) and therapy session with their primary therapist (TCX). BOSCC Core Total and Social Communication (SC) domain scores were calculated across both contexts at entry (T1), 6-weeks (T2) and 16-weeks (T3) after study entry. Change over time was analyzed using linear mixed effects models with participant included as a random intercept and time (T1, T2, T3), context (TCX, CCX), and their interaction included as fixed effects. Treatment outcomes for this trial will be reported in a pending paper.

Results: At T1 there was a small to moderate correlation between BOSCC TCX and CCX Total scores ($r=0.32; p <.001$) and SC domain scores ($r=0.28; p <.001$). Further, there was a significant interaction between time and context where children saw a significantly greater reduction (signifying improvement) in BOSCC SC Domain scores between T1 and T2 ($b=-2.86, SE=0.71, p<0.001$) and between T1 and T3 ($b=-2.98, SE=0.70, p<0.001$) in the TCX compared to the CCX condition. This effect was also seen in Total BOSCC scores from T1 to

Objectives: To evaluate whether the BOSCC is sensitive to change over time in a sample of school-aged minimally verbal children with autism and whether the amount of change differs based on administration contexts.

Methods: All participants received a social communication intervention (Kasari et al., 2021; Smith et al., 2001) as a part of a registered intervention trial (Clinical Trial: NCT01751698). Inclusion criteria were that children must: (1) be between 5-8 years old, (2) use less than 20 spontaneous words on a language sample, and (3) have a non-verbal cognitive ability greater than 12 months. Descriptive information is provided in Table 1. The BOSCC (Grzadzinski et al., 2016) was coded from two contexts, a play interaction between children and their caregivers (CCX) and therapy session with their primary therapist (TCX). BOSCC Core Total and Social Communication (SC) domain scores were calculated across both contexts at entry (T1), 6-weeks (T2) and 16-weeks (T3) after study entry. Change over time was analyzed using linear mixed effects models with participant included as a random intercept and time (T1, T2, T3), context (TCX, CCX), and their interaction included as fixed effects. Treatment outcomes for this trial will be reported in a pending paper.

Results: At T1 there was a small to moderate correlation between BOSCC TCX and CCX Total scores ($r=0.32; p <.001$) and SC domain scores ($r=0.28; p <.001$). Further, there was a significant interaction between time and context where children saw a significantly greater reduction (signifying improvement) in BOSCC SC Domain scores between T1 and T2 ($b=-2.86, SE=0.71, p<0.001$) and between T1 and T3 ($b=-2.98, SE=0.70, p<0.001$) in the TCX compared to the CCX condition. This effect was also seen in Total BOSCC scores from T1 to
T2 (b=-2.63, SE=0.80, p<0.001) and from T1 to T3 (b=-3.04, SE=0.79, p<0.001). Change scores across the CCX and TCX from T1 to T2 were not significantly correlated for either SC Domain Scores (r=-0.04; p=0.62) or Total BOSCC Scores (r=-0.01; p=0.87) nor from T1 to T3 (r=-0.01; p=0.87 and r=-0.03; p=0.75 respectively). See Table 2 for mean scores across time.

Conclusions: While progress was seen across both assessment contexts, larger and sustained change was seen in BOSCC’s coded from TCXs compared to CCXs. It is also notable that a significant portion of the observed change across both contexts occurred within the first 6-weeks of the treatment and then seemed to plateau. It will be important to evaluate the effects of supplementing and modifying treatment on children’s progress.

421.077 (Poster) Investigation of Shifts in the Phenotypic Measures and Sociodemographics of Autism Spectrum Disorders

E. War#, A. Kashki#, A. Iaboni#, J. Croshie#, R. Schachar#, S. Georgiadis#, R. Nicolson#, E. Kelley#, M. Ayub#, J. Jones#, M. J. Taylor#, J. P. Lerch# and E. Anagnostou#, (1)Autism Research Center, Bloorview Research Institute, Toronto, ON, Canada, (2)Autism Research Centre, Bloorview Research Institute, Toronto, ON, Canada, (3)Autism Research Centre, Bloorview Research Institute, Holland Bloorview Kids Rehabilitation Hospital, Toronto, ON, Canada, (4)University of Toronto, Toronto, ON, Canada, (5)Department of Psychiatry, The Hospital for Sick Children, Toronto, ON, Canada, (6)Offord Centre for Child Studies, McMaster University, Hamilton, ON, Canada, (7)Department of Psychiatry, University of Western Ontario, London, ON, Canada, (8)Department of Psychology, Queen's University, Kingston, ON, Canada, (9)Department of Psychiatry, Queen's University, Kingston, ON, Canada, (10)Diagnostic Imaging, Hospital for Sick Children, Toronto, ON, Canada, (11)Wellcome Centre for Integrative Neuroimaging, University of Oxford, Oxford, ON, United Kingdom, (12)Autism Research Centre, Bloorview Research Institute, University of Toronto, Toronto, ON, Canada

Background: Autism spectrum disorder (ASD) is a highly heterogeneous condition, motivating large cohort studies. As the data for such studies may be collected over the span of several years, changes in participant demographics, assessment instruments, and diagnostic constructs may result in data shifts across time. These shifts can confound the analyses of these data, further increasing the heterogeneity of research findings in ASD.

Objectives: Our objective was to examine data shifts in recruitment practices, participant demographics, symptom domains, and adaptive functioning in the Province of Ontario Neurodevelopmental Disorders (POND) cohort.

Methods: We use data collected through POND from 2012 to 2021. The sample consisted of 853 children and youth with a diagnosis of ASD (age=11.3±3.65 years; 21.2% female). Autism traits, ADHD symptoms, and obsessive compulsive symptoms were quantified using the Social Communication Questionnaire (SCQ), Strengths and Weaknesses of ADHD-symptoms and Normal Behaviour (SWAN), and the Toronto Obessive Compulsive rating scale (TOCS). Externalising and internalising symptoms, IQ, and adaptive functioning were measured using the Child Behaviour Checklist (CBCL), the Wechsler family of measures and Stanford-Binet (SB), and the Adaptive Behaviour Assessment System Second Edition (ABAS-II). The time variable was computed as the time elapsed since the inception of the POND network (2012). Linear regression was used to test if there was a main effect of time (i.e. a data shift) for each of the above measures as well as participants’ age, sex, family income and education level. The data were transformed (Box-Cox/Yeo-Johnson) and the regression analysis was repeated for the results with non-normal residuals.

Results: Linear regression results revealed a small, but significant decrease in time for CBCL-externalizing (coeff=-0.28±0.1234, R2 = .01, F(1, 804) = 5.17, p = .023) and TOCS (coeff=-0.73±0.3096, R2 = .07, F(1, 827) = 5.63, p = .018), and a significant increase for FSIQ (coeff = 0.77±0.3455, R2 = .01, F(1, 676) = 5.31, p = .0215). Time effects for the ABAS-II, SCQ, SWAN, and CBCL-internalizing were not significant. For demographics, our results showed a significant decrease in percentage of participants with household income below the provincial median (coeff=-0.03±0.01, R2=. , F(1)=3.14, p=0.01), but not in age, proportion of females, and primary caregiver’s education level.

Conclusions: Overall, we found small but significant data shifts in the POND cohort. These findings motivate the inclusion of time as a potential covariate in future studies.

421.078 (Poster) Artificial Intelligence Identification of Autism Using a Smart Tablet Serious Game for Preschool Children: Results from a Phase 3 Diagnostic Trial of 779 Children in Sweden and the United Kingdom

J. Delafield-Butt#, S. C. Lu#, K. Sobota#, R. Young#, L. Thompson#, M. Thorsson#, C. Tachtatzis#, I. Andonovic#, P. Rowe#, P. Wilson#, H. Minnis#, A. McConnachie and C. Gillberg#, (1)Laboratory for Innovation in Autism, University of Strathclyde, Glasgow, United Kingdom, (2)University of Warsaw, Warsaw, Poland, (3)Robertson Centre for Biostatistics, University of Glasgow, Glasgow, United Kingdom, (4)Institute of Health and Wellbeing, University of Aberdeen, Aberdeen, United Kingdom, (5)Gillberg Neuropsychiatry Centre, Department of Psychiatry and Neurochemistry, Institute of Neuroscience and Physiology, Sahlgrenska Academy, University of Gothenburg, Gothenburg, Sweden, (6)Department of Electronic and Electrical Engineering, University of Strathclyde, Glasgow, United Kingdom, (7)Department of Biomedical Engineering, University of Strathclyde, Glasgow, United Kingdom, (8)Institute of Health and Wellbeing, University of Glasgow, Glasgow, United Kingdom
Background:

Early detection of autism spectrum disorder (ASD) allows early intervention and potentially the best lifelong health outcomes. However, ASD’s complex symptomatology makes diagnosis complex, time-consuming and requires specialist clinical input. Waiting times for diagnosis can be many months or years. Recent evidence suggests the motor system is linked with autism aetiology, providing an accessible modality for computational assessment. Further, most children with or without autism are attracted to smart tablet gameplay. Its touch screen and inertial sensors enable collection of reliable motor kinematic and behavioural data, suggesting a promising new route for accessible, scalable early assessment. This study set out to test promising pilot results of an iPad serious game assessment paradigm (Anzulewicz, Sobota, & Delafield-Butt, 2016) with a gold-standard blinded, multi-site phase 3 diagnostic trial (Millar, McConnachie, Minnis, et al., 2019).

Objectives:

To determine the predictive accuracy of a serious smart tablet game for the early identification of autism using pre-trained algorithms naïve to trial data collected in two sites using blinded comparison against clinical diagnosis.

Methods:

A registered phase 3 prospective, diagnostic classification study (NCT03438994) tested the predictive accuracy of a smart tablet serious game with artificial intelligence data analytics to identify autism. Three cohorts aged 3 – 6 years participated: children typically developing (TD); children with a clinical diagnosis of autism (ASD); and children with diagnoses of other non-autism neurodevelopmental disorders (OND). 779 children were recruited from Scotland (Glasgow) and Sweden (Gothenburg). Children played two 5-minute games on an iPad. One commercial algorithm and four research algorithms were trained on a previous cohort of children collected prior to this trial (n=767). Algorithms were tested naïvely on these new, blinded trial participant data to classify gameplay patterns as positively or negatively associated with an ASD diagnosis. Classification results then compared against medical diagnosis by a clinical trial unit. Strengths and Difficulties Questionnaire (SDQ), ESSENCE-Q, and adaptive function scores were collected for a subset of participants. Sensitivity and specificity of the algorithms to differentiate ASD children from TD children are reported.

Results:

694 participants (331 TD, 185 ASD, and 178 OND) were included in the final analysis. Research algorithms produced up to 0.80 sensitivity and 0.84 specificity. The commercial algorithm underperformed with sensitivity of 0.29 and specificity of 0.47. Peak performance was obtained by the combination of research algorithms and SDQ, yielding up to 0.95 sensitivity and 0.95 specificity. Differences in accuracy between genders, ages, sites, and severity levels will be discussed.

Conclusions:

This phase 3 diagnostic accuracy study of a digital health smart tablet assessment of autism demonstrates sensitivities and specificities useful in clinical diagnostic pathways. Furthermore, the assessment is based on computational analysis of motor patterns, indicating strong predictive value of the motor system in early identification of autism. Performance can be enhanced by the inclusion of a brief questionnaire additionally taking into account social and emotional factors. Future work is required to further improve algorithms and develop this system into a clinic- or school-ready tool amenable to integration with screening, assessment or diagnostic pathways.

421.080 (Poster) Assessment of ‘Subtle’ ASD Using the M-ASD Questionnaire: A Validation Study

M. L. Bezemer, H. van de Sluis and E. M. Blijd-Hoogewys, INTER-PSY, Groningen, Netherlands

Background:

There are concerns of underrecognition of autism spectrum disorders (ASD) in women, because of subtler manifestations of social and communication difficulties, and less evident repetitive behavior (APA, 2022). Women, but also men, with more subtle ASD manifestation suffer in silence, because their autism is not recognized.

A timelier identification could lead to better prognosis, prevent secondary problems, reduce family stress and societal costs (García-Primo et al., 2014). We developed the M-ASD (50 items; Bezemer & Blijd–Hoogewys, 2018), an instrument that also considers these ‘subtle’ ASD manifestations (INSAR poster 2018 & 2022).

Objectives:

Validating the M-ASD in a clinical setting.
Methods:
Retrospective diagnostic data from a clinical sample, suspected of ASD, referred to a general mental healthcare institution, were analyzed. All underwent extensive ASD diagnostic assessment, which included the M-ASD and the AQ (Baron-Cohen et al., 2001).

The research group consisted of 603 adults (see Table 1), of which 65% received an ASD diagnosis (ASD group). The others received other psychiatric diagnoses (non-ASD group). A sub-group participated in retesting the M-ASD \( (n = 21; \text{max} = 2-8 \text{ weeks interval}) \).

For analyses, M-ASD total-scores and AQ total-scores were used (both range 0-50, based on dichotomous item-scoring). Descriptive statistics, correlations, T-tests, Cronbach’s alpha, ROC and PPV/NPV-analyses were performed.

Results:
Cronbach’s \( \alpha \) for the M-ASD was .935; correlation with the AQ was strong \( (n = 603; r = .749, p <.001) \). The test-retest reliability of the M-ASD was excellent \( (n = 21, M_1 = 24.81, SD_1 = 11.45; M_2 = 25.62, SD_2 = 11.96; r = .95, p <.001) \).

The ASD total group had a significantly higher M-ASD total-score than the non-ASD total group (see Table 2). The same was true for women and men. All consisted of large effects, except for a medium effect in men. Also, ASD women had a significant higher M-ASD total-score than ASD men \( (p <. 001; \text{Cohen’s } d = .346) \).

The AUC for the total group was .718 \( (p <.001) \). The best Youden’s index resulted in a cut-off score of 26 for women, and 20 for men. Sensitivity was .527 for women and .569 for men. Specificity was .838 and .747 respectively. Positive predictive value was 86% for women and 80% for men; negative predictive value was 53% and 50% respectively. In both women and men, in 63%, the M-ASD and the clinical diagnostic agreed regarding the classification of ASD \( (C^\text{women}(1,341) = 42.46, p < .001; C^\text{men}(1,262) = 24.43, p < .001) \). Agreement was fair for both women \( (K = .309) \) and men \( (K = .285) \).

Conclusions:
The internal consistency and test-retest reliability of the M-ASD is excellent. Sensitivity and specificity findings are in line with other ASD questionnaires in a clinical setting. ASD women scored higher on the M-ASD than ASD men, indicative of more ASD problems.

One should keep in mind that there was still a large group of ‘missed patients’ based on the M-ASD (50-52%). Diagnosis remains a clinical one and should not be based on a particular questionnaire.

421.081 (Poster) Autistic Adults’ Perspectives and Experiences of Play-Based Assessments Administered By Professionals
E. Pritchard1, C. de Lemos1, K. Howard2 and J. L. Gibson1, (1)University of Cambridge, Cambridge, United Kingdom, (2)University of Exeter, Exeter, United Kingdom

Background: Professionals often observe and note play behaviours for the purpose of autism diagnostic assessment. However, play-based assessments tend to focus on deficits and are based on comparisons to non-autistic ‘norms’. According to the neurodiversity paradigm, it is important to center autistic voices and promote a holistic perspective on difficulties, differences, and strengths. As there is a lack of understanding about how autistic people think about and experience play-based assessments, focusing on autistic perspectives on this topic can inform how professionals can better implement play-based diagnostic assessments in the future.

Objectives: To understand autistic adults’ experiences of assessments of play used by professionals.

Methods: Consultation with autistic and non-autistic stakeholders informed the topic and approach. Semi-structured interviews were conducted with 22 autistic adults aged 18-57 (either clinically confirmed diagnosis or self-diagnosed) who live in the UK. Autistic stakeholders were consulted about the interview procedures and questions. Participants were asked about their perspectives and experiences of play-based assessments and could reflect on childhood or contemporary experiences. To identify themes, the interview transcripts were analysed using interpretative phenomenological analysis.

Results: Three themes were identified relating to: (1) type of assessment; (2) benefits of using play; (3) issues around using play. Autistic adults’ experiences were varied, with some completing diagnostic assessments like The Autism Diagnostic Observation Schedule (theme: type of assessment). Participants discussed the benefits of using play in diagnostic contexts, such as play giving useful insights into autistic ways of being and play differences that could be identified in this context. Participants also discussed a variety of issues around using play, such as issues relating to autistic heterogeneity and deficit-focused assessment.
Objectives: To assess whether group differences in response to the SenseToKnow app are specific to autism and the effect of pre-term birth on the computer-vision-based proposed metrics.

Methods: In total, 449 toddlers participated (mean age at administration was 20.9 months, SD = 3.6 months). Subgroups included those who were born full-term (>37 weeks) with (n = 28) and without autism (n = 349) and those born premature (<37 weeks) with (n = 12) and without (n = 60) autism. Diagnosis was based on the ADOS. Participants were assessed in clinic-based settings using the SenseToKnow app, which displays brief, strategically designed movies on a tablet while the child’s behavioral responses are recorded using the camera embedded in the device. Computer vision was used to extract information related to (1) gaze (e.g., percent time attending to social vs. non-social stimuli, and clustering of gaze in coordination with speech of actors in the movies) (2) how often and quickly participants responded to their name being called, and (3) frequency of head movements while watching the app. A 2 (premature vs. full-term) x 2 (autism vs. no autism) MANOVA was used to assess the effects of prematurity and autism on the variables described above.

Results: Only autism diagnosis emerged as a significant predictor for the outcomes as a group, $F(1,287) = 7.51, p < .001, \eta^2_p = .22$, neither prematurity, $F(1,287) = 1.67, p = .08, \eta^2_p = .06$, nor the interaction between autism diagnosis and prematurity reached significance, $F(1,287) = 1.76, p = .06, \eta^2_p = .06$. Specificity of outcome measures was dependent on the stimulus type and measures selected. For example, attention to social relative to non-social stimuli was more strongly associated with autism, $F(1,297) = 26.01, p < .001$, than prematurity, $F(1,297) = 5.33, p = .02$ (Fig 1). In contrast, gaze clustering on one or the other speaker in a dialogue was significantly related to prematurity, $F(1,297) = 6.53, p = .01$.

Conclusions: The SenseToKnow app shows promise for early detection of autism in toddlers. This study presents further evidence that certain behavioral features quantified with computer vision analysis may be specific to autism rather than other conditions such as pre-term birth.

Background:

Anorexia Nervosa (AN), a severe eating disorder, is typically diagnosed in adolescence (Westwood & Tchanturia, 2017), while Autism Spectrum Disorder (ASD), a neurodevelopmental disorder, typically emerges early in life (APA, 2013). Research suggests a possible link between ASD and AN (Kerr-Gaffney et al., 2021) although this association needs to be investigated further (Ormond et al., 2017).

Objectives:

The aim of this pilot study is to characterize past and present behaviors of adolescent girls with AN who are referred for the first time for ASD evaluation. The objectives of this research were to characterize early developmental and emotional variables in order to try to understand why the diagnosis of ASD was postponed until adolescence. An additional objective was to help medical and psychological professionals that treat AN in adolescent girls to both detect and treat possible ASD characteristics.
Methods:

This is a pilot study of cases of four adolescent girls who were hospitalized in the psychiatric department of Hadassah Medical Center in Jerusalem, Israel due to severe Anorexia. The girls were referred by the medical and psychological staff for an ASD evaluation due to difficulties in their social skills and social adjustment. The participants’ parents were interviewed using the ADI-R and the girls were diagnosed with ADOS2 and additional information from questionnaires (SRS, SCARED, ABAS-II). All cases were brought to general consultation with the department staff to help establish an appropriate treatment plan.

Results:

All the participants had been diagnosed with general anxiety at preschool age; two of the girls were also diagnosed with selective mutism. Social challenges from early childhood were reported although the girls weren’t referred to ASD diagnosis, perhaps due to the fact that their social difficulties were perceived to be part of their anxiety. The eating disorder, later diagnosed as AN, began in early adolescent (12 to 16 years). The ADI and ADOS demonstrated challenges in social communication and intense preoccupation with social relationships, restricted eating and methods for losing weight.

Conclusions:

These preliminary findings may suggest that ASD symptoms in adolescents with eating disorder were less obvious or misdiagnosed in early childhood. The emergence of eating disorder probably highlighted the ASD symptoms which helped in the current diagnosis process. The results of this pilot case study reflect the importance of earlier detection and diagnosis of ASD that can help treatment and even reduce future AN symptoms. Further investigation in this area is necessary.

421.084 (Poster) Clinical Correlates of Head Size and Diagnostic Certainty in Autism

Background: Research suggests that a relatively large fraction of autistic individuals can be identified by experienced clinicians within a short timeframe. “Frank” autism describes this part of the autism population that expert clinicians quickly identify as autistic with high certainty. Nevertheless, the specific signs and characteristics that are associated with a high diagnostic certainty still remain unclear. Previous studies have found macrocephaly (i.e. large head size), to be associated with autism, and correlated with measures of intelligence and autism symptoms.

Objectives: The study is an investigation of the association of clinicians’ certainty of an autism diagnosis with head size, autism symptomatology, and other clinical signs in a large heterogeneous sample of individuals with autism. We also investigated how associations between signs and diagnostic certainty vary depending on the child’s age. Furthermore, we explored how head circumference correlated with IQ measures and with items of the ADI and ADOS.

Methods: The Simons Simplex Collection is a database of approximately 2800 autistic individuals and contains item-level scores for different assessment tools and tests, head circumference at time of assessment, as well as a measure of the clinician’s certainty of the given autism diagnosis. Associations between certainty and clinical signs were investigated using simple correlations, and by machine learning using ensembles of decision trees. The dataset was split into subsets according to the age of assessment, and the analyses were performed on each of these subsets. Robustness of the findings was assessed by bootstrapping. Head circumference was normalized by age, sex, height, weight, and genetic background and was correlated with IQ, diagnostic certainty, and ADI and ADOS items.

Results: Rates of highest-certainty diagnoses were found to differ significantly depending on language level (ADOS module) and age at assessment. Normalized head circumference had a positive association with certainty across ADOS modules, most pronounced in ages up to 10. Additionally, ADOS items complex mannerisms and unusually repetitive behaviours and interests were positively associated with certainty, particularly at young ages. 85% of individuals with normalized head circumference above the 97.5th percentile were diagnosed with the highest possible certainty. Head circumference correlated with several items in the communication and social interaction domains, which was consistent across individuals assessed with different ADOS modules. Furthermore, larger head circumference was significantly correlated with a lower verbal-IQ/nonverbal-IQ ratio among those assessed with ADOS module 2, even when controlling for differences in IQ tests.
Conclusions: The results show a correlation in autistic individuals between head size and the likelihood that they are recognized as autistic with the highest certainty. Furthermore, several autism symptoms correlated with head size, while others showed no such correlations. The results indicate that large head size is associated with a specific profile of autism, and that this profile may be aligned with a “frank” presentation of autism that clinicians recognize with high certainty.

421.085 (Poster) Comparison of the Psychometric Properties of a Mobile Application for Early Autism Detection (ASDetect) for Caregivers with and without Prior Concerns

J. Barbaro, N. Sadka and M. Gilbert, Olga Tennison Autism Research Centre, La Trobe University, Melbourne, VIC, Australia

Background: Early autism identification facilitates children’s developmental outcomes. ASDetect is a caregiver mobile application for early autism detection in 11-30-month-olds. Based on a psychometrically robust developmental surveillance tool for autism (Social Attention and Communication Surveillance-Revised; SACS-R; Barbaro et al., 2022), it contains short, narrated videos demonstrating key social-communication behaviours, followed by a question; automatic calculation of children’s ‘likelihood’ for autism (high/low) is then presented.

Prior data shows ASDetect has excellent psychometric properties for early autism detection (87% positive predictive value (PPV); 91% negative predictive value (NPV); 73% sensitivity; 96% specificity). It was of interest to compare the psychometrics of ASDetect for caregivers with and without prior concerns, based on previous research showing that parental/caregiver concerns alone is a strong predictor of autism (Sheldrick et al., 2019).

Objectives: To determine differences in the psychometric properties of ASDetect between caregivers with and without prior concerns about their child’s development.

Methods: 1,808 children aged 11-30 months were registered for the study. Caregivers provided family details on the study webpage, downloaded ASDetect, indicated if they had any concerns about their child’s development (e.g., language, social-communication, motor, emotion regulation, behavioural), and completed an ASDetect assessment. Caregivers were also invited to complete the Social Responsiveness Scale-2 (SRS-2) when their child was 30 months old. All children at ‘high likelihood’ for autism on ASDetect were offered a free diagnostic assessment by the ASDetect team. Children at ‘low likelihood’ for autism, but whose caregivers were concerned about their child’s development, and those who met the SRS-2 cut-off score at 30-months, were also invited for an assessment. Children were assessed by blinded clinicians at intake and every 6 months until 24-30 months, using ADOS-2, ADI-R, and cognitive/adaptive assessments.

Results: 1,547 (86%) caregivers completed at least one ASDetect assessment for their child, with 745 (48%) having prior concerns. 327 children (21%) were identified at ‘high likelihood’ for autism (307 with, and 20 without, prior concerns).

Based on the diagnostic assessments, in the “prior concerns” group, ASDetect had 88% PPV, 80% NPV, 76% sensitivity, and 90% specificity. In the “no prior concerns” group, ASDetect had 75% PPV, 98% NPV, 47% sensitivity, and 99% specificity. The prevalence of autism in the “prior concerns” group was 49%, and 4% in the “no prior concerns” group.

Conclusions: ASDetect is highly predictive of an autism diagnosis, whether prior caregiver concerns are present or not. However, ASDetect is more predictive, and sensitive, when caregiver concern is present, although even caregivers using ASDetect without prior concerns were more likely to have autistic children (4%) than current general population prevalence (2%). Sensitivity was lower in the “no prior concerns” sample, but specificity was very high. Thus, caregivers without prior concerns may under-report their child’s autism signs, or signs may become clearer across time and, therefore, identified at a later age. These finding stress the importance of caregiver education on the early sings of autism, and the addition of a 42-month ASDetect check, shown to significantly increase sensitivity of the SACS from 62% at 24-months to 96% by 42-months.

421.086 (Poster) Correct Classification of Adults As Autistic or Typically Developing, Based on Self and Parent Reports

M. Terner and O. Golan1, (1)Department of Psychology, Bar-Ilan University, Ramat-Gan, Israel, (2)Department of Psychology, Bar-Ilan University, Ramat-Gan, ISRAEL, (3)Association for Children at Risk, Givat-Shmuel, Israel

Background: The last decade has seen an increase in the diagnosis of autism in adults (Brugha et al., 2016; Dietz et al., 2020). However, although research has shown that even in adulthood, parent-report predicts diagnosis better than self-report (Poon et al., 2020), screeners for individuals seeking an ASD diagnosis in adulthood tend to focus mostly on self-report, and less on parental report. The potential value of parent report may be different for females, compared to males, since research has shown that parents often struggle to spot signs of autism in females (Little et al., 2017). Two relevant screening tools for adults with ASD are the Autism-Spectrum Quotient (AQ; Baron-Cohen et al., 2001) and the Relative’s Questionnaire (RQ; Baron-Cohen et al., 2005), which are self and parent-report questionnaires (respectively) used for screening adults without intellectual impairment who seek an ASD diagnosis.
Objectives: To test the added value of using a parent-report tool in addition to a self-report tool in improving the correct classification of adults as autistic or typically developing (TD). We will also examined the contribution of self and parent reports to correct classification in males and in females, separately.

Methods: AQ, RQ, and demographic data of 116 clinically diagnosed autistic adults (30 females) aged 17.5–54 (M=25.89, SD=7.40) were retrieved from client records of two tertiary centers that provide diagnostic assessment services for adults with autism. A waiver of consent for this retrospective records review was obtained. One hundred and eight TD adults (21 females) aged 18-50 (M=23.60, SD=3.55) completed the AQ, and their parents completed the RQ.

Results: Binary logistic regressions were computed for the entire sample and for males and females separately to examine whether AQ and RQ were associated with the likelihood of having an autism diagnosis, controlling for participants’ age. The analysis conducted for the entire sample (shown in Tables 1 and 2) revealed the AQ and the RQ (over and above the AQ) significantly contributed to the model. The entire model explained 90% (versus 79% without the RQ) of the group’s variance and correctly classified 95% (versus 90% without the RQ) of cases. When the logistic regression was conducted separately for males and for females, the picture was similar for males, but adding the RQ over the AQ did not significantly improve the model for females (Table 2).

Conclusions: Our results confirm the contribution of parent report screeners for adults seeking an autism diagnosis. However, a separate examination for males and females showed that the RQ had no added value in the correct classification of female participants to the autism or TD groups. This can be explained by the fact that the AQ in females explained 100% of the variance, creating a ceiling effect but may also highlight parents’ difficulties to recognize autistic traits in females. Future research should examine different reporter-type screening tools against a larger sample and against additional clinical populations that may mask autistic traits when relying solely on one reporter.
PedsQL:GC, which could potentially be explained by the use of a real world dataset with no specific intervention designed to impact HRQoL. These analyses add to the current literature on the use of PedsQL:GC in ASD, with shorter test-retest intervals and further longitudinal evaluation in an interventional dataset required.

**421.088** *(Poster)* Cumulative Risk Factors and Children with Profound Autism

**B. Ayalew**1, S. Enigin2, B. Villanueva3, J. Panganiban4 and C. Kasari5, (1)UCLA Semel Institute for Neuroscience & Human Behavior, Los Angeles, CA, (2)UCLA Center for Autism Research and Treatment, Los Angeles, CA, (3)Semel Institute, University of California Los Angeles, Los Angeles, CA, (4)University of California Los Angeles, Los Angeles, CA

**Background:** Accurate representation of children with autism in research studies can be difficult, particularly when discussing children with profound developmental delays. Children with profound delays can present challenges that require specialized training and experience. Researchers also face challenges recruiting families across various socio-demographic backgrounds. Families with a higher set of cumulative risk factors including single-parent status, poverty, minority status, and limited maternal education are more likely to drop out from research interventions (Bagner and Graziano, 2013). Some of these factors may also predict intellectual disability in children with autism (Pinborough-Zimmerman et al, 2012).

**Objectives:** To explore how demographic risk factors may be predictive of children with profound developmental delay

**Methods:** The current study is a secondary analysis of 156 minimally verbal autistic preschool-age children enrolled in a public, mostly Title 1 school-based intervention study. All families completed demographic questionnaires and all children were assessed prior to receiving intervention using the Mullen Scales of Early Learning (MSEL), a standardized measure commonly used to assess cognitive development in children with ASD. Seventy percent of the sample tested below the range needed to determine a valid early learning composite score, the equivalent to an IQ score. This represents a subset of the overall sample we consider to be children with profound developmental delays. We compared this subset with the rest of the sample and analyzed potential demographic predictors of families with a profoundly delayed autistic child. To do this we looked at potential risk factors that include maternal education (high school or below), single-parent status, minority status, family size, and the presence of a sibling with a developmental disability. Risk factors were dichotomized and summed to provide a cumulative risk index.

**Results:** Logistic regression analyses explored the relationship between risk factors and profoundly delayed children. Maternal education, single parent status, minority status, and the presence of a sibling with developmental delay did not individually predict profound developmental delay. Family size did significantly predict profound developmental delay ($\beta = -.74, p < .01$). Households with more children than adults were more likely to have a child with profound developmental delay. We then explored the potential role of cumulative risk and found cumulative risk was a significant predictor of having a child with profound developmental delay ($\beta = -.35, p < .05$). Families with higher scores on the cumulative risk index were more likely to have a child with profound developmental delay.

**Conclusions:** Our study demonstrates that demographic risk factors can have a cumulative effect in predicting profound developmental delay in children with autism. We know that individuals with profound delays are often excluded from research studies, and our findings highlight potential demographic barriers leading to a lack of representation. Researchers face many challenges in recruiting and enrolling individuals with profound disabilities, and it is important to consider ways to address these barriers. Bringing research to the community through school-based interventions is one way to remove these barriers for families already at higher risk. Thus, it is imperative to accommodate families in different socio-demographic circumstances.

**421.089** *(Poster)* Daily Activity Participation across Settings in Autistic Youth: Individual Variability and Temporal Stability

**Y. J. Chen**1, E. Duku2, A. Zaidman-Zait3, P. Szatmari4, I. M. Smith5, W. J. Ungar6, L. Zwaigenbaum4, T. Vaillancourt7, C. M. Kerns8, T. Bennett9, A. E. Richard7, M. Elsabbagh9, A. Thompson10 and S. Georgiades4, (1)Offord Centre for Child Studies, McMaster University, Hamilton, ON, Canada, (2)Tel-Aviv University, Tel-Aviv, ISRAEL, (3)Department of Psychiatry, The Hospital for Sick Children, Toronto, ON, Canada, (4)Dalhousie University / IWK Health Centre, Halifax, Canada, (5)The Hospital for Sick Children Research Institute, Toronto, ON, Canada, (6)Autism Research Centre, University of Alberta, Edmonton, AB, Canada, (7)University of Ottawa, Ottawa, ON, Canada, (8)University of British Columbia, Vancouver, BC, Canada, (9)Autism Research Centre, IWK, Halifax, NS, Canada, (10)Neurology and Neurosurgery, McGill University, Montreal, QC, Canada

**Background:** Participation in daily-life activities is often linked to functional independence and well-being, yet there remains a paucity of such evidence among autistic youth. Most investigations focused on group comparisons with non-autistic peers for narrowly defined categories of activities (e.g., leisure activities) in particular settings (e.g., home), with few opportunities to examine individual differences in a broader range of settings and how participation patterns may change over time among the heterogeneous autistic population.

**Objectives:** We aimed to identify subgroups of autistic youth based on parent-reported activity participation frequency at home, school, and community settings via the Participation and Environment Measure for Children and Youth, as well as their associations with youth characteristics, family demographics, and environmental supportiveness (i.e., to what extent the social/cognitive/physical/sensory demands
of activities support youths’ participation). We also examined whether the participation patterns remained stable from early (ages 11-14; T1) to middle adolescence (ages 14-16; T2).

**Methods:** The current sample (N=158) was drawn from the Pathways in ASD study, a longitudinal inception cohort in Canada. Latent profile analysis was performed for each setting to determine cross-sectional profile structures at both timepoints, followed by latent transition analysis with repeated data. Household income and caregiver education, environmental supportiveness, youth’s nonverbal IQ (WASI-II/Leiter-R-Leiter-3), and autism symptom severity (ADOS) were included as covariates of T1 latent profiles, which were then compared on their T1 adaptive functioning (VABS-II) and challenging behaviours (CBCL), adjusting for classification uncertainty.

**Results:** Three-, three- and two-profile solutions were selected respectively for home, school, and community settings at both timepoints (entropy .99-1.00, indicating high distinction between profiles; Figure 1). The most prevalent profiles were characterized by frequent home participation (HP3; 73%), low participation in non-classroom activities at school (SP1+SP2; 65%), and low community participation, particularly in social gatherings (CP1; 80%), indicating participation imbalance across settings. Youth with higher nonverbal IQ who experienced higher environmental supportiveness were more likely to be in the more active participation profiles across settings (Table 1). Those classified into the active participation profiles tended to have higher adaptive functioning ($\chi^2=7.23$ to 86.42, all $p<.01$) and lower levels of externalizing behaviour ($\chi^2=4.91$ to 14.05, all $p<.05$), but did not differ from lower participation groups in internalizing behaviour. Latent transition analysis indicated overall 75% stability in profile membership over approximately one year, with a different home participation profile characterized by limited self-care activities emerging at T2.

**Conclusions:** The results demonstrated the variable activity participation patterns among autistic youth as associated with individual, family, and environmental factors, thus stressing the need for optimizing person-environment fit to promote their participation across settings. Our longitudinal analyses revealed that most of the “movers” shifted to a higher home or school participation profile later, indicating opportunities for increasing participation in these settings among subgroups of autistic youth. However, the overall stabilizes levels of community participation across adolescence reinforces the need for continuous supports and inclusive efforts in community settings. These findings indicate that monitoring autistic youth’s participation over time can inform timely supports for individual changing needs at this crucial developmental stage.
imperfections (high ASD-psych), a group showing low ASD symptoms but elevated psychopathology (psych), and a group whose scores indicated typical development (TD). Additionally, when classes were split by sex, there was an even distribution in all three groups of males; however, females were less represented in the high ASD-psych group compared other groups. When classes were split by ASD status, as expected of the 44 children who were in the high ASD-psych group, most (28) met criteria for diagnosis; however, 16 remained undiagnosed. When classes were split by sex and ASD status, a higher percentage of boys (67.74%) in the high ASD-psych group received a diagnosis than girls (53.85%).

Conclusions: These results indicate that transdiagnostic subgrouping within a HL sample can identify clinically relevant groups. HL females are less likely to exhibit the symptom profiles more in line with an ASD diagnosis and even among the ones who do align with that profile, fewer are diagnosed than males. Thus, familial risk for ASD may be differentially expressed in males and females and diagnostic criteria based on male presentation may hinder the identification of females on the spectrum.

421.091 (Poster) Developing a Character Strength Profile of Australian Autistic Adolescents

Background: The field of positive psychology has introduced a new perspective of studying personality with a focus on character strengths (CS), defined as positively valued traits that individuals manifest through thoughts, feelings, and behaviours. The VIA Classification of Strengths was developed to define and categorise the 24 key character strengths and the six overarching virtues which they reflect.

Research has found multiple positive outcomes are predicted by CS, and evidence with neurotypical samples have suggested a positive association between the endorsement of CS and an individual’s satisfaction with life. However, less work has been done surrounding the CS of the neurodiverse population, despite growing empirical evidence supporting strengths-based models.

Objectives: This study seeks to address this short-coming by identifying the signature CS in autistic adolescents to better inform support programs.

The development of a CS profile would enable more effective support in the transition to adulthood, as well as open avenues for autistic adolescents to use their strengths in a meaningful way, improving participation outcomes and life satisfaction.

Methods:

Character strengths data from a sample of autistic adolescents (aged 13 to 17 years; n = 45) were isolated from a larger research project for independent analysis. The data consisted a parent-proxy report of The Global Assessment of Character Strengths-24 (GACS-24), in which the key 24 character strengths are rated on a 7-point Likert-scale ranging from “very strongly disagree” to “very strongly agree” in terms of how natural and effortless they are to express. Data was analysed through median comparisons to identify the significantly rated strengths among the autistic adolescent sample.

Results:

The median rating for each strength is reported in figure 1. Within group, there was a statistically significant difference in the rating of strengths, $\chi^2(23) = 212.33$, $p < .001$. Post-hoc analysis identified ten strengths that were significantly different to the overall median (Figure 1).
Conclusions:

Humour, Kindness, and Love were found to be the most natural and effortless strengths to express, consistent with the findings of existing qualitative research in which parents identified these strengths in their autistic adolescents. As such, these strengths are considered integral components of the character profile of autistic youth which should be fostered in pre-transition supports. Overall, eight strengths rated significantly higher than the median, while only two rated significantly lower. This suggests that carers draw a clearer distinction between strengths that are characteristic of their adolescent, compared with those that are not.

Furthermore, the lower rated strengths, such as Self-Regulation and Social Intelligence, are consistent with the diagnostic criteria of autism spectrum disorder and the reported challenges for autistic youth in the transition to adulthood. This highlights areas where extra support may be necessary for successful transition.

Further analysis with qualitative data from the same sample will seek to analyse the content of the questions and look for correlations between the strengths and behaviours of autistic adolescents. Future research should investigate the strengths of younger and older age groups to gain an understanding of the development and refinement of CS across maturity.

C. Pinto and S. Tiwari, (1)Department of Speech and Hearing, Manipal College of Health Professions, Manipal, India, (2)Department of speech and hearing, Manipal academy of higher education, Manipal, India

Background:

Training parents in the delivery of intervention programs has revealed better and lasting benefits for their children with Autism Spectrum Disorder (ASD). Parent-mediated Interventions are technique-focused, where the parent is the agent of change, and the child is the direct recipient of treatment.

Objectives:

To develop and validate a parent-mediated joint attention training manual for a parent-mediated joint attention intervention in the Indian context

Methods:

Numerous joint attention activities were collated from various sources, as journal articles, text books, internet, and parent training guides, as an initial step to develop the parent-mediated joint attention training manual. A consensus Delphi method was implemented to obtain consensus for the developed parent-mediated joint attention training manual. A total of 15, interdisciplinary group of experts across India, with a minimum experience of 5 years of working in the field of ASD, were selected to participate in the study. The Delphi process involved two rounds of consensus seeking. The first round comprised of validation of joint attention activities a parent-mediated joint attention intervention. The collated set of joint attention activities was shared with all the experts via Microsoft forms for agreement using a 5-point likert rating scale for the proposed joint attention activities.

The parent-mediated joint attention training manual comprises of a section of parent coaching. The parent coaching module's framework and components were developed and validated in the second round of the Delphi process. Here again, the same set of experts rated each component of the intervention module, i.e., structure of each session, frequency of parent coaching, feasibility of parent implementation, and time allotment using a 5-point Likert rating scale. Responses were collected and analysed to check for the experts' consensus on a preset agreement level of 70% for each parameter for both rounds. The researcher computed the ratings following each round and addressed suggestions received by the experts on the parent coaching and joint attention activity manual.

Results:

For round 1 of Delphi method, percentage agreement was calculated for all 5 parameters across experts on the Likert scale. Figure 1 shows the percentage agreement obtained across experts for round 1 of the Delphi process. Besides, minor modifications were suggested for 9 joint attention activities in this round. Figure 2 shows the percentage agreement obtained across experts for round 2 of the Delphi process. The suggestions given by the experts were incorporated into the parent coaching module. The modified versions of the module with summary of results were shared with the experts after each round.

Conclusions:
The study, thus, presents the development and validation of a parent-mediated joint attention activity manual for children with ASD using a robust e-Delphi method. The results of the validation showed good agreement across experts on a range of relevant parameters, offering a reliable resource for the intervention of children with ASD. Future implication can test the efficacy of this parent-mediated joint attention activity manual in facilitating joint attention skills in children with ASD in a parent-mediated joint attention intervention program.

**421.093 (Poster)** Development of a School-Age Extension of the Modified Checklist for Autism in Toddlers through Expert Consensus  

Background: Current recommendations for the detection of early signs of autism include 18- and 24-month screening (Hyman et al., 2020). Notably, it is estimated that the number of children diagnosed with autism by age 4 is about 30% lower than that of children diagnosed by age 8 (Christensen et al., 2016; Soke et al., 2017). This suggests that toddler screening and early detection strategies might miss children who show either a) stronger compensatory strategies during early childhood, making autism symptoms less noticeable, or b) have co-occurring conditions, like intellectual disability, that may overshadow autism symptoms. Children may also be missed because they are not screened, not referred, or do not present for diagnostic evaluation following early screening. This project adapts the Modified Checklist for Autism in Toddlers, Revised with Follow-up (M-CHAT-R/F; Robins et al., 2014), for use in school-age children, called M-CHAT-School (M-CHAT-S).

Objectives: To use a Delphi poll to develop a screening questionnaire for detecting children at higher likelihood of autism between the ages of 4 to 8 years.

Methods: Researchers developed a list of potential items informed by other screening tools, thorough review of literature, and their own clinical expertise. Each item was rated by four researchers/clinicians for which DSM-5 criterion the item best fit and whether it was appropriate for young school-age children. Top items for each category were shared with scientist-practitioner experts in diagnostic assessment of autism to offer two rounds of feedback. Experts were asked to rate the quality of the item (e.g., importance of symptom, clarity of wording), relevance to verbal and/or minimally verbal school-age children, appropriateness for parent and/or teacher informants, and to provide overall feedback. In round 2, poor items were eliminated, and feedback was shared in aggregate form. Experts re-rated the remaining items, after reviewing the aggregate feedback, to develop the final item set.

Results: Review of existing screening tools yielded 438 items which were rated by four clinicians/researchers. From these, the most highly rated items (n=65) across all the DSM-5 criteria were shared through the Delphi poll. In round 1, 35 experts (4 male) completed the Delphi poll. Of these, 24 identified as researcher or scientist, 5 as clinical providers or educators, and 6 as both. Majority were in the discipline of psychology (n=27), with an average of 24 years (range 9-46) experience working with autistic individuals. Based on the feedback, 26 items were retained for round 2, with wording changed based on feedback. In round 2, 29 of the 35 experts completed the survey in full and provided further feedback on items and screener format. Based on this feedback, 24 items were retained, and 2 open-ended questions were added.

Conclusions: Through expert consensus feedback, we developed the 26-item M-CHAT-S, to be used with young school-age children. Future steps involve obtaining input on the items from caregivers of school-age children as well as educators working with autistic children, and psychometric testing to create a valid and reliable measure to identify children with autism who are undiagnosed by early school age.

**421.094 (Poster)** Development of an Assessment Tool to Detect Anxiety in Autistic Individuals Who Speak Few or No Words  
J. Mingins, E. Pearson, G. Edwards, C. Oliver, J. Tarver, and J. Waite, (1)Aston University, Birmingham, United Kingdom, (2)University of Birmingham, Birmingham, United Kingdom

Background: Despite mental health problems being prevalent, there are a lack of assessment measures for mental health for autistic people with intellectual disability (ID), particularly people who speak few or no words. Assessment measures that are currently used have limitations, including not being sensitive to the profile of behaviours observed in autism, or inclusion of behavioural indicators of distress that overlap with physical health issues (e.g. pain). These limitations may lead to mental health difficulties being missed.

Objectives: To develop an assessment tool for the detection of anxiety that is suitable for autistic individuals who speak few or no words.

Methods: A new assessment measure for anxiety was developed through a process of reviewing literature on behavioural indicators of anxiety and anxiety assessments, and by interviewing clinicians (N = 9) and parents of autistic individuals (N = 21) about anxiety related behaviours. 311 parents/carers of children and adults with ID (with and without a diagnosis of autism) then completed the newly developed assessment measure. Participants with ID ranged in age from 4-83, (M= 21.59, SD= 12.00); 61.4% were male, 67% spoke no/few words, 50% had an autism diagnosis. Test-retest reliability was collected from a subset of participants. Convergent validity was ascertained by
Background: Early identification of autism spectrum disorder (ASD) is critical for timely access to early intervention. Artificial intelligence and machine learning algorithms are innovative, cost-effective approaches to increase access to clinical services. Despite recent progress in digital autism phenotyping, there are no established objective methods to measure core ASD features at the transition between the ASD prodromal period and symptom onset (Age: 14 months). As the field accelerates into the digital era, there is a prime opportunity to develop accessible mobile technology to improve the objectivity and granularity of remote automated measurement of core social communication behaviors in young children.

Objectives: Using an interdisciplinary approach, we aim to develop an automated, digital, movement-based measure to improve the early identification of core ASD features involving social communication behaviors.

Methods: We apply an established video-based automated movement tracking pipeline (Corman et al., 2021) to a well-phenotyped and characterized, prospective, longitudinal dataset of 14-month-olds at elevated (EL) and low likelihood (LL) for autism with 36-month diagnostic outcomes (Landa et al., 2020). Participants in the current sample include 46 toddlers at elevated and low likelihood for ASD with diagnostic outcomes of ASD (n=22; 73% male) or non-ASD (n=24; 42% male) based on the ADOS, DSM-5 ASD criteria, and clinical best estimate. Using dense manual annotations by research reliable coders, a neural network is then trained to recognize salient social communication behaviors from video segments (e.g., gaze to face, gaze to object, gesture to face, gesture to object, etc.). Because we are interested in the co-occurrence of specific social communication behaviors (e.g., gaze to an object plus gesture to an object), we train a single model to predict the presence of multiple behaviors for a given instance in time.

Results: Using 17% of the current participant sample for each of the validation and test splits and the rest for training, our preliminary results show that even training on a subset of the data with single frame pose and object keypoints gives ~64 mean average precision (mAP; a metric commonly used by the machine learning community for multi-label classification tasks [Liu et al. 2018]) with average precision (AP) as high as 82.4 for gaze to objects. Intuitively, the metric (minimum=0; maximum=100) captures the fraction of correct classification among those classified as positives averaged over all behaviors and thresholds.

Conclusions: Our current movement-based model recognizes subtle differences in social communication behaviors that differentiate 14-month-olds with and without later ASD. We anticipate that as our sample size grows, results will improve. In contrast to previous digital phenotyping efforts, we aim to incorporate rich scene information into our models. This will be a critical next step for moving this metric beyond traditional lab-controlled settings to home-based, unconstrained video recordings of parent-child interactions.

421.095 (Poster) Development of an Automated Movement-Based Measure for Digital Autism Phenotyping Prior to Age 2

R. Reetzke1, A. Shah1, R. Roemmich1, B. Hicks1, S. Ray1, J. Stenum1, J. Morrel2, R. Chellappa1 and R. Lande5. Development of an Objective Autism Risk Index Using Arabic Remote Eye Tracking Paradigm

F. Alshaban. Qatar Biomedical Research Institute, Doha, Qatar

Background:
Deficits in eye gaze are a hallmark feature of autism spectrum disorder (ASD) and are included in gold standard diagnostic instruments. More than a decade of research into abnormalities of eye gaze has confirmed social attention deficits as a key feature of ASD. Across studies, diverse stimulus paradigms have elicited social attention abnormalities, ranging from decreased fixation to others’ eyes and social scenes as early as 6 months of age, to gaze abnormalities during dyadic or joint attention bids in preschoolers and older children, to aberrant gaze toward dynamic social stimuli in older high-functioning individuals.

Gaze patterns, particularly those based on dynamic temporal analysis, may be a promising objective risk marker of ASD as well as a quantitative measure of autism symptoms spanning the full continuum of behavior. Developing an Arabic version of eye tracking stimuli paradigm mimic the English ones used by previous studies to be used for Arabic speaking individuals is challenging but promising.

Objectives: The primary aim of the present study was to create an objective, eye tracking-based autism risk index using Arabic version stimuli paradigm.

Methods: Children were recruited for comprehensive multidisciplinary evaluation of ASD and subsequently grouped by clinical consensus diagnosis (ASD n=106, non ASD 100). Remote eye tracking using Arabic version stimuli. Dwell times were recorded to each priori-defined region of interest (ROI) and averaged across ROIs to create an autism risk index.

Results: Similar to the previous findings, the autism risk index had high diagnostic accuracy with area under the curve (AUC) = .89 and .84, 95% CIs=.80-.97 and 070-.95, was strongly associated with Autism Diagnostic Observation Schedule-Second Edition severity score.

Conclusions: The autism risk index is a useful quantitative and objective measure of risk for autism in at-risk settings. Using the Arabic remote eye tracking paradigm proved to be as effective as the English version used in previous research projects. Future research in larger samples is needed to cross-validate these findings. If a validated scale for clinical use, this measure could inform clinical judgment regarding ASD diagnosis and track symptom improvements.

Background: Concerns have been raised that standardized diagnostic instruments like the Autism Diagnostic Observation Schedule-2 (ADOS-2) would be less sensitive for girls than for boys with autism spectrum disorder (ASD), due to lower scores for girls than boys on the ADOS-2. Research on the validity of the ADOS-2 in boys and girls with and without ultimate DSM ASD diagnoses may add knowledge on the diagnostic utility of the ADOS-2 in general practice.

Objectives: The present study investigated the validity of the ADOS-2 in young boys and girls undergoing diagnostics, in relation to their best estimate DSM classification (ASD or non-ASD).

Methods: Retrospective ADOS-2 and other diagnostic data from a clinical sample of 681 children (n=507 ASD, n=174 non-ASD; aged 2-6 years), referred to a mental health clinic, were analyzed. Due to concerns of ASD that emerged at any point in their diagnostic trajectory, an ADOS-2 was administered. The percentage of agreement between the ADOS-2 classification and the DSM ASD classification was calculated for boys and girls. Chi-square tests (p < .05) were performed to test whether significant differences in percentage of agreement existed. Kappa’s, sensitivity, specificity, positive and negative predictive value were established for boys and girls separately. To further investigate possible differences in boys and girls with and without a DSM ASD classification on the Social Affect (SA) and Restricted and Repetitive Behavior (RRB) ADOS-2 domain scores, ANCOVA’s were performed with age as covariate.

Results: Boys and girls with and without a DSM classification of ASD did not differ on age and IQ. In 81% of all children, the ADOS-2 and the DSM classification agreed regarding ASD without sex differences (boys 82%, girls 77%; C^2 (1) = 1.7, p = .19). Agreement was fair for girls (κ.37) and moderate for boys (κ.49). Sensitivity was .85 for girls, .92 for boys. Specificity was .53 for girls, .52 for boys. Positive predictive value was .85 for girls and .84 for boys, negative predictive value was .51 for girls and .71 for boys. Boys with clinical ASD diagnoses had higher SA (7.1) and RRB (6.4) calibrated severity domain scores compared to girls with clinical ASD diagnoses (6.5, p <.05; 5.9, p <.05 respectively).

Conclusions: In a sample of young children referred for diagnostic assessment, the ADOS-2 and the ultimate DSM classification had fair agreement. Sensitivity and specificity findings are in line with earlier research. The fair level of agreement for girls seems to be explained mainly by a low predictive value of a negative test, indicating that young girls with a clinical DSM ASD classification do not always reach the cut-off on the ADOS-2. Additionally, although boys with a DSM classification of ASD scored statistically significantly higher than...
girls on both ADOS-2 domains, the clinical relevance of this finding seems small: mean severity levels of ASD-symptoms are similar for boys and girls with a DSM classification of ASD, i.e. of moderate concern.

421.098 (Poster) Different Symptom Measures Sensitive to Different Symptom Groups of Children with Autism Spectrum Disorder
I. C. Chuang, K. L. Chen, C. H. Lin and C. Y. Huang. (1)Department of Occupational Therapy and Graduate Institute of Behavioral Sciences, Chang Gung University, Taoyuan, Taiwan, (2)Department of Physical Medicine and Rehabilitation, National Cheng Kung University Hospital, College of Medicine, National Cheng Kung University, Tainan, Taiwan, (3)Department of Psychiatry, Chi Mei Medical Center, Tainan, Taiwan, (4)School of Occupational Therapy, College of Medicine, National Taiwan University, Taipei, Taiwan

Background: The Social Responsiveness Scale, Second Edition (SRS-2) and Childhood Autism Rating Scale™, Second Edition (CARS-2) are useful assessments for identifying symptoms of autism. Moreover, the CARS-2 is available in two versions, namely, the standard (CARS-ST) and high functioning (CARS-HF) versions, to address different symptom levels of children with autism spectrum disorder (ASD). The three measures may have different focuses on autism symptoms. To use the measures more appropriately in clinics and for research, it is essential to investigate the associations among the CARS-ST, CARS-HF, and SRS-2.

Objectives: The aims of the study were to investigate (1) the consistency of symptom levels between the CARS-ST and CARS-HF, and (2) the correlations among the CARS-ST, CARS-HF, and SRS-2.

Methods: Children aged 3 to 12 years with a diagnosis of ASD were recruited in our study. The SRS-2 and CARS-2 were used to assess the children’s autism symptoms. All children were assessed with the CARS-ST, and their caregivers were asked to complete the SRS-2. Children aged more than 6 years with Verbal Comprehension Index scores > 80 were additionally assessed with the CARS-HF. Cohen’s Kappa coefficients (κ) were used to investigate the consistency of symptom levels between the CARS-ST and CARS-HF. Pearson correlation coefficients were used to examine the correlations among the CARS-ST, CARS-HF and SRS-2.

Results: A sample of 207 children with ASD was recruited in the study. The mean age of the children was 6.5 years (SD= 2.2), and most of them were boys (85.2%). All the children were assessed with the CARS-ST and SRS-2, and 48 were additionally assessed with the CARS-HF. The results revealed that the CARS-ST had high correlations with the CARS-HF (r = 0.945, p < .001). The consistency of severity levels between the CARS-ST and CARS-HF was low (κ = 0.02). Children identified as “minimal to no symptoms” on the CARS-ST tended to be identified as “mild to moderate symptoms” on the CARS-HF. Moreover, children identified as “severe symptoms” on the CARS-HF tended to be identified as only “mild to moderate symptoms” on the CARS-ST. The correlations between the CARS-ST and the SRS-2 were low to moderate (r = 0.26–0.44, p < .001), while the correlations between CARS-HF and the SRS-2 were moderate to high (r = 0.56–0.73, p < .001).

Conclusions: Consistent with the design purposes of the CARS-2, the CARS-ST is sensitive to children with typical ASD, and the CARS-HF targets children with high functioning ASD. Moreover, the correlations between the CARS-2 and the SRS-2 revealed that, like the CARS-HF, the SRS-2 may also be more sensitive to children with high functioning ASD. Better understanding of the associations among the CARS-ST, CARS-HF and the SRS-2 will help clinicians and researchers choose suitable measures when addressing autism symptoms.

421.099 (Poster) Early Features of Autism in Genetic Conditions Associated with Intellectual Disability: The Role of Development
E. A. Will, R. M. Hantman and C. E. Knott; (1)Department of Psychology, University of South Carolina, Columbia, SC, (2)The University of South Carolina, Columbia, SC, (3)Psychology, University of South Carolina, Columbia, SC

Background:
Down syndrome (DS) and fragile X syndrome (FXS) are genetic conditions partially characterized by elevated likelihood for co-occurring autism spectrum disorder (ASD). Estimated co-occurrence rates are ~20% and 60% for DS and FXS respectively; consequently, empirical and clinical efforts to identify co-occurring ASD during early development have increased. However, the early delays associated with eventual intellectual disability and some limitations of available diagnostic tools for these populations pose challenges for early detection and differential diagnosis in these conditions.

Objectives:
In 12 – 24-month-old children with DS and FXS, we aimed to 1) characterize infant profiles of ASD features; 2) determine the correspondence between ASD features from 12 – 24-months; 3) examine the association between developmental level and ASD features; and 4) evaluate differences in these patterns between DS and FXS.

Methods: Participants included 34 infants with DS and 32 with FXS. The Mullen Scales of Early Learning (MSEL) provided a nonverbal mental age (NVMA) estimate derived from Visual Reception and Fine Motor Age Equivalent Scores. Measures also included the Autism Observation Scale for Infants (AOSI) total raw scores, and the Autism Diagnostic Observation Schedule – 2nd Edition (ADOS-2) Toddler Module Social Affect and Restricted/Repetitive domains domain raw scores, where higher scores indicate elevated symptomatology. We
Background: Autism spectrum disorder (ASD) is thought as an innate and long-life neurodevelopmental disorder and characterized by impaired social interaction and communication, as well as restricted and repetitive behavior and interest. Thus, it is important for early detecting and early diagnosis in toddlers with ASD before 36 months of age. However, the diagnosis of ASD poses particular difficulty because there are no biomarkers used in diagnostic process. Over past decades, some studies reported that prevalence of ASD has increased markedly. However, compared to Western countries, the prevalence of young children with ASD in Taiwan is still lower. Previous studies reported that early intervention improved outcomes for toddlers with ASD (Clark et al., 2018; Landa et al., 2011; Rogers et al., 2019). The benefits of early intervention highlighted the importance of earlier identification of toddlers with ASD. Knowing the importance of early identification, the American Academy of Pediatrics (AAP) has recommended that all infants receive universal screening for autism less than 24 months of age (Johnson et al., 2007). However, the diagnosis of ASD is still often delayed because some factors, including limitations in utility of screening instruments etc.

Objectives: The current study, there are two studies to examine the utility of using the Taiwanese version of the Screening Tools for Autism in Two-Year-Olds: Short Form (T-STAT: BF) for toddlers with ASD before 36 months of age.

Methods: The T-STAT is a 12 items interactive autism-specific screening tool, including four behavioral domains: Play (2 items), Requesting (2 items), Joint attention (4 items) and Imitation (4 items). This study examined the discriminatory power of all item of the T-STAT and then yield the T-STAT:BF.

Results: Study 1, there are 40 toddlers with developmental disabilities, including 20 toddlers with ASD and 20 toddlers with developmental delays (DD). The chi-square test ($\chi^2$ test) was used to decide the strongest discriminatory items from the T-STAT. Finally, 5 out of 12 items were selected ($p < .003$), including Play: Turn-Taking, Requesting: Food and Bubbles, and Joint Attention: Bag of Toys and Balloon. Each item of the TSTAT:BF is scored as 0 (pass) or 1 (fail). Using signal detection procedures, the optimal cutoff of the T-STAT:BF score was decided. The results revealed that 3 was the best cutoff. Using the 3 of the T-STAT:BF score as cutoff, the sensitivity and specificity are .85 and .90, respectively. In addition, positive predictive value (PPV) is .89 and negative predictive value (NPV) is .86. Study 2, there are 201 toddlers with developmental disabilities, including 83 toddlers with ASD and 118 toddlers with DD. Using the 3 as cutoff, the sensitivity and specificity are .92 and .84, respectively. In addition, PPV is .80 and NPV is .93.

Conclusions: The findings of the current study showed that the T-STAT:BF is a promising good tool to differentiate toddlers with ASD and those with DD before 36 months of age. The finding of this study could provide implications for early identification.
421.101 (Poster) Evaluating the Overall Utility of Measures of Functioning for School-Aged Children on the Autism Spectrum

M. Hayden-Evans, B. T. Milbourn, E. D’Arcy, A. Chamberlain, B. Afsharnejad, K. Evans, A. J. Whitehouse, S. Bolte and S. J. Girdler

Background: Autism is a neurodevelopmental condition characterised by social and communication differences, and the presence of persistent, repetitive behaviours, which can impact an individual’s ability to function in everyday life. Due to the heterogeneous nature of autism, the functional impact can vary significantly between individuals. However, it is becoming increasingly important to accurately measure functioning in individuals on the autism spectrum, to ensure equitable access to services, supports, and funding. Currently, the highest prevalence of autism is in school-aged children, which encompasses a critical period of development, during which children are developing their identities and required to function across multiple contexts.

Objectives: To evaluate the overall utility of measures of functioning suitable for use with school-aged children on the spectrum, including the content validity of these measures in relation to the International Classification of Functioning, Disability and Health (ICF) and ICF Core Sets for Autism.

Methods: A scoping review of the literature was conducted in two phases. First, relevant measures of functioning suitable for school-aged children were identified. Then, targeted literature searches were conducted to identify articles reporting on the psychometric properties of the eligible measures. The Outcome Measures Rating Form (OMRF) was used to evaluate the overall utility of the measures. Content validity of the measures for school-aged children on the autism spectrum was determined by identifying the meaningful concepts in each item and linking these to the ICF and ICF Core Sets for Autism, following established ICF linking rules.

Results: Thirteen measures of functioning were identified for inclusion in the review. The methodological quality of studies evaluating their psychometric properties were predominantly strong. Psychometric properties varied between assessments, with the Adaptive Behaviour Assessment System (ABAS-3) receiving the highest overall utility rating on the OMRF. Content validity of the measures against the ICF and ICF Core Sets for Autism also varied; very few measures considered the influence of Environmental Factors on functioning. The ABAS-3 had the greatest total number of codes linking to the Comprehensive ICF Core Set for Autism while the Vineland Adaptive Behaviour Scales had the greatest number of unique codes linking to both the Comprehensive ICF Core Set for Autism and the Brief ICF Core Set for Autism (6-16 years).

Conclusions: Assessing functioning of school-aged children on the spectrum can be challenging. However, it is important to accurately capture the unique strengths and challenges of this population, to ensure a holistic understanding of their functioning and needs for support. Although a variety of measures currently exist that are suitable for assessing functioning of school-aged children on the spectrum, there is currently no single measure best suited for this purpose. Health professionals should consider their psychometric properties, including content validity for this specific population, when selecting an appropriate measure to aid them in determining the level of functioning of school-aged children on the spectrum.

421.102 (Poster) Evaluation of Psychometric Properties and Factorial Structure of Social Communication Questionnaire in Rural Kenya

A. Abubakar, P. Kipkemoi, J. Gona and C. R. Newton

Background: Children can be reliably diagnosed with autism spectrum disorder (ASD) as early as three years of age, and early interventions are initiated (Guthrie et al., 2013). There is often a significant gap between the age of onset of symptoms (2-3 years) and diagnosis (8-10 years) in Africa (Bakare et al., 2019). Due to diagnostic delays, the initiation of interventions that could improve developmental outcomes are not carried out early on. Screening and diagnostic efforts, regardless of a child’s age, require the use of appropriate measures that are valid and reliable. This can be challenging, particularly in the African context, where we have a limited number of mental health care providers and limited culturally appropriate tools for screening and diagnosis (Abubakar et al., 2016). Given these limitations, we conducted a study to validate the social communication questionnaire (SCQ) as a screening instrument in a rural setting in Kenya.
Objectives: We specifically aimed to examine the performance of the SCQ by assessing its reliability, confirming the factorial structure, testing the specificity and sensitivity of the SCQ through receiver operative curves (ROC) analysis, and while using an item response theory (IRT) framework, examine the item difficulty and discrimination.

Methods: The study was conducted in Kilifi and Mombasa counties, along the Kenyan Coast, where the healthcare systems for mental and neurodevelopmental disorders are not under-resourced. 172 of the study participants had a neurodevelopmental disorder (NDD) diagnosis, with 84 of these including children with an ASD diagnosis and 112 controls. Participants were recruited from special schools and neurology clinics in the two counties. Verbal and written consent were sought from all parties. Statistical analysis was done using STATA version 15 and R statistical software (version 3.6.3). Internal consistency was evaluated through the use of Cronbach’s alpha, confirmatory factor analysis (CFA) with maximum likelihood procedure to assess the conceptual model for the SCQ. Additionally, the sensitivity and specificity of cut-off scores using ROC analysis by comparing the overall SCQ score against case-control status, difficulties and discrimination quality using an IRT framework was also assessed.

Results: Factor analysis revealed an adequate fitting model for the three-factor DSM-IV-TR (root mean squared error of approximation (RMSEA) = 0.050; Comparative Fit Index (CFI) = 0.974; Tucker-Lewis Index (TLI) = 0.973) and two-factor DSM-5 factor structure (RMSEA = 0.050; CFI = 0.972; TLI = 0.974). The reliability coefficient alphas for the whole group for all items (Cronbach’s α = 0.90) and all three domains (Cronbach’s α = 0.68 – 0.84) were acceptable to excellent. The recommended cut-off score of 15 yielded 72% sensitivity and 100% specificity in the ASD group compared to the typically developing group. In comparison, a cut-off score of 7.5 yielded a sensitivity of 90% and specificity of 98% in this group.

Conclusions: The present study provides early evidence of the adequate factor structure and more than acceptable internal consistency of the SCQ. We also note that the recommended cut-off yielded sufficient predictive validity. We will further report the item functioning of the SCQ.

421.103 (Poster) Examining Inter-Rater Reliability and Assessment Fidelity of the Autism Observation Scale for Infants Administered Via Telehealth
E. Campi, A. Q. Phillips, M. R. Talbott and G. T. Baranek, (1)Chan Division of Occupational Science and Occupational Therapy, University of Southern California - T.H. Chan Division of Occupational Science and Occupational Ther, Los Angeles, CA, (2)Chan Division of Occupational Science and Occupational Therapy, University of Southern California, Los Angeles, CA, (3)Psychiatry and Behavioral Sciences; MIND Institute, UC Davis MIND Institute, Sacramento, CA

Background: Level one screening for autism is commonly completed via parent questionnaires for infants without known risk of autism (Petrocchi et al., 2020). For those with parent-report-identified elevated likelihood of autism and/or those with parent or provider concerns, level two screening using behavioral observation is often helpful to ascertain an accurate understanding of early signs of autism (Khowaja, Robins, & Adamson, 2018). The COVID-19 pandemic and other circumstances that limit access to in-person observational screening yielded a shift to the use of telehealth to provide access to those in need of level two screening. However, there is limited empirical evidence supporting the reliability and validity of level two screening via telehealth (Dahiya et al., 2020; Talbott et al., 2020).

Objectives: To examine inter-rater reliability and assessment fidelity of the Autism Observation Scale for Infants (AOSI) administered via a parent coaching telehealth format to screen for elevated likelihood of autism in a community sample of infants aged 6-16 months.

Methods: Data for this study was drawn from a larger longitudinal study examining sensory and social communication development in infants and toddlers. Participants were 28 parents and their infants ages 6-16 months with no known genetic conditions or major sensory or motor impairments. The primary measure was the Autism Observation Scale for Infants (AOSI; Bryson & Zwagenbaum, 2014), a 19-item semi-structured observational screening tool for early signs of autism in 6-18-month-olds. The AOSI was administered remotely using a parent coaching model developed from Talbott and colleagues (2020). We also applied an assessment fidelity checklist, developed for the purposes of this study, to examine the presence or absence of parent behaviors that are consistent with expected administration of each item. The total score on the assessment fidelity checklist represents the proportion of items that were administered correctly. Data analyses included calculation of mean proportions of correctly administered items, as well as intraclass correlation coefficients (ICC) and Kappa statistics as measures of inter-rater reliability.

Results: Parent-administered items were conducted with an average of 82% fidelity (SD = 6%; Range = 71-93%). The majority of items were administered correctly in at least 75% of observations. In terms of inter-rater reliability, ICC were 0.94-0.95. Kappa values ranged from 0.38-1.00 across items.

Conclusions: Based on the results of this study, telehealth parent coaching is a valid and reliable method for conducting semi-structured observational screening for autism with the AOSI. Further analysis using direct comparison between in-person and telehealth administration of this measure is needed to examine potential differences in reliability and validity based on administration context.

421.104 (Poster) Hebrew Adaptation of a Clinical Questionnaire for Preschool Children with ASD
E. Dromi, A. Tavor and P. Gur, (1) Constantiner School of Education, Tel Aviv University, Tel Aviv, Israel, (2) Language Therapy, The Israeli Center for the Treatment and Research of Autism, Tel Aviv, Israel, (3) Language Therapy, OTI - The Israeli Autism Association, Tel Aviv, Israel

Background:

Speech Language Pathologists (SLP) all over the world seek efficient clinical tools that will facilitate the assessment of communication, language and early speech of preschoolers with ASD (Muller et al., 2020). The Pre-Verbal Communication Schedule (PVCS) is a well accepted clinical questionnaire that was created in England by Kiernan & Reid (1987) for the assessment of communicative skills in profoundly cognitive impaired non-verbal individuals.

The Israeli Center for the Treatment and Research of Autism, runs 300 preschools for children with ASD, all over the country. In these preschools more than 400 SLPs provide clinical services for the children and their parents.

Objectives:

The goal of the present study was to create and to validate an Hebrew modified version of the PVCS to be used in the assessment procedure of preschoolers with ASD in the Israel.

Methods:

The adaptation process of the PVCS was done in a focus discussion group of 8 SLPs experts in early communication and language acquisition and impairments, who supervise the clinical programs that are delivered in the preschools of the Israeli Center for the Treatment and Research of Autism. The questionnaire was validated via content validation process through experts judgments by 10 researchers in the area of language development and language disorders, who were not involved in the construction of the tool (Fernández-Gómez, E., et.al., 2020).

Results:

The modified Hebrew questionnaire consists of the following 7 out of the 13 original subtests in the English source: 1) Visual Behaviors, 2) Cognitive Representational Skills, 3) Communication, 4) Social Orientation, 5) Language Comprehension, 6) Vocal/Verbal Productions, 7) Augmentative/Alternative Communication. Each subtest contain items that are developmentally listed from early to late emerging attainments. Examples of typical activities of young children with ASD are provided next to each item to facilitate the process of filling in the questionnaire by the SLPs. An additional sub-test in which non-communicative behaviors are listed was also created. This subset refers to RRBI rituals characterizing ASD. The scoring sheet in which the frequency of occurrence of each item is noted allow the revealing of the comprehensive clinical profile of each child, that lead to the selection of intervention goals in the areas of communication, language and speech. In order to demonstrate how a clinical profile of a child emerges from the analysis of the questionnaire’s data, a case of one 3 years old girl with ASD will be presented (see table 1 bellow).

Conclusions:

The modified Hebrew PVCS –ASD is a new tool for depicting the clinical profile of young children with ASD. Preliminary results point to its utility for selecting targets for early intervention on the basis of the comprehensive clinical profile.

421.105 (Poster) Factors Associated with DSM-5 Severity Ratings for Black and Hispanic/Latinx Children with ASD

Background: Diagnostic and Statistical Manual of Mental Disorders (5th ed., DSM-5; APA, 2013) diagnoses of ASD require clinicians to assign severity ratings of the impact of social communication (SC) and restricted and repetitive behavior (RRB) symptoms. Ratings for each domain range from 1 (requiring support), 2 (requiring substantial support), or 3 (requiring very substantial support). A small body of research has found associations between ASD severity level ratings and standardized measures, including cognitive functioning, parent report questionnaires, and the Autism Diagnostic Observation Schedule (ADOS-2) (Mazurek et al., 2019; Ellison et al., 2019). However, racial and ethnic minority groups have not been well-represented in this literature.

Objectives: To examine associations between clinician-rated DSM-5 ASD levels of severity and norm-referenced behavioral symptom measures in a clinical sample of Black and Hispanic/Latinx children.
Results: Spearman correlations were examined between clinician DSM-5 severity ratings and assessment measures. For White Hispanic/Latinx children, SC severity was associated with ADOS-2 Social Affect (SA) severity ($r_s=.60,p<.001$), ADOS-2 Total severity ($r_s=.61,p<.001$), NVIQ ($r_s=.42,p<.001$), and ASRS SC T-score ($r_s=.42,p<.001$). A similar pattern was found for Black Non-Hispanic children: ADOS-2 SA ($r_s=.59,p<.001$), ADOS-2 Total ($r_s=.49,p<.001$), NVIQ ($r_s=.70,p<.001$), ASRS SC ($r_s=.31,n.s.$). For White Hispanic/Latinx children, RRB severity was associated with ADOS-2 RRB severity ($r_s=.49,p<.001$), ADOS-2 Total severity ($r_s=.42,p<.001$), NVIQ ($r_s=.45,p<.001$), BASC-3 Internalizing T-Score ($r_s=-.24,p<.05$) and BASC-3 Adaptive T-score ($r_s=-.28,p<.01$). A similar pattern was found for Black Non-Hispanic children, ADOS-2 RRB ($r_s=.31,n.s.$), ADOS-2 Total ($r_s=.26,n.s.$), NVIQ ($r_s=-.52,p<.01$).

Conclusions: Similar patterns of association between clinician DSM-5 severity ratings and other behavioral and cognitive measures were found for both groups, although there were fewer associations with the smaller sample of Black children. DSM-5 severity ratings in a clinical sample appear to be influenced by a variety of cognitive and behavioral factors. Implications for clinicians examining these measures in a diagnostic setting will be discussed.

421.106 (Poster) Feasibility of Adequate Data Capture for “Off-the-Shelf” Eye-Tracking Technology As a Possible Aide to Autism Diagnostic Assessment with Young Children

A. Aulich, L. Chetcuti, D. W. Tan, A. Clark, C. A. Bent, C. C. Green, J. A. Smith, K. Fordyce, A. J. Whitehouse and K. Hudry, (1)La Trobe University, Melbourne, VIC, Australia, (2)Telethon Kids Institute, Perth, Western Australia, Australia, (3)La Trobe University, Melbourne, VIC, AUSTRALIA, (4)Childhood Autism Phenotype Team, La Trobe University, Melbourne, VIC, Australia, (5)Laurel House, North Molton, TAS, Australia, (6)Telethon Kids Institute, Perth, Western Australia, AUSTRALIA

Background: There is a strong international effort to identify and diagnose autism early. Diagnosis is currently based on the clinical judgement of behavioural presentation (Whitehouse, Evans, Eapen, & Wray, 2018) and while the average age of ASD diagnosis in childhood is estimated after age 4 even in well-resourced settings (Bent, Barbaro, & Dissanayake, 2015), confident diagnosis is possible and highly stable from age 2 (Barbaro & Dissanayake, 2016). Developed and manufactured by JVCKENWOOD Corporation (JKC), Gazefinder is a relatively new eye-tracking device with potential to support autism diagnosis, evidenced through existing research conducted in Japan, including with children aged 5-17 years (Tsuchiya et al., 2021) and adolescents and adults (Fujioaka et al., 2016).

Objectives: To test the feasibility/acceptability, and safety of Gazefinder ahead of potential future use as an aide to early childhood autism diagnosis, by examining whether this non-invasive, brief (approx. 2-minute), automated, standardised assessment is tolerated by, and returns adequate data for, young autistic and non-autistic children aged between 2-4 years.

Methods: 203 children completed Gazefinder eye-tracking assessment 1) 102 children with confirmed community autism diagnosis (81% male; $M_{age}=44$ months); and 2) 101 controls (57% male; $M_{age}=40$ months) screened as likely typically developing without any parent-reported concerns related to autism/other developmental conditions or autism among immediate family members. For children with autism, Gazefinder assessment occurred alongside a comprehensive clinical/behavioural assessment including the Autism Diagnostic Observation Schedule-Revised (ADOS-2), Mullen Scales of Early Learning (MSEL), and Vinelad Adaptive Behaviour Scales-2nd edition (VABS-II) while controls completed Gazefinder and VABS-II only. All assessments were completed by clinical (i.e., non-technical) researchers, who recorded: 1) number of attempts to complete Gazefinder, 2) child behaviour during eye-tracking, 3) any adverse events. Automated data collected by Gazefinder included calibration attempts/success and overall % gaze tracking rate per child.

Results: In the autism group, most children met ADOS-2 Total Algorithm ‘Autism’ classification (n=87), and MSEL composite standard scores suggested significant developmental delay for a substantial subgroup (i.e., 36% with floor-level scores) corroborated by low group mean VABS-II scores (M=74.96; SD=12.39, vs. control M=111.24; SD=13.53). All 101 controls successfully completed Gazefinder assessment, compared to 94% of children with autism. Only four children with autism could not be calibrated despite multiple attempts, and Gazefinder assessment was not attempted for two due to earlier unrelated adverse responses to behavioural assessment. Most controls (97%) and fewer autistic children (77%) calibrated on the first attempt. Autistic children who needed multiple attempts for calibration had lower MSEL Non-Verbal abilities (M=50.92, SD=7.13) than those who calibrated quickly (M=70.64, SD=21.94). Only seven controls had overall tracking rates <70%, vs. 34 autistic children. For autistic children who were successfully calibrated, lower overall tracking rate was associated with lower MSEL Non-Verbal and Verbal abilities (relative to age).
Conclusions: Gazefinder was very well-tolerated by all 101 controls and most of the 102 children with autism assessed, even in the context of significant clinical presentation identified in the latter group. We are currently also investigating, and will report on, acceptability and ease-of-use by community clinicians.

421.107 (Poster) Feasibility of Building a Streamlined Birth Cohort to Examine Biomarkers Related to Autism in a Community-Based Health System

Background: Community-based health systems with large numbers of annual births could advance autism etiologic research by enabling prospective cohorts with rich data across multiple metrics in diverse and representative populations. In particular, capitalizing on biosamples collected via routine clinical practice presents the opportunity to develop a “streamlined birth cohort” approach that minimizes participant burden but opens the potential for multi-omics work, with potential addition of follow-up measures of child behavior relevant to the autism phenotype. However, the feasibility of such an approach has not been tested. To address this gap, we piloted the implementation of a streamlined birth cohort based in a community-based health system with a large number (>7,000) of annual births.

Objectives: We examined the feasibility of building a streamlined birth cohort within a community health system across multiple indicators.

Methods: We examined the following as indicators of feasibility: (1) enrollment of at least 100 pregnant women over six months, (2) demographic representativeness of enrolled participants, (3) successful collection of biosamples, including umbilical cord blood, umbilical cord tissue, placenta tissue, and meconium (stool from babies’ first bowel movements) from enrolled participants by birth hospital staff integrated with routine clinical practice followed by transmission to a central laboratory, (4) enrollment of a subsample of 50 initially enrolled participants into a follow-up study of babies at age 6 months, with collection of (a) caregiver-reported data on child social behavior using the Socialization Subscale of the Vineland Adaptive Behavior Scales, and (b) markers of early social behaviors relevant to autism derived from Computer Vision Analysis of mobile-device-captured infant attentional engagement in response to on-screen social stimuli. Due to covid-related disruptions, subsample enrollment eligibility was extended to include babies up to 24 months of age.

Results: We were able to successfully enroll 99 women over a 6-month period. Demographic profiles (i.e., 66% White/ 25% Black/11% Hispanic) were consistent with the census data for the counties were participants lived. Biosamples were successfully collected by birth hospital staff integrated with routine clinical practice followed by transmission to a central laboratory, with 76% of eligible women contributing at least one delivery biospecimen (n=71). COVID-19 impacted recruitment timelines for the follow-up study and necessitated a shift to remote (home-based or virtual) data collection. However, we successfully enrolled 30 participants (representing 60% of phase 2 goal) who completed at least one follow-up measure. Computer Vision Analysis data from mobile-device-captured infant attentional responses to social stimuli were successfully obtained for 27 participants (90% of those enrolled in Phase 2).

Conclusions: Indicators of participation rate, demographic profiles, implementation of data collection at birth, and follow-up, suggest that it is feasible to build a representative streamlined birth cohort within community healthcare systems. The characterization of children across biological and behavioral measures relevant to the autism phenotype from birth in the context of community health system offers the potential to advance our understanding of prenatal and early emerging markers associated with autism-related phenotypes.

421.108 (Poster) Gender Differences in Dyadic Emotional Availability in Children with ASD

E. Paolizzi, S. Perzolli, A. Bentenuto, S. Lavecchia, A. Peripoli and P. Venuti, (1)Department of Psychology and Cognitive Science, Laboratory of Observation, Diagnosis, and Education (ODFLab) - University of Trento, Rovereto (TN), Italy, (2)Department of Psychology and Cognitive Science, University of Trento, Rovereto, Italy, (3)Department of Psychology, University of Trento, Rovereto, Italy, (4)Laboratory of Observation, Diagnosis, and Education (ODFLab), University of Trento, Rovereto, Italy

Background: Females with Autism Spectrum Disorder (ASD) might present better socio-communicative abilities, though future research needs to focus on narrower constructs in order to comprehend better the mechanisms that lead females’ under-recognition (Lai & Sztatmari, 2020). Recent research showed that females present better interpersonal synchrony with greater engagement during the interplays (Paolizzi et al., 2022). Though, engagement has been investigated using only one parameter, which did not allow for fully grasp child responsiveness and involvement in the interaction.

Objectives: In the present study, we aimed to study gender differences related to the Emotional Availability construct with a specific focus on child dimensions: responsiveness and how the child involves the adult. Based on current literature, we expect females to be more responsive and more involving toward the adult compared to males.
Methods: N=67 parent-child dyads interactions, of 37 children with mothers and fathers, both when available, have been analyzed. Specifically, there are 18 males (mean chronological age=38.40 months, sd=10.50) and 19 females (mean=44.10 months, sd=11.00) with a confirmed diagnosis of ASD. The females sample size has been determined by availability constraints and the male’s one has been selected matching the females’ by general development quotient. Children received a complete clinical assessment, the cognitive profile has been assessed using the Griffith Mental Development Scales (GMDS) and the behavioral profile using the ADOS-2. Further, parent-child dyads have been requested to play as they typically would in a quiet room for 10 minutes with a standard set of toys. These interactions have been video recorded and coded by two independent observers, blind to child diagnosis and research aims, using the Emotional Availability Scales 4th Edition (Biringen, 2008).

Results: The females sample received the diagnosis significantly later than the males’ one (t(65)=2.21, p=0.03, d=0.54). Preliminary analysis showed gender differences in the child dimensions but not in the parents’ ones. Specifically, females showed higher responsiveness levels (W=750, p=0.02, r=0.30), with greater emotion regulation of affects and behaviors abilities (W=721, p=0.04, r=0.26), better positive physical positioning (W=704, p=0.04, r=0.25) and greater orientation toward the adult while playing (W=720, p=0.03, r=0.27). Gender differences also emerged in relation to involvement dimensions, in particular, females showed greater ability in the involvement of the adult in a positively elaborated interaction (W=790, p=0.003, r=0.36) and used the adult more oriented toward the emotional needs and playful exchange concerning instrumental use (W=772, p=0.003, r=0.36). Further, females presented a greater use of eye contact and nonverbal channels to involve the adult (W= 714, p=0.03, r=0.26). Analysis conducted using two-way ANOVAs studying EAS’s parameter differences including child sex and parent as factors showed no differences related to parent gender. Data will be further studied using linear models.

Conclusions: Child gender differences have been highlighted in the responsiveness and involvement, potentially disclosing mechanisms involved in the late diagnosis of females with ASD and stressing the need to investigate narrower constructs when studying gender differences in ASD phenotypes. Further, these preliminary results suggest the absence of differences in fathers’ and mothers’ Emotional Availability.

421.109 (Poster) Hazard Perception in Male Autistic Children in Jakarta: An Investigation of Their Skills and Parents' Subjective Evaluation

H. Dirix, J. Syahputri, K. Brijs, W. Alhajyaseen, T. Brijs, G. Wets and V. Ross, (1)School of Transportation Sciences, Transportation Research Institute (IMOB), UHasselt – Hasselt University, Hasselt, Belgium, (2)Qatar Transportation and Traffic Safety Center, College of Engineering, Qatar University, Doha, Qatar, (3)Department of Civil and Architectural Engineering, College of Engineering, Qatar University, Doha, Qatar

Background: Children in Indonesia are vulnerable to road injuries and fatalities. Data from previous studies showed that children between 0 – 14 years old made up for almost 1/3 of all traffic fatalities in Indonesia. Within this group, children between 10-14 years old were the most represented percentage-wise. A possible reason for this overrepresentation may be children's deficiency in hazard perception (HP) skills. Previous studies suggested that these deficiencies may be more present among autistic children, making them even more vulnerable to road injuries and fatalities. Generally, parents play an essential role in educating their children about safe travel behaviors. They determine how much supervision is needed for their child throughout the developmental process of their HP skills. Since a more negative view of a child's HP skills can limit the development of HP skills (i.e., by limiting their learning opportunities), the accuracy of parents' perception of their children's skills is important. This can be even more limiting for autistic children as they generally experience more problems with HP skills.

Objectives: The objective of the current study was twofold: (1) compare the hazard perception skills of autistic and non-autistic children in Jakarta, Indonesia, and (2) investigate the autistic parents' perception of their child's HP skills and examine if there is a potential relationship between their perception and their child's performance.

Methods: Data was collected through online questionnaires. Children were presented with photos of traffic situations in Jakarta on which they had to indicate if and where a hazardous situation could occur. Hazards were divided into four categories: behavioral prediction (BP), environmental prediction, dividing and focusing attention (DF), and no hazards. Parents were asked for their opinions on their child's HP skills and predicted their child's test performance.

Results: Twenty male autistic children (ages: 10 – 15) and their mothers participated, together with 34 male non-autistic children (ages: 10 -14). Analyses showed that autistic children significantly identified fewer BP, EP, and DF hazards. They also responded slower to all types of hazards compared to the non-autistic children. No differences were found for the photos where no hazard was present. Parents could accurately predict their children's total number of correct answers on the test. However, they tended to overestimate their children's reaction time. Further analyses showed that parents whose children could identify fewer hazards and reacted slower tended to overestimate their children's HP skills. Interestingly, the more days a week children walked around in their neighborhood, the more accurate their parents' prediction was.

Conclusions: The current study offered valuable insights into the HP skills of autistic children. Results showed that autistic children significantly performed worse on the HP test, and their parents tended to overestimate their reaction time. Moreover, children with more...
exposure to hazards scored better on the test, indicating that increased exposure in a safe environment positively affected their HP skills. Future research could focus on the factors that may influence the HP skills of autistic children and/or could include females, other age groups, or children from different countries.

421.110 (Poster) Executive Functioning Predicts Age of Diagnosis in School-Aged Youth with Co-Occurring ASD and ADHD

Background:
Executive functioning (EF) is impaired in autism spectrum disorder (ASD) and attention-deficit/hyperactivity disorder (ADHD), and we previously identified exacerbation of EF challenges in youth with co-occurring ASD and ADHD (ASD+ADHD). Delayed identification of ASD poses risk for social and emotional difficulties, but the impact of EF on diagnostic timing of ASD has yet to be explored.

Objectives:
This study aimed to parse EF to identify predictors of age of ASD diagnosis, particularly in late-diagnosed school-aged youth who may present with more complex EF presentations. We hypothesized 1) ASD+ADHD youth are more impaired in EF compared to autistic youth without ADHD (ASD-only) and 2) ASD+ADHD youth are at significant risk for delayed ASD diagnosis. As an exploratory aim, we investigated whether greater EF challenges predicted earlier age of ASD diagnosis in both diagnostic groups.

Methods:
Participants included 400 youth seen for neuropsychological evaluation who received an ASD diagnosis after the age of 5, drawn from a clinic-based research sample of >2500. Youth with a co-occurring ADHD diagnosis were in the ASD+ADHD group (n=297); youth without co-occurring ADHD were in the ASD-only group (n=100). Parent-reported EF was measured with the BRIEF-2. The BRIEF-2 taps nine subdomains (Inhibit, Self-Monitor, Shift, Emotional Control, Initiate, Working Memory (WM), Plan/Organize (PO), Task Monitor (TM), and Organization of Materials (OM)) that form three indices (Behavior Regulation, Emotional Regulation, Cognitive Regulation) and a Global Executive Composite score (GEC). Independent samples t-tests were used to compare EF impairment and age of ASD diagnosis between the ASD+ADHD and ASD-only groups. Pearson correlations examined the association between age of ASD diagnosis and EF for each diagnostic group. Hierarchical linear regressions further probed significant relationships to determine whether specific EF subdomains concurrently predicted age of ASD diagnosis after controlling for assigned sex at birth, FSIQ, and ASD symptom strength (SRS-2 T-scores).

Results:
ASD+ADHD youth had greater impairments in EF overall, and specifically in Inhibit, Initiate, WM, PO, TM, and OM (t’s>3.19, p’s<.01). ASD+ADHD youth received ASD diagnoses earlier than ASD-only youth. In ASD-only youth, age of ASD diagnosis was significantly correlated with PO, but no other EF subdomain. In ASD+ADHD youth, age of ASD diagnosis was significantly correlated with Initiate, WM, PO, TM, and OM. After controlling for assigned sex at birth, FSIQ, and SRS-2 T-scores, the regressions revealed PO as a significant predictor of age of ASD diagnosis in the ASD-only group, and PO, TM, and OM as significant predictors of age of ASD diagnosis in the ASD+ADHD group.

Conclusions:
Parents of youth with ASD+ADHD report greater impairment in overall EF skills, and specifically with cognitive regulation EF skills, compared to parents of youth with ASD-only. Contrary to our hypothesis, findings suggest ASD+ADHD youth are diagnosed with ASD earlier than ASD-only youth in this clinic-ascertained sample, perhaps due to higher clinical impairment. Results also suggest greater EF impairment predicts later age of ASD diagnosis, with planning/organization as the most consistent predictor.

421.111 (Poster) Age of Autism Diagnosis in Asian American Versus White Youth in a US Clinical Sample
A. Khuu and A. B. Ratto, Center for Autism Spectrum Disorders, Children's National, Washington, DC

Background: Asian American youth are widely under-represented in autism research, so much so that in most surveillance years, the CDC has been unable to estimate a national prevalence rate of autism in this group. Little is known about diagnostic timing of autism among Asian American youth, though prior research indicates these families experience unique stressors related to the autism experience. It is
important to further explore the relationship between race and diagnostic timing of autism, and to evaluate the moderating effect of race on previously identified predictors of age of autism diagnosis (e.g., autism symptom strength and cognitive ability).

Objectives: For this study, we hypothesized 1) Asian American youth will be diagnosed later than White youth and 2) race will moderate factors predicting age of autism diagnosis, specifically parent-reported autism symptom strength and cognitive ability.

Methods: Data from a clinic-based research database was extracted for 673 participants who were seen for neuropsychological evaluation and met the following criteria: 1) first-time diagnosis of autism, 2) identified as Asian American (n=83) or White (n=590), and 3) SRS-2 data available. Full-scale IQ (FSIQ) was available for a subset (Asian American: n=42; White: n=345).

Results: On average, Asian American youth (M=7.71, SD=4.65) received their first autism diagnosis significantly earlier than White youth (M=8.76, SD=4.44), \(t(671)=-2.02, p=.044\). When the sample was split by early diagnosis (before age 6) and later diagnosis (age 6+), a Chi-squared analysis revealed a significant over-representation of White youth in the later diagnosed group, \(\chi^2(1)=5.67, p<.05\). There were no significant differences in age of autism diagnosis between Asian American and White youth in the early diagnosis group (t(228)=-1.21, \(p=.23\)) nor the later diagnosis group (t(441)=-.05, \(p=.96\)). Child Opportunity Index scores were not significantly correlated with age of autism diagnosis (\(r=.09, p=.18\)). Age of autism diagnosis was significantly correlated with autism symptom strength (\(r=.18, p<.001\)) and FSIQ (\(r=.10, p<.05\)) in the full sample, such that higher SRS-2 total T-scores and higher IQ were associated with later age of autism diagnosis. Hierarchical regressions revealed that independently, autism symptom strength and FSIQ were predictors of age of autism diagnosis, but race did not moderate these relationships (Table 1).

Conclusions: Findings suggest Asian American youth receive their first-time autism diagnosis earlier than White youth on average. However, this finding could be unique to our sample, which was drawn from individuals who were seen at a specialized autism center. Additionally, this finding should be considered in conjunction with the finding that compared to White youth, Asian American youth are less likely to receive an autism diagnosis after the early intervention period, indicating that Asian American youth with more subtle profiles may go undiagnosed. Higher levels of parent-reported autism symptom strength and higher cognitive abilities were both predictors of later age of diagnosis, but neither relationship was moderated by race. Future research is needed to identify and bring awareness to the profile of older Asian American youth who might be less recognized as having autism and/or are experiencing barriers to accessing services at a medical center.

421.112 (Poster) Adapted Clinical Interview for Autism (ACIA): Improving Episodic Memory Recall in Autistic Individuals for CBT Treatment
A. Jongco1, E. George1, R. Arena1, S. Bell-Hyland1, K. Cooper2, A. Russell2 and K. L. Maras4, (1)University of Bath, Bath, United Kingdom, (2)University of Bath, Bath, UNITED KINGDOM, (3)Psychology/Centre for Applied Autism Research, University of Bath, Bath, UNITED KINGDOM, (4)university of bath, bath, United Kingdom

Background:
High rates of anxiety and depression are reported to co-occur with autism. Cognitive behavioural therapy (CBT), an effective treatment for anxiety and depression, relies on an initial assessment interview to develop a collaborative formulation and devise a treatment plan. The client is asked to recall a recent problem episode, reflecting on their thoughts, feelings, and actions. This is likely to be especially difficult for an autistic person, as anxiety, depression and autism are all associated with episodic memory recall differences. Previous research in police interviewing has led to scaffolded interviewing techniques (e.g., the Witness Aimed First Account method, ‘WAFA’) that support differences in how autistic people remember and report events, improving recall quality.

Objectives:
To investigate an Applied Clinical Interview for Autism (ACIA) adapted from WAFA for use in CBT assessment.

Research questions:
1. Does the adapted interview (ACIA) improve recall compared to standard CBT assessment interview format (‘CBT-as-usual’)?
2. Is anxiety and depression associated with episodic recall during CBT assessment, and is this moderated by interview type?

Methods:
A 2 (Group: autistic vs. non autistic) x 2 (Interview: CBT-as-usual vs. ACIA) between-subjects design was used. Autistic (n=30) and non-autistic (n=32) adults randomly allocated to ACIA or CBT-as-usual interview recalled a negative event (via Microsoft Teams).
CBT-as-usual participants were asked to engage in uninterrupted free recall attempt of their chosen negative event, before being asked follow-up questions about the event (who, what, where, when, how) and their experience (thoughts, feelings, behaviours and sensations).

ACIA interview participants were first asked to segment their event into its constituent parts, which were displayed on virtual post-it notes on screen (Figure 1). Each segment was revisited, whereby the participant freely recalled as much as they could from the segment, followed by the same prompts used in the CBT-as-usual interviews supported by a worksheet with visual cues (see Figure 2).

Each new unit of information recalled was coded as episodic (specific to the time, e.g., feeling sick during the meeting) or semantic (non-event-specific information e.g., generally sick before meetings), and represented thought, behaviour, feeling, sensation, or event/context. Participants also completed the WASI-II and the Hospital Anxiety and Depression Scale (HADS).

Results:

There was a main effect of interview ($p<.001$, partial $\eta^2=.42$): more episodic details about the event and behaviours, thoughts, feelings, and sensations (all $ps<.005$) were recalled in ACIA interviews. There was no effect of Group or Group x Interview for episodic information ($ps>.518$) or semantic information (all $ps>.162$).

For the autistic group, interview condition moderated the relationship between HADS scores and episodic recall scores ($p=.032$, $sr^2=.15$): there was a positive relationship between episodic recall scores and HADS scores for autistic participants in the CBT-as-usual condition ($p=.017$, $sr^2=.19$), but not the ACIA condition ($p=.097$, $sr^2=.08$). No such effects were found for the non-autistic group ($p=.586$, $sr^2=.01$).

Conclusions:

The ACIA is effective in supporting recalling of past events for CBT assessment, particularly for autistic individuals with higher anxiety and depression scores. Further research to investigate use of the ACIA in practice is indicated.

421.113 (Poster) Are Autism and ADHD Traits Associated with Performance on a Cognitive Behavioural Therapy Skills Task?  
M. Payne, J. Chivers, A. Russell and K. Cooper, (1)University of Bath, Bath, United Kingdom, (2)Psychology/Centre for Applied Autism Research, University of Bath, Bath, UNITED KINGDOM, (3)University of Bath, Bath, UNITED KINGDOM

Background: Autistic people are more likely to experience mental health problems compared to non-autistic people, with a lifetime prevalence of 42% for anxiety and 37% for depression. Adapted cognitive behavioural interventions show promise in supporting autistic people experiencing anxiety and depression. To engage effectively in CBT, an individual should have skills in identifying, distinguishing, and describing cognitions, behaviours and emotions, also referred to as CBT skills. Such abilities may be influenced by being neurodivergent, particularly having autistic or ADHD traits.

Objectives: To understand whether autism and ADHD traits impact on CBT skills task performance, and if number of co-existing neurodivergent diagnoses/identities influenced CBT skills.

Hypotheses:

1. Higher autism traits will be associated with lower CBT skills performance.
2. Higher ADHD traits will be associated with lower CBT skills performance.
3. Individuals with a higher number of co-existing neurodivergent conditions will have lower CBT skills scores.

Methods: In total, a convenience sample of 186 participants, aged 16-30-years-old, were recruited from community settings to complete an online survey (see Table 1). Participants provided demographic information including their history of diagnoses and/or self-identification with neurodivergent conditions including autism, ADHD, and other specific learning difficulties such as dyslexia.

To assess autism and ADHD traits, participants completed the AQ-10 and ASRS-V1.1 screener.

Participants then completed a novel CBT skills task. In this task, they were asked to read two 100-word vignettes with a fictional account of an individual with a mental health condition (depression and social anxiety). Participants were then asked to identify the subject’s thoughts, feelings and behaviours, to indicate whether these could be connected, and to apply this understanding to develop a plan to help reduce the subject’s distress. A higher total score indicated greater proficiency in utilising the skills required when engaging in CBT (maximum = 23). The measure had moderate internal consistency ($\alpha = .780$).
Results: We found support for the first hypothesis: a hierarchical multiple regression revealed a significant negative relationship between AQ-10 and CBT skills task scores (Table 2).

We did not find support for the hypothesis that ADHD traits would predict lower CBT skills task performance. In fact, there was a significant positive relationship between ASRS-V1.1 screener and CBT skills task scores.

We did not find support for the third hypothesis: there was no relationship between the total number of diagnosed/self-identified neurodivergent conditions and CBT skills task performance.

Conclusions: Individuals with high autistic traits may experience barriers to effectively engaging in CBT. This highlights the importance of developing appropriate autism treatment adaptations, to increase the inclusivity of CBT. However, possessing ADHD traits positively impacted on CBT skills. It may be that individuals with high ADHD traits face barriers at a later stage of CBT compared to those with autistic traits, i.e., such individuals are more likely to possess the prerequisite skills for CBT, but may struggle with attending to and implementing information learned in CBT sessions. It is recommended that future research explores the identified relationships in greater depth by using more complete measures of neurodivergence.

Background:
Gathering detailed information through clinical interview, a key aspect of Cognitive Behaviour Therapy (CBT), helps develop a formulation and treatment. Open questions and Socratic enquiry, hallmarks of CBT interviews, are less accessible for autistic people, reducing the quality and quantity of information available.

Objectives:
To investigate CBT therapists’ and adults’ views about the acceptability and utility of an adapted clinical interview.

Methods:
The Adapted Clinical Interview for Autism (ACIA) was developed following methods used in previous interviewing research (Maras et al. 2020). Sixty- two adults (n=30: Autistic, n=32: Non-autistic; 28.4% Male; 83.1% White, 5.7% Black, 11.4% Asian ethnicity) were randomly allocated to CBT-as-usual (CBT-AU) or ACIA interview. Interviews, conducted online, asked participants to recall in detail a recent episode associated with negative emotion with questions about situational triggers, thoughts, feelings, bodily sensations and behaviours (CBT-AU). In ACIA interviews, participants self-segmented their recall into chunks and recalled each in turn. Visual cues were used to prompt detail about thoughts, feelings etc. Six CBT therapists (blind to group) developed a cross-sectional formulation from 49 of the interview transcripts and rated them on acceptability and utility (14 items). Formulations were coded for percentage completeness. Interviewees also rated acceptability and utility (17 items). Open text boxes invited comments from therapists and interviewees for subsequent content analysis.

Results:
A 2 (group: Autistic vs. non-autistic) x 2 (interview: ACIA vs CBT) between subjects ANOVA found a significant main effect of interview type on therapist utility ratings, $F(1,45)=15.73, p<.001$, $\eta^p=.26$, with the ACIA rated as having significantly higher utility than CBT-AU. There was no significant main effect of diagnosis, $F(1,45)=3.05, p=.088$, $\eta^p=.06$, or interaction, $F(1,45)=1.27, p=.266$, $\eta^p=.03$.

For therapist acceptability ratings, there was a significant main effect of interview, $F(1,45)=9.42, p<.01$, $\eta^p=.17$, with the ACIA rated as significantly more acceptable than CBT-AU. There was no significant main effect of diagnosis, $F(1,45)=2.15, p=.149$, $\eta^p=.05$, and no interaction, $F(1,45)=1.29, p=.263$, $\eta^p=.03$.

All formulations were at least 80% complete. Formulation completion was not associated with interview type ($p=.211$). Content analysis of open text comments identified four themes (Table 1). All clinicians reported that ACIA format helped them develop a more precise formulation, but also highlighted concerns about the time intensive nature of the interview.
Autistic and non-autistic participants rated both interview formats as useful and acceptable (Figure 1). There were no significant effects or interactions of interview type on utility ratings (all ps>0.5) but there was a significant main effect of Group on acceptability ratings, (B=0.29, SE=0.13, 95% bootstrapped CI for B [0.01, 0.57], t(49)=2.17, p<.05), with non-autistic interviewees finding all interviews more acceptable than autistic interviewees. There was no effect of interview or group x interview interaction (all ps>0.08).

Conclusions:

An adapted clinical interview was rated as acceptable and useful by autistic and non-autistic adults and clinicians, with the latter valuing more detailed information with which to develop a formulation. Qualitative feedback suggested refinements to improve the interview which now requires evaluation in more naturalistic clinical setting.

421.115 (Poster) “You’re Simply the Best”: IQ and Baseline Vineland “Better Than All the Rest” at Predicting Adaptive Functioning Among Youth with Autism Spectrum Disorder

S. S. Glynn, Department of Psychology, University of California, Los Angeles, Los Angeles, CA; Data Coordinating Center, Massachusetts General Hospital, Boston, MA

Background: Standard cognitive assessments have been identified as the most robust predictor of later adaptive functioning in youth with autism spectrum disorder (ASD), but IQ may be less accessible or limited in its predictive ability for children with greater autism severity (e.g., Liss et al., 2001). Common ASD co-occurring conditions, like psychiatric issues, gastrointestinal problems, and sleep disturbance, are more accessible for families and clinicians to assess and are mostly unrelated to ASD symptom severity (e.g., Simonoff et al., 2008; Neumeyer et al., 2018). Previous literature found associations between adaptive functioning and psychological problems and physical health problems (Baghdadli et al., 2012; Hus Bal et al., 2015; Taylor et al., 2012). However, past studies have not assessed behavioral and physical health issues in comparison to previously identified predictors of adaptive functioning (e.g., IQ).

Objectives: The objective of this study is to compare the predictive strength of multiple baseline predictors (i.e., demographic information, cognitive ability, adaptive skills, behavioral health issues, and physical health issues) of adaptive skill development four years later.

Methods: A total of 565 children with ASD (ages two to 17; 80% male; average IQ of 77), who were previously enrolled in the Autism Treatment Network (ATN) Registry and follow-up, were selected for the current study. The follow-up assessment took place roughly four years after their baseline assessment. Prediction of follow-up VABS was estimated in three models using multivariable regressions. Each model groups the variables into different groups to assess how these variables function as scale scores or as larger sets of predictors. Model 1 evaluated three sets of predictors: demographics (age, race, sex, income, education, Vineland Aberrant Behavior Scale (VABS) scores, and IQ), behavioral health (ADOS scores and Child Behavior Checklist internalizing and externalizing problems scores), and physical health (gastrointestinal and constipation problems, seizures, and Child Sleep Health Questionnaire score). Model 2 treated each measure’s scale scores as predictors. Lastly, model 3 treated each individual subscale score as a variable. Semi-partial coefficients of determination (R-squared) were used to provide estimates of the amount of variance in follow-up VABS that could be independently explained in each model.

Results: A little less than half of the variance in follow-up VABS was explained by the model with all focal predictors (42.4%). Almost all the variance was accounted for by the demographic variables. Baseline VABS significantly and independently explained the largest portion of variance (13.4%, p < .001) followed by age (1.6%, p < .001) and IQ (1.5%, p < .001). Behavioral measures as a group collectively independently explained 0.5% of the variance and physical health measures independently explained 0.7% but were not significant.

Conclusions: Our findings replicate the pre-existing literature among a diverse and representative sample of children in the autism population and suggest clinicians and caregivers should seek out IQ and Vineland assessments to best assess later social and functional outcomes for children with ASD. And although our model did not find health measures to be significant predictors, these measures may still indirectly contribute to adaptive functioning outcomes.

431 - Diagnostic, Behavioral & Intellectual Assessment II

431.076 (Poster) Leveraging Eye-Tracking Biomarkers to Improve ASD Diagnostic Accuracy in the Primary Care Setting

B. Keehn, B. Enneking; T. Ryan Lengacher, A. M. Martin, A. Paston and R. McNally Keehn; (1)Speech, Language, and Hearing Sciences, Purdue University, West Lafayette, IN, (2)Pediatrics, Indiana University School of Medicine, Indianapolis, IN

Background: Laboratory studies, many using prospective longitudinal designs of infants at elevated likelihood for developing autism, have demonstrated that several eye-tracking indices may be sensitive to autism risk. However, the accuracy of these novel biomarkers for the
Objectives: To determine whether a battery of eye-tracking biobehavioral markers can reliably differentiate young children with and without ASD in a high-risk community-referred sample collected during clinical evaluation the primary care setting.

Methods: Early Autism Evaluation (EAE) Hubs have been established in primary care practices across the state of Indiana. Participants included 158 children (M=2.6 years; SD=0.6; 73% male; 71% non-Latinx White) from 7 EAE Hubs. Children were diagnosed with ASD (n=112) or with a non-ASD developmental disorder (e.g., global developmental delay, language delay; n=46) based on a follow-up blinded research-grade evaluation conducted by ASD experts (including caregiver DSM-5 interview, Mullen Scales of Early Learning [MSEL], Vineland Adaptive Behavior Scales [Vineland-3], Autism Diagnostic Observation Schedule [ADOS-2]). The biomarker assessment included a short battery of eye-tracking measures (approximately 10 mins), which indexed non-social preference, attentional disengagement, basic oculo-motor dynamics, pupillary response, and blink rates using a series of flexibly administered experimental paradigms.

Results: Non-social preference (percentage looking time) was significantly higher in children with ASD (M=48%; SD=22) compared to non-ASD children (M=22%; SD = 12; \( p < 0.001 \)). Attentional disengagement, as measured using by gap-effect scores, did not differ significantly between ASD (M=148ms; SD=133) and non-ASD (M=146ms; SD=126) children. For basic oculomotor indices (i.e., fixation duration and saccade amplitude and velocity), children with ASD showed significantly longer fixation durations across two separate conditions (baseline [dynamic central fixation], animated cartoons; all \( ps < 0.005 \)). For animated cartoons, children with ASD also showed significantly reduced saccadic amplitude (\( p=0.008 \)). Measures of resting pupil diameter and spontaneous blink rates, which may index norepinephrine and dopaminergic systems, respectively, did not differ between ASD and non-ASD groups (\( p>0.05 \)).

Conclusions: Consistent with prior findings, children with ASD displayed increased non-social preference and oculomotor indices of reduced visual exploration (i.e., longer fixation durations, reduced saccade amplitude). However, contrary to previous results that compared children with ASD and neurotypical children, we did not find evidence of slower disengagement, larger pupil size, or decreased blink rates. Thus, it may be that some biomarkers may not differentiate those with and without ASD in high-risk neurodevelopmental cohorts. The present study demonstrates that eye-tracking markers of ASD risk can be successfully acquired in the primary care setting; future research will examine whether a combination of clinical and biobehavioral measures can be combined to improve accuracy of ASD diagnostic outcome for non-specialist primary care clinicians.

Background:

Underlying genetic factors influence assessed risk for later autism spectrum disorder (ASD). First-degree relatives of children with ASD are more likely to develop or present with the disorder, and there is an elevated rate of subclinical ASD characteristics in parents of children with ASD. These subclinical features, referred to as the Broad Autism Phenotype (BAP), include communication, personality, and behavioral characteristics that reflect the phenotypic expression of broader autism traits. Thus, maternal BAP characteristics may be associated with ASD symptomatology in their infant offspring and serve as one predictor of infant risk of developing the disorder.

Objectives:

To examine whether maternal self-reported BAP characteristics are associated with infant features related to ASD risk in participants from an ongoing birth cohort study.

Methods:

Maternal report data of the Broader Autism Phenotype Questionnaire (BAPQ) and the First Year Inventory Lite (FYI Lite) were collected for English and Spanish-speaking mother-infant dyads (n = 112, female = 68, male = 44) at 12-15 months of age.

The BAPQ is a 36-item Likert scale questionnaire with three subscales: Pragmatic Language, Rigidity, and Aloofness. The FYI Lite contains a subset of 25 questions from the full FYI, with social communication and sensory regulatory risk subdomains resulting in a dichotomous risk indicator.
Results:

A positive correlation ($r = 0.234, p < 0.05$; Table 1) was found between maternal self-reported Pragmatic Language ($M = 2.348, SD = 0.677$) and maternal report of infant social communication ($M = 1.718, 0.511$). A simple linear regression was performed to further evaluate this association ($R^2 = 0.046, F[1,110] = 6.385, p = 0.013$) with higher maternal pragmatic language difficulties being positively associated with FYI social communication risk ($b = 1.303, p < 0.001$; Figure 1). We explored the correlations of the following covariates: infant sex, maternal age, maternal education, race, and risk associated with having a family member with ASD in this initial set of infants; none were significant. There was a preliminary finding of difference in slope based on sex groups, but this may be explained by outliers. Data collection is ongoing, and we will continue to explore and report the impact of these covariates as appropriate.

Conclusions:

Mothers who self-reported higher levels of BAP characteristics, specifically in pragmatic language, reported higher levels of social communication risk characteristics in their infants. Given that ASD is influenced by underlying genetic risk factors, maternal phenotypic characteristics of social communication deficits might result in offspring displaying similar or more pervasive language impairment as well as ASD risk. Beyond this potential genetic link, home language environment may play a role, with altered maternal interaction with infant and other family members contributing to a cascading sequelae of environmental features that may interact with genetic predispositions to influence emerging ASD symptomatology. We note the findings are limited by lack of direct observation and reliance on maternal report. While the relationship between parental BAP traits and offspring ASD symptomatology is not fully understood, these results indicate it may be a key component in early ASD identification and intervention.

431.078 (Poster) Maternal Multiple Sclerosis and Risk of Neurodevelopmental Disorders: A Focus on Developmental Profile and Socio-Communicative Skills.

1) Biomedicine and Prevention, Policlinico Tor Vergata, University of Rome Tor Vergata, Rome, Italy, 2) Child and Adolescence Psychiatry Unit, Policlinico Tor Vergata Hospital, Rome, Italy, 3) Child and Adolescence Psychiatry Unit, University of Rome Tor Vergata, Rome, Italy, 4) Biomedicine and Prevention, University of Rome Tor Vergata, Rome, Italy, 5) Multiple Sclerosis Clinical and Research Unit, University of Rome Tor Vergata, Rome, Italy, 6) Adult Psychiatry Unit, Policlinico Tor Vergata Hospital, Rome, Italy, 7) System Medicine, Division of Child Psychiatry, University of Catania, Italy, Rome, ITALY

Background: In the context of maternal pathological condition, to be aware of the possible impact of parental disorders on offspring’s developmental trajectory represents a key health issue. The cognitive-behavioral and developmental profile of children exposed to maternal Multiple Sclerosis (MS) – pharmacologically treated or not - has not been delineated in depth. Whereas most of clinical and research attention has been given to the pregnancy adverse outcome (spontaneous abortion, ectopic pregnancy, non-live birth, congenital malformation) related to the maternal condition. Starting from the literature’s limits, and given our research background on the early detection of warning signals within population at risk, we have performed the following study.

Objectives: To characterize the cognitive and behavioral phenotype of offspring of women with MS - with a specific focus on the possible increase of Autism Spectrum Disorder risk – in comparison to age matched groups: a) children of women affected by Perinatal Depression (PD); b) control group of children not exposed to maternal MS or PD during pregnancy.

Methods: Women enrollment was conducted in the context of a health safeguard project developed to support women during pregnancy and post-partum, and to early detect child warning signals of a derailed development. Here we present preliminary data on a group of 16 children of mothers with MS in comparison to 2 groups of age matched mother-child pairs: women who suffered from Perinatal Depression (PD) and a control group of women not affected by MS and PD. Offspring of each group of women (MS, PD and control) underwent, at a mean age of 41 months, a standardized neuropsychiatric evaluation of: developmental-cognitive and adaptive skills (Griffith-III Scale, Adaptive Behavior Assessment System II), behavioral problems (Child Behavior Checklist), autism symptoms (Autism Diagnostic Observation Schedule–Second Edition) and parental stress (Parental Stress Index Short Form). Women belonging to MS and PD group received pharmacological therapy during pregnancy according to their clinical condition (Figure).

Results: Preliminary results on a sample of 48 children (16 individuals for each group) homogeneous for age $p = 0.73$, revealed that there are no statistically significant differences in terms of cognitive/developmental issues ($p = 0.17$), adaptive skills ($p = 0.19$), level of autism symptoms (ADOS-2 Calibrated Severity Score $p = 0.72$), social skills (ABAS_SAD $p = 0.44$) and behavioral problems (CBCL Internalizing Symptoms $p = 0.81$, Externalizing $p = 0.65$, Total $p = 0.09$) (Figure). Finally, the level of parental stress measured during child evaluation did not differ among groups (Total $\chi^2 = 2.0; p = 0.368$).

Conclusions: Our results on a limited sample size, even if don’t permit to lead to conclusions, suggest that maternal Multiple Sclerosis does not significantly impair child developmental profile, socio-communicative skills and behavioral phenotype. We depict a preliminary picture - through the administration of standardized instruments - of cognitive and behavioral profile of children of women affected by Multiple Sclerosis which absolutely need to be confirmed on wider samples taking into consideration maternal confounding factors (ie.
comorbid psychiatric disorders and symptoms, habits during pregnancy including smoking and exposure to maternal pharmacological treatment).

**431.079 (Poster) Measuring Intolerance of Uncertainty: Factor Structure and Measurement Invariance of the IUS-12 with Autistic and Non-Autistic Adults.**

**S. Brice**, J. Rodgers, J. Whitney, D. Mason, B. Ingham, J. R. Parr and M. Freeston. (1)Population Health Sciences Institute, Newcastle University, Newcastle upon Tyne, United Kingdom, (2)Cumbria, Northumberland, Tyne and Wear NHS Foundation Trust, Newcastle upon Tyne, United Kingdom, (3)Northern Lincolnshire and Goole NHS Trust, Scunthorpe, United Kingdom, (4)Social, Genetic and Developmental Psychiatry Centre, Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, United Kingdom, (5)Cumbria, Northumberland, Tyne & Wear NHS FT, Newcastle upon Tyne, (6)School of Psychology, Newcastle University, Newcastle upon Tyne, United Kingdom

**Background:** Intolerance of uncertainty (IU) is the belief that uncertainty is negative and to be avoided. It is an important transdiagnostic construct implicated in a range of anxiety conditions, and a recent meta-analysis indicates that this may also be true for autistic people. However, there is yet not yet a validated tool for measuring IU for autistic adults. The IUS-12 is a widely used tool for measuring IU in the general population and is the most frequently used to assess IU in studies with autistic people. It is vital that we have psychometrically robust measures of IU for research and clinical practice, particularly given the recent development of promising interventions targeting IU with autistic people (e.g., Coping with Uncertainty in Everyday Situations [CUES]).

**Objectives:** This study aimed to assess the factor structure and measurement invariance of the IUS-12 with autistic and non-autistic adults.

**Methods:** Archival data from 1326 non-autistic adults (mean age 39.5; 25.4% male) and 526 autistic adults (mean age 41.6; 42.4% male) were analysed. Data from autistic adults were available from the Adult Autism Spectrum Cohort – UK (ASC-UK) for a study about anxiety; data from non-autistic adults available through opportunity sampling. To conduct exploratory (EFA) and confirmatory (CFA) factor analysis on separate groups, each dataset was randomly split into two subgroups, stratified by age and gender. IUS-12 total scores were significantly higher for autistic people (median = 45) than non-autistic people (median = 25); however, there was no significant difference in IUS-12 scores between the subgroups from the autistic person dataset nor the subgroups for the non-autistic dataset. Several factor models were tested based on theoretical considerations and empirically tested, including a single factor, two correlated factors and a bi-factor model. Measurement invariance between autistic and non-autistic groups was also assessed.

**Results:** In both autistic and non-autistic groups, the theoretical bi-factor model including a general IU factor and two group factors relating to the traditional subscales of the IUS-12 (Prospective Anxiety and Inhibitive Anxiety) represented the greatest model-fit, more so than the empirically derived bi-factor models resulting from EFA. In each case, there was a strong general IU factor but weaker support for the group factors, indicating that the total score should be considered the most accurate indicator of IU. Measurement invariance was not supported between the groups.

**Conclusions:** Although the total score is reliable, the IUS-12 may measure different constructs in autistic compared to non-autistic people therefore comparisons of scores between these groups is not advised. Future research should attempt to assess why the IUS-12 may not be invariant by, for example, investigating the interpretation of items by autistic people and exploring conceptual differences in autistic people’s experience of IU. This could inform adaptations to improve the tool for autistic adults (e.g., changing wording; adding/removing items) and may lead to the development of a more theoretically driven factor structure that more accurately represents the overall construct. This would lead to a more psychometrically robust measure of IU for autistic people with potential utility as an outcome measure.

**431.080 (Poster) Meta-Analysis of the Modified Checklist for Autism in Toddlers, Revised/Follow-up for Screening for Autism Spectrum Disorder.**

**R. Aishworiya**, V. K. Ma, S. Stewart, R. Hagerman and H. Feldman. (1)Paediatrics, National University Hospital, Singapore, Singapore, (2)UC Davis MIND Institute, Sacramento, CA, (3)UC Davis MIND institute, Sacramento, CA, (4)UC Davis, Sacramento, CA, (5)University of California Davis, Davis, CA, (6)Stanford University, Palo Alto, CA

**Background:** The Modified Checklist for Autism in Toddlers, Revised with Follow-Up (M-CHAT-R/F) is one of the most widely used screening instrument for autism spectrum disorder (ASD) worldwide. It is applied both to well low-risk and high-risk children and has been translated and employed in multiple languages.

**Objectives:** To calculate the psychometric properties of the M-CHAT-R/F questionnaire in English and other languages for subsequent diagnosis of ASD using meta-analysis.
Naturalistic Observation Diagnostic Assessment-Enhanced (NODA-E) Telehealth Vs. in Person Assessment for Early Autism Spectrum Disorder (ASD) Diagnosis

M. J. Morrier, A. J. Schwartz, C. Rice, A. V. Krishnan, S. Oberleitner and R. Oberleitner. (1) Department of Psychiatry & Behavioral Sciences, Emory University School of Medicine, Decatur, GA, (2) Division of Human Development and Disability, Centers for Disease Control and Prevention, Atlanta, GA, (3) Emory University, Atlanta, GA, (4) Behavior Imaging Solutions, Boise, ID

Background: Diagnosis of Autism Spectrum Disorder (autism) is possible before 2 years of age; however, age of diagnosis is still lagging between 4.0-5.7 years of age. Telehealth systems have been designed for treatment, and a few have been designed to facilitate initial autism diagnosis (e.g., TELE-ASD-PEDS; NODA; CanvasDx). The Naturalistic Observation Diagnostic Assessment - Enhanced version (NODA-E) expands upon NODA’s asynchronous platform to include e-referrals, imported screeners, additional 3rd-party assessments, and a new synchronous real-time telehealth tool enabling “live-tagging” of child behaviors.

Objectives: Our objective was to compare agreement between results of NODA-E and an in-person assessment (IPA) on presence of DSM-5-TR diagnostic criteria, severity of autism diagnostic criteria, and final diagnosis of autism. It was hypothesized that the NODA-E assessment results would be comparable to the IPA.

Methods: Fifty families with children aged 16-33 months were recruited from a university autism assessment clinic following a moderate to high-risk screen administered by a pediatrician or the university clinic. Following consent, families were randomly assigned to one of two assessment teams and clinicians within the team were randomly assigned to either NODA-E or IPA. Assessment order was also randomly assigned. NODA-E provided the parent(s) with a smartphone app interface with instructions to complete assessments and record different scenarios with the child. The clinician reviewed and tagged video segments and conducted a telehealth interview with families. The IPA was the full gold standard assessment conducted at the clinic. After completion of both assessment protocols, clinicians compared diagnostic criteria endorsed, diagnostic severity endorsed, and final diagnosis of autism. Due to NODA-E variable data being constant for most DSM-5-TR criteria (i.e., always marked as present), percent agreements are reported and Kappas are provided where calculations were possible.

Results: Thus far, 26 families have completed NODA-E and IPA assessments. Agreement for the 3 autism social communication and social interaction (SCI) diagnostic criteria was near perfect (A1 = 96%; A2 = 96%; A3 = 96%, respectively). Overall agreement for SCI severity ratings were fair (Kappa = .360, p = .017). Agreement for the 4 restricted interests and repetitive behaviors (RRBs) diagnostic criteria were also near perfect (B1 = 96%; B2 = 96%, Kappa = .283, p = .143; B3 = 96%, Kappa = -.017, p = .925; and B4 = 96%, Kappa = -.040, p = .838, respectively) and overall agreement for RRB severity ratings were high (96%, Kappa = .237, p = .086). Agreement for final diagnosis of autism was near perfect (96%).

Conclusions: Preliminary results indicate that use of the smartphone app NODA-E to document the presence and severity of autism symptoms and make a diagnosis of autism is comparable to an IPA. These findings suggest that use of synchronous telehealth techniques have promise for autism assessment and diagnosis. Advantages of this model are increased access to diagnostic services and possibly...
decreased wait time for those services. Some challenges may be reliance on/access to a smartphone and time needed to capture and upload videos for clinician review.

**431.082 (Poster) Naturalistic, Non-Invasive Method for Capturing Biometric Data during Autism Diagnostic Evaluations**

**Background:**

Computational approaches are emerging as promising, objective methods to capture the complex and granular repertoire of behaviors associated with Autism spectrum disorder (ASD). However, developed for exclusive contexts, most tools are limited to specific environments and modalities and require participants to wear devices or restrict their movement by remaining front-facing to the camera. The work presented here focuses on a model of computer vision and machine learning analyses with the capacity to capture and quantify domains of social, language, and early motor behaviors within administration of the Autism Diagnostic Observation Schedule-Second Edition (ADOS-2).

**Objectives:**

(1) Demonstrate technical validity by analyzing and appraising how our non-invasive methods detect and monitor social-communication behaviors within standard clinical contexts.

(2) Establish the clinical association and validity between biometrics captured through these computational AI-based methods and their targeted clinical conditions.

**Methods:**

We recruited 60 participants, 13 Non-ASD (Age mean=6.4, SD=±2.4 years, % Female= 53.8%) and 47 with a history of ASD or neurodevelopmental conditions with suspected ASD (Age mean=8.5 SD=±2.9 years, % Female= 40.4%) from June 2017 to August 2019. Participants received standard diagnostic evaluations including the ADOS-2 (Modules 1, 2, 3) and cognitive assessment (Mullen, WISC, WASI-II, Stanford Binet, or DAS-Early Years). In addition, demographics, NIH medical history, and ACE family medical history were collected. ADOS-2 footage was recorded using off-the-shelf 2D cameras and Tobii Pro Glasses 2 worn only by the examiner during the session. Captured footage was analyzed using computational Artificial Intelligence (AI) methods, with a focus on capturing a specific subset of visual and auditory domains corroborated by clinicians. Our AI-based analysis pipeline captured 283 biometrics including gaze, facial expressions, speech paralinguistics and affect, and gait features (Figure 1).

**Results:**

Biometrics for analysis were selected previously based on test-retest reliability (Brune et al, 2022) and content validity. Preliminary analysis on a subset of 24 age-matched ASD and Non-ASD participants suggests that ASD participants demonstrated shorter speech duration and fewer occurrences of reciprocal conversation and hand contact engagement than Non-ASD participants. Our metrics provide a continuous, quantitative variable for these domains (Table 1).

**Conclusions:**

Our results showed a variety of nuanced key biometric social markers differed by group across domains including gaze, gestures, social communication skills, speech, and sentiment. The relevant analytical validity of the captured biometrics is further established through the production of high-quality and reliable data during dynamic contextual environments. The clinical utility of our results was also demonstrated by assessing differences in such quantified biometrics between participants with and without ASD. Further analysis on additional biometric domains is ongoing and includes responsive gaze, initiations across joint attention tasks, and conversational exchange between groups. These findings demonstrate the predictive power and potential for a dynamic, non-invasive computational approach to analyzing social communication behaviors during standard-clinical evaluations. Future directions include evaluating applicability in phenotyping and treatment outcomes in clinical and research settings.

**431.083 (Poster) Neuropsychological Characteristics in Individuals with Anorexia Nervosa and High Autism Spectrum Traits**

**E. Saure, A. Raevuori, T. Lepistö-Paisley and M. Laasonen,** (1)Department of Psychology and Logopedics, Faculty of Medicine, University of Helsinki, Helsinki, Finland, (2)Department of Psychiatry, Division of Adolescent Psychiatry, Helsinki University Hospital, Helsinki, Finland, (3)Clinicum, Department of Public Health, University of Helsinki, Helsinki, Finland, (4)Department of Child Neurology, University of Helsinki, Helsinki, Finland
Background: Anorexia nervosa (AN) is associated with neuropsychological difficulties, such as challenges in complex emotion recognition, set-shifting and central coherence. These difficulties may contribute to the length and severity of AN but are also common in autism spectrum disorder (ASD), which appears to be overrepresented among individuals with AN. However, the proportion of individuals with AN suffering from these neuropsychological difficulties is unclear. In addition, it is unknown whether they are a part of the neuropsychological profile of AN or merely reflect underlying ASD in a subpopulation of individuals with AN.

Objectives: We aimed to examine challenges in complex emotion recognition, set-shifting and central coherence among individuals with AN and high versus low ASD traits versus healthy controls (HCs) with low ASD traits. We also aimed to assess whether neuropsychological characteristics predict low body mass index (BMI), other eating disorder symptoms, and duration of AN.

Methods: Participants (18–30 y) included 18 women with AN and high ASD traits, 24 women with AN and low ASD traits, and 38 HC women with low ASD traits. Complex emotion recognition was assessed with face photographs. Set shifting was assessed with the Berg’s card sorting test and central coherence with the Fragment picture task. ASD traits were assessed with a self-reported questionnaire.

Results: Individuals with AN with high ASD traits performed poorer in tasks measuring complex emotion recognition, set-shifting, and central coherence when compared to HCs (p = 0.002, p = 0.014, p = 0.001, respectively). In addition, individuals with AN with high ASD traits also performed poorer in tasks measuring set-shifting and central coherence than individuals with AN + low ASD traits (p = 0.048, p = 0.035, respectively). There were no significant group differences between individuals with AN with low ASD traits and HCs. Difficulties in complex emotion recognition predicted increased duration of AN only in individuals with AN with high ASD traits (R² = 0.296, p = 0.036).

Conclusions: Neuropsychological difficulties appear to be present specifically in a subgroup of individuals with AN and high ASD traits. Among this subgroup, challenges in complex emotion recognition may contribute to the prolongation of AN.

431.085 (Poster) Parents and Teachers’ Perspectives on Autism and Co-Morbidity Symptom Severity of Young Autistic Children over One Academic Year

E. Avni1, E. Ben-Itzchak2, R. Saban-Bezalel3 and D. A. Zachor4, (1)The Autism Center/ALUT, Pediatrics, ALUT-Israeli organization for Children with ASD, Zerifin, Israel, (2)Bruckner Center for Research in Autism, Communication Disorder, Ariel University, Ariel, Israel, (3)Communication disorders, Ariel University, Ariel, Israel, (4)The Autism Center/ALUT, Pediatrics, Ditza Antebi Zachor Prof, Zerifin, Israel

Background:

It is a well-accepted practice to collect information from multiple sources when conducting medical and developmental assessments of autistic children. However, most studies assessed parent and teacher perceptions at only one point during the academic year. The few longitudinal studies in the literature examined parent–teacher reports, focused only on perception of autism severity, yielding conflicting results. The current study seeks to extend the existing research to include not only the contribution of parent/teacher perceptions of autism severity among young autistic children across time but also their perception of ADHD and anxiety co-morbidities.

Objectives:

- To compare parents and teachers’ ratings of autism, ADHD, and anxiety symptom severity of autistic children attending special education classes both at the start (T1) and the end (T2) of the school year.
- To assess changes in parent and teacher reports on the above domains, separately, from T1 to T2.
- To examine correlations between parent and teacher reports at T1 and T2 in the examined measures.

Methods:

The study included 73 participants (M=61) aged 2:10-7:6 years (M =4:10, SD=1:0) diagnosed with autism, who possessed different levels of functioning, were attending special education classes, and were receiving intensive intervention. At two timepoints, parents and teachers completed different measures: for autism severity, the Social Responsiveness Scale (SRS); for ADHD, the Conners’ Rating Scales; and for anxiety, the Spence Children’s Anxiety Scale (SCAS).

Results:
For SRS scores, a 2x2 (Rater x 2 Times) MANOVA with repeated measures for time revealed a significant Time effect \([F(2,53)=3.34, p=.04, \eta^2=.11]\) and a significant Time X Rater Interaction \([F(2,53)=5.69, p=.006, \eta^2=.18]\). When examining SRS subdomains, only social-communication and interaction (SCI) scores showed a significant Time X Rater interaction \([F(1,54)=9.83, p=.003, \eta^2=.15]\). At T1, teachers evaluated significantly more severe SCI deficits than parents \([F(1,64)=9.14, p=.004, \eta^2=.12]\). However, only teachers reported less severe SCI subdomain symptom scores after one academic year \([F(1,69)=9.91, p=.005, \eta^2=.14]\). Regarding ADHD, a 2X2 MANOVA with repeated measures for Time revealed a significant interaction only on the Conners Inattention subdomain \([F(1,43)=5.15, p=.03, \eta^2=.11]\). Only at T1 teachers rated Inattention subdomain scores higher than parents, \([F(1,64)=9.15, p=.004, \eta^2=.12]\). A decrease in teachers’ Inattention scores was noted at T2 \([F(1,56)=13.94, p<.001, \eta^2=.20]\). Regarding anxiety, a 2X2 MANOVA with repeated measures for Time revealed a significant Rater effect \([F(1,56)=10.79, p=.002, \eta^2=.16]\), but not a Time effect nor a significant Time X Rater interaction. Parents rated total SCAS scores higher than teachers. Significant correlations between parents and teachers’ reports were noted for autism severity at T1 and T2.

Conclusions:

At start of the academic year teachers described more severe social-communication impairments and inattention symptoms than parents, but significant improvement in teachers’ ratings was noted at year’s end. At both timepoints, parents reported more elevated anxiety symptoms than teachers. The study emphasizes the contribution of multiple perspectives for better collaboration between home and school environments. Obtaining accurate information from parents and teachers at start of the school year may help identify factors needed for better adjustment at school and better addressing of difficulties at home.

431.086 (Poster) Participation in Standardized Academic Assessments and Academic Achievement of Children with Autism and Neurodevelopmental Disorders in Ontario, Canada

R. Jezrawi, C. Reid-Westoby and M. Janus, Offord Centre for Child Studies, McMaster University, Hamilton, ON, Canada

Background: Developmental skills associated with Autism Spectrum Disorder (ASD) and those with other neurodevelopmental disorders (NDD) contribute to elementary school-age children’s difficulties in achievement of age-appropriate reading, writing, and math academic skills. This knowledge is largely based on clinical assessments, as there is a wide assumption that children with ASD and NDD are usually exempt from completing the routine standardized educational assessments, suggesting that existing assessments are not inclusive for students with a neurodiversity.

Objectives: In this study, we explore the impact of a childhood diagnosis of ASD or NDD on first, the likelihood of children completing standardized assessments, and second, their academic achievement on those assessments, in the context of social and health characteristics.

Methods: In a quantitative longitudinal study design, we linked data on children’s development in kindergarten from 2010 to 2012 in Ontario publicly funded schools, collected using the Early Development Instrument (EDI), to standardized provincial assessments in grades 3 (years 2013-2015) and 6 (years 2016-2018). Information on children’s diagnoses was recorded on the EDI in kindergarten. Sociodemographic variables came from kindergarten data and included: sex, English/French Language Learners (EFLL), special needs, poor early development, and existence of functional impairment. The main outcome was first, participation in the assessment, and second, meeting provincial expectations in Grade 3/6, i.e., passing above a threshold score in reading, writing, and mathematics. We used cross tabulation (Pearson Chi-Square 2-sided test) and binary logistic regression analysis using SPSS.

Results: Among 121,967 children, 1,256 had ASD and 1,520 had NDD. There were greater proportions of males and children with Grade 3 or 6 Individual Education Plan (IEP) among the children with ASD than NDD, and the reverse was true for percentage of children with EFLL (p<0.001). We found that 63%-81% children with ASD and 68%-80% with NDD were either exempt from or did not participate in the assessments (i.e., had no scores available, Table 1). Logistic regressions showed that children with NDD were about 1.5 times (odds ratio range 1.436-1.542, p=0.012-0.037) more likely to participate in assessments than those with ASD. Having an IEP, EFLL, or poor early development was associated with decreased likelihood of participation. Among those who participated, there was no difference between the two groups in the likelihood of meeting provincial expectations.

Conclusions: The results of our study indicate that provincially mandated standardized educational assessments were designed with typically developing children in mind only, as they did not appear to be inclusive, since more than 60% of children with ASD or NDD did not participate in them. Being a student with ASD or NDD did not change the likelihood of meeting standardized test expectations. Our study suggests that implementing a more effective, inclusive methodology to monitor academic progress for children with ASD and NDD to ensure that their abilities are both measured and measured in an equitable manner. Understanding the patterns of school-age achievement for children with ASD and NDD – something that is currently lacking at a population level - is critical to facilitating inclusive education.

431.087 (Poster) Phenotypic Profiles of Children Diagnosed with ASD after Being Identified By a School-Based Universal Screening Questionnaire

S. James, C. J. Smith and N. L. Matthews, (1)Southwest Autism Research & Resource Center, Phoenix, AZ, (2)Southwest Autism Research and Resource Center, Phoenix, AZ
Background: Despite research suggesting that autism spectrum disorder (ASD) can be reliably diagnosed by the second year of life, the average age of diagnosis remains between 4-5 years. Many individuals are not identified as having ASD until adolescence or adulthood (Li et al., 2022), which suggests that symptoms of ASD at younger ages are missed/overlooked/misdiagnosed. This is especially true for children exhibiting more subtle symptoms, where functional impairments may not emerge until school-age or later. Identifying ASD before functional difficulties become clinically significant is important for mitigating potential adverse outcomes like social rejection and vocational challenges. Further, because services for adolescents/adults are limited relative to children, earlier identification could lead to improved functional outcomes. Our team recently implemented a school-based universal screening program to identify undiagnosed children with ASD that was both feasible and acceptable (James & Smith, 2022). Examination of phenotypic profiles of children identified through school-based universal screenings and subsequently diagnosed with ASD may provide insight into nuanced ASD presentations, which can help inform earlier identification.

Objectives: To examine phenotypic profiles of children diagnosed with ASD after being identified by school-based universal screenings.

Methods: Over four years (2019-2022), teachers from 13 charter schools in Phoenix, Arizona completed 4,672 screenings using the Social Challenges Screening Questionnaire (SCSQ) (Smith et al., 2015). Of the completed screenings, 183 scored in the concern range, and parents of 66 students agreed to be contacted about receiving a free follow-up diagnostic evaluation. Of the 66 families who agreed to be contacted, parents of 29 students declined evaluations. Formal diagnostic evaluations were conducted with the remaining 37 students by licensed psychologists. Evaluations included diagnostic history interviews, Autism Diagnostic Observation Schedule, Second Edition (Gotham et al., 2007; Lord et al., 2009; 2012), Kaufman Brief Intelligence Test, Second Edition (Kaufman & Kaufman, 2006), and Vineland Adaptive Behavior Scales, Third Edition (Sparrow et al., 2016). Of the students evaluated, 81% (n=30) met full diagnostic criteria for ASD. Phenotypic profiles of these 30 children were examined in this study (see Table 1 for descriptive statistics).

Results: While the sample IQ was average (m=112), overall adaptive functioning (m=86) was significantly lower relative to intelligence (t(29)=8.67, p<.001), and approximately one standard deviation below the normative mean. Domain scores indicated the greatest impairment relative to intelligence was in Socialization (t(29)=9.66, p<.001), followed by Communication (t(29)=7.33, p<.001), then Daily Living Skills (t(29)=5.86, p<.001).

Conclusions: Students in the current study had statistically and clinically significant adaptive impairments. Yet, compared to findings from comparable samples of school-age children/adolescents without intellectual disability (Klin et al., 2007; Matthews et al., 2015), students in the current study had substantially higher adaptive functioning scores, most notably for Daily Living Skills. This could indicate that universal screening at school-age helped identify children with ASD before more significant adaptive impairments emerged who may have otherwise gone undiagnosed until adolescence or adulthood. More research using matched samples is needed to better understand the extent to which children identified through screening may differ to children who are evaluated because of parent concern.

431.088 (Poster) Predicting Autism Spectrum Disorders in Infant Siblings Using Machine Learning Classifiers Built with 12-Month Data
K. B. Reid, L. A. Sacrey, L. Zwaigenbaum, I. M. Smith and J. A. Brian, (1)Autism Research Centre, Edmonton, AB, Canada, (2)Autism Research Centre, University of Alberta, Edmonton, AB, Canada, (3)Dalhousie University / IWK Health Centre, Halifax, Canada, (4)Autism Research Centre, Bloorview Research Institute, Holland Bloorview Kids Rehabilitation Hospital, Toronto, ON, Canada

Background: Growing access to sophisticated computational technology in research and healthcare settings has facilitated the use of powerful computer science techniques, including machine learning. Though becoming more common in clinical and research fields, research into autism spectrum disorder (ASD) has yet to fully leverage this technology. To date, Bussu et al. (2018) is the only study to have generated supervised machine learning classifiers using Autism Observation Scale for Infants (AOSI) data.

Objectives: (1) Generation of supervised machine learning classifiers using 12-month AOSI and Mullen Scales of Early Learning (MSEL) data in a cohort of infant siblings (n=373), and (2) assessment of classifier performance at predicting 36-month ASD diagnosis in infant siblings from two Canadian longitudinal studies (n=92; n=90).

Methods: Supervised machine learning classifiers using logistic regression (with and without regularization) and support vector machines using linear, polynomial, and radial basis function kernels were generated in R/Studio using combinations of participant biological sex, 12-month MSEL standard scores (Visual Reception, Receptive Language, Expressive Language, Fine Motor, and Early Learning Composite), and 12-month AOSI item-level and Total Score data. Factor analysis (informed by principal axis parallel analysis) was used as a means of reducing item-level AOSI data dimensionality during machine learning modelling to mitigate model overfitting. Classifiers were assessed by their ability to predict 36-month ASD diagnosis in subsets of infant siblings (n=92; n=90) from two Canadian longitudinal cohorts.

Results: Machine learning classifiers had fair performance. The best-performing classifiers across all algorithm types were between 76-77% accurate and had areas under the curve (AUC) between 0.73 and 0.76. Specificity of these classifiers was excellent (0.94-1.0), but they showed extremely poor sensitivity (0-0.19). Relative to the performance of a 12-month AOSI Total Score cut point of 7 (informed by Youden index assessment; AUC = 0.66, sensitivity = 0.52, specificity = 0.74) at predicting 36-month ASD diagnosis, machine learning
classifiers had enhanced AUC and specificity, but significantly decreased sensitivity. The best-performing classifiers in this study yielded higher accuracy, AUC, and specificity (but not sensitivity) relative to the best performing classifier generated by Bussu et al. (2018) using 14-month data (accuracy = 64%, AUC = 0.71, sensitivity = 0.61, specificity = 0.67) and similar machine learning methodology.

**Conclusions:** Though the best-performing classifiers in this study performed below levels recommended for early screening, accuracy, AUC, and specificity were moderately improved relative to those generated by Bussu et al. (2018) using 14-month AOSI data. Further exploration into feature selection, extraction, or inclusion of 12-month AOSI and MSEL data may allow continued refinement of machine learning models built using 12-month clinical data and capable of predicting ASD at 36-months.

**431.089 (Poster) Predicting Discrepancies in Broader Autism Phenotype Ratings of Parents from the Simons Simplex Collection**

**R. K. Ramsey and K. M. Walton, Nisonger Center, The Ohio State University, Columbus, OH**

**Background:**

Studies with simplex families indicate ratings of parent broader autism phenotype (BAP) traits can differ by sex and BAP measure (Davidson et al., 2014). Findings from the Simons Simplex Collection (SSC) also indicate some BAP trait differences for race and ethnicity, which vary by the measure and informant (Ramsey & Walton, INSAR 2019). Understanding what influences discrepancies in ratings of BAP traits of parents can help assess the utility of different BAP measures and informants across different race/ethnicity groups or in different contexts.

**Objectives:**

This study explores predictors of BAP rating discrepancies between self-reports on the Broader Autism Phenotype Questionnaire (BAPQ) and other parent ratings on the Social Responsiveness Scale (SRS).

**Methods:**

Hierarchical linear regression models (HLMs) were conducted to analyze predictors of discrepancies between BAPQ self-reports and SRS other parent ratings. The sample included 2,476 mothers (77.2% Non-Hispanic/Latinx White, 3.5% Hispanic/Latinx White, 4.1% Black, 5.1% Asian) and 2,513 fathers (78.4% Non-Hispanic/Latinx White, 3.4% Hispanic/Latinx White, 4.9% Black, 4.4% Asian) from the SSC. Separate HLMs were performed for the Non-Hispanic/Latinx White, Hispanic/Latinx White, Black, and Asian parent groups. Residualized difference scores for the BAPQ and SRS were included as a continuous outcome variable in a two-level random intercepts model. Individual level-1 predictors included sex, age, and education. Level-2 predictors included parent dyad race concordance, marital status, and annual household income.

**Results:**

Race discordance did not significantly predict residualized difference scores for parents of any race/ethnicity group. Marital status emerged as a significant predictor for Asian ($\gamma=-17.56, t=-2.13, p=.03$), Hispanic/Latinx White ($\gamma=-15.50, t=-2.64, p=.009$), and Non-Hispanic/Latinx White ($\gamma=-11.46, t=-9.97, p<.001$) parents. Married parents had smaller residualized difference scores than unmarried parents. No significant predictors emerged for Black parents. Sex, parent age, and annual household income emerged as significant predictors of residualized difference scores for Non-Hispanic/Latinx White parents, such that mothers, older parents, and lower income parents had greater discrepancies between BAPQ and SRS ratings ($p$’s<.05, Cohen’s $d$ -0.16 to 0.36).

**Conclusions:**

Significant predictors of BAP rating discrepancies emerged, which varied by race/ethnicity group. Marital status was a significant predictor for all race/ethnicity groups, except Black parents. For unmarried parents, other parent BAP ratings may diverge from self-reports due to informant biases or fewer opportunities to observe the other parent. Sex, age, and income predicted discrepancies for Non-Hispanic/Latinx White parents, which may indicate these BAP measures are more sensitive for this group. There were few racially discordant couples in the SSC sample, which may have impacted our ability to detect this as a significant predictor. This research helps inform best practices for estimating BAP traits in individuals. Davidson et al. (2014) proposed averaging BAP ratings to provide a best estimate; however, aggregating scores may introduce more noise if informant biases exist. Future research should examine race concordance, language concordance, and cross-cultural factors that may impact BAP rating agreement. Understanding informant biases may help identify which BAP measures are appropriate for different groups or contexts. This has implications for research on the prevalence and genetic transmission of autistic traits in diverse populations.
Background: Younger siblings of autistic individuals are at elevated likelihood (EL) of receiving an autism spectrum disorder (ASD) diagnosis. Compared to the general population prevalence of ~1–2% (Maenner et al., 2020), approximately 20% of EL siblings receive an ASD diagnosis (Ozonoff et al., 2011), and another 28% exhibit subthreshold features (Ozonoff et al., 2014), suggesting a substantial genetic contribution to autism. Girault et al. (2020) demonstrated that older sibling autism traits predict younger sibling diagnostic outcomes at 24 months but did not identify trait associations in sibling pairs. We aimed to replicate these findings and explore associations between sibling traits—both at and before 24 months—using additional autism screeners and assessments.

Objectives: Explore associations between older sibling autism traits and younger sibling traits/outcomes at and before 24 months.

Methods: We assessed whether older sibling (proband) scores on the Social Communication Questionnaire (SCQ) \(M_{age}(SD) = 7.2(3.4)\) years predicted younger sibling diagnostic outcomes, scores on the Autism Diagnostic Observation Schedule, Second Edition (ADOS), and scores on the Mullen Scales of Early Learning (MSEL) at the 24-month visit \(N = 42\) sibling pairs. Logistic regression was used in the outcome analysis, and linear regressions evaluated the predictive ability of proband SCQ scores for younger sibling ADOS and MSEL scores. Linear regressions were also used to assess whether proband scores on the Social Responsiveness Scale, Second Edition (SRS) predicted younger sibling scores at 9, 12, and 18 months on the Early Screening for Autism and Communication Disorders (ESAC) \(N = 34\) pairs, the Systematic Observation of Red Flags (SORF) \(N = 33\) pairs, and the Communication and Symbolic Behaviors Scales – Developmental Profile (CSBS) \(N = 39\) pairs (proband \(M_{age}(SD) = 5.5(2.5)\) years).

Results: Proband SCQ scores predicted younger sibling scores on the MSEL expressive language subscale \(\beta = - .312; p = .044\), even after controlling for age and sex of both siblings \(\beta = - .344; p = .037\). Proband SCQ did not predict younger sibling outcome \(p > .176\) or autism traits as indexed by ADOS scores \(p > .239\). Proband SRS total t-scores predicted younger sibling ESAC total scores \(\beta = .440; p = .009\) and CSBS speech domain scores at 9 months \(\beta = -.418; p = .008\) but not 12 or 18 months \(p > .090\). SRS scores did not predict SORF total scores, CSBS social scores, or CSBS symbolic scores at any time points \(p > .106\).

Conclusions: Preliminary results support Girault et al.’s (2020) finding that proband autism traits predict younger sibling expressive language. Their remaining analyses were not replicated in our sample, which may be due to differences in sample size and characteristics. Immediate next steps include expanding sample size to better understand the relevance of older sibling profiles in guiding early identification and intervention for younger siblings. Further, we found that autism traits predicted younger sibling scores on the ESAC and CSBS at 9 months but not 12 or 18 months, suggesting that the genetic contribution to autism traits may vary over developmental time, which would inform optimal windows for intervention.

431.091 (Poster) Predictive Validity of the ADOS-2 Toddler Module at Age 2 for Diagnostic Outcome at Age 3 to 4 in a Swedish Sample

J. R. Spak1, T. Falck-Ytter1 and S. Bolte2, (1)Center of Neurodevelopmental Disorders at Karolinska Institutet (KIND), Department of Women’s and Children’s Health, Karolinska Institutet, Stockholm, Sweden, (2)Department of Psychology, Uppsala University, Uppsala, Sweden

Background: The Autism Diagnostic Observation Schedule (ADOS-2) is considered a “gold standard” diagnostic instrument in the assessment of autism. There are few validation studies of the Toddler module (ADOS-T) in non-English speaking populations.

Objectives: We evaluated the validity of ADOS-2 toddler module in Swedish high vs low autism likelihood samples at age 2 to predict autism diagnosis and other outcomes at age 3 to 4.

Methods: Toddlers, aged 23 - 27 months, \(N = 147\) at familial high likelihood (HL) of autism and/or ADHD and toddlers without familial likelihood (LL) participating in the “Early Autism in Sweden” (EASE) study were assessed with the ADOS-T, and followed up diagnostically at age 35 - 48 months applying a best clinical estimate process. Diagnostic outcomes were defined as a) ASD according to DSM-5, b) ASD broader phenotype (ASD BROAD), c) provisional diagnosis of ADHD and/or language disorder (P-ADHD), and d) non clinical (NC). In the analysis, ASD was considered the target outcome in cases with co-occurring outcomes (Table 1). First, multivariate and univariate ANOVAs were conducted to investigate differences in ADOS-T algorithm scores associated between groups of high vs low autism likelihood status, age and gender. Then, we computed a multinomial logistic regression with ADOS-T item scores at age 2 as independent variables and diagnostic outcome at age 3 to 4 as independent variables. Finally, a discriminant analysis was conducted to investigate the classification accuracy of a model created from the items in ADOS-T to predict outcome at follow up.

Results: The HL sample scored significantly higher than the LL sample multivariately for ADOS-T algorithm scores \(\eta^2 = .083, p = .002\) and univariately for social affect \(\eta^2 = .032, p = .031\) and repetitive behavior subscales \(\eta^2 = .075, p = .001\). Seventeen (out of a total of 41)
Background: Symptoms of autism spectrum disorder (ASD) are typically noticeable within the first 3 years of life (Ozonoff & Iosif, 2019). Instruments for early detection and diagnosis of ASD are critical, as these will promote better clinical outcomes (Dawson, 2008; Shresta et al., 2019). The Toddler Autism Symptom Inventory (TASI; Coulter et al., 2021) is an instrument designed to assess behaviors consistent with autism symptoms in toddlers through parent report, showing adequate diagnostic predictive value among English-speakers. However, there is limited knowledge about its predictive value among Spanish-speaking children. Due to the significant challenges in the diagnosis of ASD in Latino children (Fountain et al., 2011; Valicenti-McDermott et al., 2012), the effectiveness of diagnostic instruments in Spanish-speaking Latino populations is paramount for accurate early identification.

Objectives: To examine the relationship between the Spanish version of the TASI and ADOS-2 scores and to assess preliminary predictive value of the TASI in a Latino sample of autistic children.

Methods: This exploratory study is part of a broader project examining the predictive value of autism screeners in Latino children. Participants were recruited from local ASD parent support group organizations, and consisted of 16 Spanish-speaking child-parent dyads ($n_{\text{total}}=16$), with an average child’s age of 39 months (SD=10.78). Participants completed the Spanish version of the TASI and the ADOS-2 with bilingual examiners. Descriptive and bivariate correlation analyses were conducted to examine the relationship between the Spanish TASI and the ADOS-2 scores.

Results: The mean ADOS-2 calibrated severity score was 5.57 (SD=2.98). The mean total score for the TASI was 19.38 (SD=8.20). The mean score for the Social Affect (SA) and the Restricted and Repetitive Behaviors (RRB) domains from the ADOS-2 were 12.94 (SD=7.23) and 3 (SD=2.98), respectively. As for the TASI, the mean score for ASD Criterion A of the DSM-5 was 10.94 (SD=6.11) and 8.31 (SD=3.73) for Criterion B. Results indicated that there was a moderate positive correlation between the calibrated severity scores of the ADOS-2 and total score of the Spanish TASI, r(16) = .629, p = .01. Additionally, there was a strong positive correlation between the SA domain from the ADOS-2 and the Criterion A section from the Spanish TASI, r(16) = .704, p = .002. There was no significant relationship between the RRB domain from the ADOS-2 and the Criterion B section from the TASI.

Conclusions: Preliminary data from this study suggests that the Spanish TASI may be a useful instrument in the identification of ASD among Latino children. Having reliable instruments that can accurately elicit endorsement of symptoms of ASD from parents of children under age 3 is critical. However, it is imperative to have clinically valid instruments that are equally sensitive to linguistic and culturally diverse populations. Furthermore, establishing psychometric properties of instruments in Spanish, freely available to the community, such as the TASI, can help decrease ASD diagnostic barriers in underserved communities.

431.093 (Poster) Predictors of Diagnostic Delay in Children with Neurodevelopmental Conditions

K. A. Boulton, A. Hedge, N. Ong, N. Silove and A. J. Guastella, (1)Brain and Mind Centre, Children’s Hospital Westmead Clinical School, Faculty of Medicine and Health, University of Sydney, Sydney, NSW, Australia, (2)Sydney Children’s Hospital Network, Sydney, NSW, Australia, (3)University of Sydney, Sydney, Australia, (4)Brain and Mind Centre and Children’s Hospital Westmead, Sydney, NSW, Australia

Background: For children with neurodevelopmental conditions, early developmental assessment is crucial for implementing effective support and intervention practices. There has been limited research about factors contributing to delays in public developmental assessment clinics for vulnerable families. It is critical to examine predictors of diagnostic delays in patients attending publicly funded assessment services, where children are likely to have multiple concerns, and families have limited access to supports. Such knowledge can advance both policy and intervention practices to improve outcomes.
Objectives: This study examined factors that contributed to an (a) older age of the child when caregivers first became concerned about their child’s development and an (b) older age of the child at the point of entry into a multi-disciplinary developmental and diagnostic assessment. We also aimed to quantify how factors contributed to risk of children not receiving an assessment by 5 years.

Methods: This cross-sectional study collected information about caregiver developmental concerns, family history and child characteristics. Participants were 880 consecutively enrolled children aged 6 months to 17 years with neurodevelopmental concerns, and their caregivers. Participants were attending a large, publicly funded hospital-based pediatric developmental assessment service. A developmental history questionnaire was completed by primary caregivers of all participants.

Results: The average age that caregivers identified developmental concerns was 3.0 years of age but the average age of a receiving a developmental diagnostic assessment was 6.5 years. Only 47% of children received a diagnostic assessment by five years of age, even though 88% of caregivers were concerned about their child’s development by that age. Parental age, relationship status, education level, prior use of support services, and being from a culturally and linguistically diverse background contributed to age at identification of concern, age at diagnostic assessment and the likelihood of receiving a diagnostic assessment by five years. To illustrate, children whose parents were separated were twice as likely not to receive a diagnosis by the age of 5 years.

Conclusions: The study shows a substantial delay in diagnostic assessments that leaves most vulnerable children without an assessment by school age and highlights contributors to delays. A number of modifiable risk factors can be targeted through education and intervention programs. These delays highlight the complexity of delivering early intervention and support policies that rely on swift and appropriate developmental assessment to vulnerable families.

431.094 (Poster) Professionals’ Perspectives on Strengths-Based Autism Diagnostic Assessment
E. Pritchard and J. L. Gibson, University of Cambridge, Cambridge, United Kingdom

Background: Autism diagnostic assessment tends to focus on deficits and be based on observations of behaviour which are compared to non-autistic ‘norms’. This approach is challenged by the neurodiversity paradigm, which emphasizes the importance of centering autistic voices and understanding autism holistically in terms of differences, difficulties, and strengths. Understanding how professionals can apply a neurodiversity-informed perspective to autism diagnostic assessment has the potential to improve the way diagnostic assessments are carried out. Thinking about assessment in terms a ‘strengths-based approach’, which shares similarities with the neurodiversity paradigm, could be beneficial in this respect. Accordingly, we conducted an interview-based study aimed to understand the perspectives of professionals involved in a multidisciplinary team on strengths-based autism diagnostic assessment.

Objectives: What are the perspectives of professionals working as part of a multidisciplinary autism team on strengths-based autism diagnostic assessment?

Methods: This pre-registered, qualitative study focuses on autism diagnostic assessment for children and young people (up to age 19). Autistic adults and parents/carers of autistic children were consulted about the interview schedule. Interviews were conducted with 19 professionals from a range of clinical backgrounds, and focused on professionals’ views on what a strengths-based assessment could involve and its benefits and limitations. Interviews will be analysed using reflexive thematic analysis to identify themes.

Results: N/A

Conclusions: This study will provide insight into professionals’ views on strengths-based autism diagnostic assessment. This may have implications for areas to focus on for future research. In practice, the findings may inform how professionals could conduct autism diagnostic assessment in a more neurodiversity-informed way. This has the potential to improve diagnostic assessment in ways that support autistic people to flourish.

431.095 (Poster) Psychometric Properties of the Brief Problem Monitor (BPM) 6-18 in a Sample of Children from a Neurodevelopmental Disorder Clinic

Background: The Child Behavior Checklist 6-18 (CBCL/6-18) is a widely used caregiver-report instrument for identifying emotional and behavioral problems, which is commonly applied in studies of children with autism spectrum disorder (ASD). While the CBCL/6-18 has been shown to have good psychometric properties in both typically developing children and children on the autism spectrum, it has over 100 items and can be time consuming to complete for already overloaded families. The Brief Problem Monitor 6-18 (BPM-P) was developed using item response theory analyses to identify the 19 most robust items. The BPM-P includes three subscales (attention,
Race Predicts Diagnosis of Co-Occurring Intellectual Disability in Autism

A. B. Ratto and J. Nielsen, (1)Center for Autism Spectrum Disorders, Children's National, Washington, DC, (2)Children's National Hospital, Washington, DC

Background: Prior research has demonstrated that race is associated with diagnosis of intellectual disability (ID), such that higher rates of ID and lower rates of ASD are reported in predominantly Black (Howard et al., 2020) and Latinx (Palmer et al., 2011) communities. Within autism, there is evidence that co-occurring ID is more often diagnosed in Black and Latinx than in White children (Becerra et al., 2014; Jarquin et al., 2011), but most research has focused on diagnostic substitution of ID for ASD.

Objectives: The aim of this study was to evaluate demographic (race, socioeconomic status) and clinical predictors (FSIQ, adaptive behavior) of diagnosis of co-occurring ID among a sample of Black, Latinx, and White youth with ASD.

Methods: A sample of 231 children ages 6-18 years (mean=11.25y, SD=3.50y; 75.3% male) was drawn from a clinical research registry at an ASD specialty clinic. All individuals had item-level data and total raw scores, and a subset of 117 had t-scores available on both the BPM-P and the CBCL/6-18. Confirmatory factor analysis (CFA) was performed to test the three-factor structure of the BPM-P. Cronbach’s alpha was calculated for the full set of items from the BPM-P as well as the three subscales to examine internal consistency. Pearson’s correlation coefficients between the BPM-P and CBCL/6-18 raw and t-scores were calculated. All analyses were performed using R version 4.1.3.

Results: The three-factor structure (including Internalizing, Externalizing, and Attention factors) of the BPM-P showed adequate fit: the comparative fit index (CFI) was 0.96, and the root mean square error of approximation (RMSEA) was 0.08. All the items showed sufficient factor loadings (larger than 0.3) on respective factors (Table 1). Cronbach’s Alpha for the BPM-P was above 0.80 for the full item set as well as the Internalizing and Externalizing scales, and 0.77 for the Attention scale, indicating acceptable to good internal consistency for both the subscales and the full scale. Correlations between the BPM-P and the CBCL/6-18 raw and t-scores were above 0.80 for all scales.

Conclusions: The BPM-P presents a similar three-factor structure in this ASD referral sample to that found in a general population sample. The BPM-P also shows good internal consistency and high correlations with the CBCL/6-18 in a sample of children from an ASD specialty clinic. Thus, the BPM-P has potential utility for substantially reducing burden in measurement of behavior problems among children with ASD. We plan to further explore the clinical utility of the BPM-P by examining the screening agreement for clinical range concerns between the BPM-P and the CBCL/6-18, as well as demographic (age, gender) and phenotypic (IQ, language levels) factors associated with higher or lower agreement.

431.096 (Poster) Race Predicts Diagnosis of Co-Occurring Intellectual Disability in Autism

A. B. Ratto and J. Nielsen, (1)Center for Autism Spectrum Disorders, Children's National, Washington, DC, (2)Children's National Hospital, Washington, DC
In a subsequent confirmatory diagnostic review, 2 additional blinded clinicians independently reviewed all available assessment measures that differentiate ASD from non-ASD outcomes.

Objectives: This project aims to: 1. Understand the role of family and provider race, culture, and relationships as potential barriers during the ASD diagnostic process, 2. Examine associations between barriers and timely, accurate ASD diagnosis, and 3. Assess a wider range of BIPOC youth than has been previously studied.

Results: On average, time to ASD diagnosis was 5.16 months (SD=6.78 months) and 83.5% of parents reported an accurate initial diagnosis. 70% of parents reported the diagnostic provider did not share their same race/ethnicity, and of those, 50% indicated that the process would have been improved if they had shared the same race. Shared race was not associated with a timelier diagnosis, t (88) = 1.41, p = .08, however, it was significantly associated with accurate diagnosis, χ²(1) = 4.58, p = .032: children who initially received an inaccurate diagnosis were more likely to have not shared race (92% vs. 8%). The most frequently reported barriers were (see Table 1): Difficulty understanding the medical system, Appointments were uncomfortable for my child, Evaluations were expensive, and Difficulty trusting the provider. Structural barriers did not differ by race, F(3, 99) = 3.46, SD=.65, which did not differ by race, F(3, 99) = .99, p = .93. Greater provider family-centeredness was associated with parents’ perceptions of fewer structural barriers, and greater provider understanding of parents’ cultural beliefs and language, but not timely diagnosis (see Table 2). Hierarchical multiple and logistic regression models revealed that neither family-centered nor structural barriers predicted timeliness nor accuracy of diagnosis and this did not vary by race.

Conclusions: Although shared race with diagnostic providers was important to families, it did not play a significant role in perceived barriers or timely diagnosis. It was significantly associated with accurate diagnosis. Shared race may lead to better detection of potential racial nuances in symptom presentation or lessened bias in symptom interpretation. Although our findings indicated that structural barriers and family-provider relationships were not associated with timely or accurate diagnosis, they may contribute to parents’ feelings of stress and being unsupported during an already stressful time. Data collection is ongoing and analyses will be reconducted on the full dataset.

Background: Significant disparities exist in accurate and timely autism spectrum disorder (ASD) diagnoses for Black, Indigenous, Persons of Color (BIPOC) children in the US. Research has focused primarily on structural/logistical barriers to ASD diagnosis and targeted predominantly Latinx families. Little research has examined barriers such as family race, culture, family-provider relationships, or whether barriers differ amongst other ethnic groups.

Objectives: Determine RRs for ASD in a more recent sample of EL younger siblings (enrolled between 2012 and 2020) and identify assessment measures that differentiate ASD from non-ASD outcomes.

Methods: 100 BIPOC parents of a child with ASD (M child age = 6.36 years, SD= 2.82 years) participated in our national online survey. Parents completed the Oregon English/Spanish ASD Survey (OESAS) assessing structural barriers, and The Family Centered Care Assessment (FCCA) assessing degree providers offered a family-centered approach, through respectful, culturally-sensitive, family–provider partnerships. Parents reported on family demographics, length of time to and accuracy of ASD diagnosis.

Results: On average, time to ASD diagnosis was 5.16 months (SD=6.78 months) and 83.5% of parents reported an accurate initial diagnosis. 70% of parents reported the diagnostic provider did not share their same race/ethnicity, and of those, 50% indicated that the process would have been improved if they had shared the same race. Shared race was not associated with a timelier diagnosis, t (88) = 1.41, p = .08, however, it was significantly associated with accurate diagnosis, χ²(1) = 4.58, p = .032: children who initially received an inaccurate diagnosis were more likely to have not shared race (92% vs. 8%). The most frequently reported barriers were (see Table 1): Difficulty understanding the medical system, Appointments were uncomfortable for my child, Evaluations were expensive, and Difficulty trusting the provider. Structural barriers did not differ by race, F(3, 99) = 3.46, SD=.65, which did not differ by race, F(3, 99) = .99, p = .93. Greater provider family-centeredness was associated with parents’ perceptions of fewer structural barriers, and greater provider understanding of parents’ cultural beliefs and language, but not timely diagnosis (see Table 2). Hierarchical multiple and logistic regression models revealed that neither family-centered nor structural barriers predicted timeliness nor accuracy of diagnosis and this did not vary by race.

Conclusions: Although shared race with diagnostic providers was important to families, it did not play a significant role in perceived barriers or timely diagnosis. It was significantly associated with accurate diagnosis. Shared race may lead to better detection of potential racial nuances in symptom presentation or lessened bias in symptom interpretation. Although our findings indicated that structural barriers and family-provider relationships were not associated with timely or accurate diagnosis, they may contribute to parents’ feelings of stress and being unsupported during an already stressful time. Data collection is ongoing and analyses will be reconducted on the full dataset.
information to arrive at a diagnosis. RRs were first calculated using the latest CBE available and again using diagnoses obtained from the diagnostic review process. To determine which assessment measures most strongly predicted outcomes, binary logistic regressions including ADOS-2 sub-scores (social affect [SA] and restricted and repetitive behaviors [RRB]) and MSEL sub-scales (visual reception [VR], fine motor [FM], receptive language [RL] and expressive language [EL]) were performed.

**Results:** Using CBE data, the RR of ASD within our sample was 40.00%. A total of 25.00% of the sample was classified as broader autism phenotype, 5.00% as non-ASD developmental delays, and 30.00% as unaffected. The RR of ASD was 48.75% when using diagnoses obtained from the diagnostic review process. Driving factors behind this increased RR will be investigated further. In examining between-group differences, the model using ADOS-2 sub-scores scores was statistically significant ($X^2(4)=97.732, p<.001$). RRB sub-score and total score were independently significantly predictive of CBE ($p=.049$, .043) and most strongly differentiated ASD from non-ASD CBEs. The model with cognitive MSEL sub-scales was also statistically significant ($X^2(6)=29.011, p<.001$), though EL was the only sub-scale that independently differentiated between ASD and non-ASD CBEs ($p=.018$).

**Conclusions:** From 2012 to 2022, CDC estimates of ASD prevalence increased from one in 69 (Christensen et al., 2012) to one in 44 (Maenner et al., 2021). As our understanding of what constitutes ASD has broadened, we hypothesized that RRs would increase to encompass atypical development not previously classified as ASD. While our RR of 40.00% is notably higher than previous literature, it parallels the heightened prevalence and increasing inclusivity and awareness of autism that has consistently occurred over time. Our findings underscore the criticality of developmental monitoring and surveillance of EL younger siblings and provide areas for caregivers and providers of EL children to pay increased attention to during early development.

431.099 (Poster) Reliability Metrics on the ADOS-2: Findings from GAIN
A. Constantine, K. Christopher, H. Brown and S. M. Kanne, (1)Weill Cornell Medicine, White Plains, NY, (2)University of California, Los Angeles, Los Angeles, CA

**Background:**

The Autism Diagnostic Observation Schedule-Second edition ([ADOS-2]; Lord et al. 2012) has established a global reputation as a “gold-standard” tool utilized in diagnostic assessments for autism spectrum disorder (ASD). This complex tool requires substantial cost, practice, proficiency, and fidelity. Few individuals have access or resources to support ongoing practice and calibration with ADOS-2 experts. Global Autism Interactive Network (GAIN) seeks to fill this gap by establishing a network of clinically- and research-trained practitioners to strengthen and refine their skills in support of ongoing mastery of this tool over a digital platform that allows them to join from around the world.

**Objectives:**

We compared ADOS-2 reliability between clinically trained and research-reliable GAIN participants and determined the most and least reliable individual items.

**Methods:**

Participants met monthly from 2019 to 2021 and represented various professions and levels of training. Each participant independently watched an ADOS-2 module and submitted codes via REDCap database (Module 1: $n = 670$; Module 2: $n = 401$; Module 3: $n = 593$; Module 4: $n = 230$; Toddler Module: $n = 309$). During the monthly meeting, experts discussed consensus codes.

**Results:**

Across all modules, the agreement was significantly higher for research-reliable participants compared to clinically trained participants (see Table 1). Algorithm item-level analyses thus far revealed that on Modules 1, 2, 3, and 4 Eye Contact had the greatest reliability ($n = 670$, $M = 94.46\%$; $n = 401$, $M = 81.00\%$; $n = 593$, $M = 73.82\%$; $n = 230$, $M = 76.86\%$), respectively. The most reliable code on the Toddler Module was Response to Name ($n = 309$, $M = 98.28\%$). The least reliable item for Module 1 was Spontaneous Initiation of Joint Attention ($M = 33.88\%$), while Descriptive, Conventional, Instrumental, or Informative Gestures had the lowest reliability on Module 2 ($M = 38.00\%$). The least reliable items were Hand and Finger and Other Complex Mannerisms in Module 3 ($M = 45.10\%$) and Quality of Social Response in Module 4 ($M = 37.99\%$). Finally, the least reliable item for Toddler Module was Unusual Eye Contact ($M = 15.52\%$).

**Conclusions:**

In conclusion, research-reliable coders performed better than clinically trained participants, which demonstrates that the increased training level needed to attain research reliability translates into greater accuracy. These findings suggest the need for consistent practice, consensus coding, and discussions to strengthen reliability. In addition, findings shed light on common coding challenges and provide areas to target
in future ADOS-2 training. Potentially, programs to improve fidelity, such as GAIN, suggest that clinicians and researchers may continue to sharpen ADOS-2 skills and boost overall autism acumen.

431.100 (Poster) Late Diagnosis of Autism Spectrum Disorder - What Do We Lose in the Meantime?  
A. Kawalec, K. M. Wilczyński\(^1\) and M. Janas-Kozik\(^2\), (1)Department of Psychiatry and Psychotherapy of Developmental Age, Medical University of Silesia, Katowice, Poland, (2)John Paul II Paediatric Center in Sosnowiec, Sosnowiec, Poland

Background:
Autism spectrum disorders constitute a heterogeneous group of disorders with a diverse clinical presentation. Additionally, the literature describes significant differences in symptomatology between females and males. For this reason, ASD diagnosis is a major challenge for clinicians and sometimes obtaining an appropriate diagnosis is delayed. As a consequence, in the case of many people on the autism spectrum, the introduction of appropriate therapeutic and rehabilitation interventions is significantly postponed. Due to this reason, there is a significant number of adolescents who are admitted to the psychiatric inpatient care with various symptoms, such as suicidal tendencies, hallucinations or aggression, who are diagnosed with an autism spectrum disorder in the course of treatment of comorbid mental disorders.

Objectives:
The aim of the study was to analyze the factors influencing the age of diagnosis and the time needed to make it from the first visit to the diagnostician.

Methods:
Data analyzed in the study was extracted from the medical records of patients admitted to one of the biggest child and adolescent psychiatry wards in Poland. The sample consists of 211 patients with diagnosis of autism spectrum disorder, 54% (\(n=114\)) of which were boys. The statistical analysis was made using StatSoft Statistica v. 13.0.

Results:
The median age of diagnosis was 12.48 (SD±3.78). Over the half of participants presented elevated risk of suicidal tendencies. At the admission, 40% (\(n=81\)) were in mood decline and 27.5% (\(n=58\)) were aggressive. Delusions were present in 34% (\(n=70\)) of patients, and hallucinations in 23% (\(n=47\)) of them. Both hallucinations (p<0.001) and mood decline (p<0.001) appeared more often in girls. The authors also reviewed the literature concerning time and age of diagnosis in various countries in Europe and the United States.

Conclusions:
Despite the constant improvement of the available diagnostic criteria and a lot of attention devoted to the training of future diagnosticians, the process of clinical evaluation of people on the autism spectrum leaves much to be desired. Meanwhile, postponing the diagnosis significantly increases the risk of other mental disorders, which is visible, for example, in the female population where the problem of underdiagnosis is particularly common.

Y. C. Chiu\(^1\), C. Y. Huang\(^2\), Y. T. Yu\(^3\) and K. L. Chen\(^4\), (1)Department of Occupational Therapy, College of Medicine, National Cheng Kung University, Tainan, Taiwan, (2)School of Occupational Therapy, College of Medicine, National Taiwan University, Taipei, Taiwan, (3)Department of Physical Medicine and Rehabilitation, National Cheng Kung University Hospital, College of Medicine, National Cheng Kung University, Tainan, Taiwan, (4)Institute of Allied Health Sciences, National Cheng Kung University, Tainan, Taiwan

Background: Children with autism spectrum disorder (ASD) are described as having deficits of social interaction, communication and restricted repetitive behavioral patterns. The Childhood Autism Rating Scale™, Second Edition (CARS2) was designed to measure the symptom severity of children with ASD and is one of the most widely used assessment tools used for this purpose. The CARS2 can provide a profile of a child’s autistic symptom severity and effectively discriminate among children with mild, moderate, and severe ASD symptoms. The Chinese version of the CARS2 (CARS2-C) has been developed, and its psychometric properties need to be verified.

Objectives: This study aimed to investigate the reliability and validity of the CARS2-C, including the internal consistency and convergent validity.

Methods: Children with ASD aged from 3 to 12 years were recruited in this study. The CARS2-C includes two versions: the standard (CARS2-C-ST) and high function (CARS2-C-HF) versions. All participating children were assessed with the CARS2-C-ST, and
participants whose IQs were higher than 80 were additionally assessed with the CARS2-C-HF. To collect data on their social behaviors, their caregivers were asked to complete the socialization domain of the Vineland Adaptive Behavior (VABS) and Social Responsiveness Scale, Second Edition (SRS-2). Cronbach's \( \alpha \) and Pearson's correlation coefficients were respectively used to examine the internal consistency and convergent validity of the two versions of the CARS2-C with the VABS and SRS-2.

Results: A total of 98 ASD children participated in this study (82 boys; age range: 36–125 month), and 48 of them were additionally assessed with the CARS2-C-HF (39 boys, age range: 60–125 months). Both versions of the CARS2-C showed good internal consistency (CARS2-C-ST: Cronbach’s \( \alpha = 0.856 \); CARS2-C-HF: Cronbach’s \( \alpha = 0.834 \)). The results showed that both versions of the CARS2-C had good convergent validity with the socialization domain of the VABS (CARS2-C-ST, \( r = -0.740 \); CARS2-C-HF, \( r = -0.754 \), all \( p < .05 \)). Moreover, both versions of the CARS2-C were also significantly associated with the SRS-2 (CARS2-C-ST, \( r = 0.723 \); CARS2-C-HF, \( r = 0.767 \), all \( p < 0.05 \)).

Conclusions: Our results provide psychometric evidence on the CARS2-C. The CARS2-C has good internal consistency and convergent validity in measuring the symptom severity of children with ASD. These findings suggest that the CARS2-C is a reliable and valid assessment for measuring symptom severity in children with ASD in Taiwan.

431.102 (Poster) A Rasch Analysis of the M-CHAT-R/F Questionnaire in a Community Sample

E. Bonney, L. Hantzsch, C. Borja, S. Jacob, J. J. Wolff and J. T. Elison, (1)University Of Minnesota - Minneapolis, MN, Minneapolis, MN, (2)University of Minnesota, Minneapolis, MN, (3)Department of Psychiatry, University of Minnesota - Twin Cities, Minneapolis, MN

Background: The modified Checklist for Autism in Toddlers-Revised, with Follow-Up questionnaire (MCHAT-R/F) is a 20-item scale designed to facilitate early identification of autism in low-risk populations. Despite its widespread use, its psychometric integrity has not been comprehensively investigated in community samples.

Objectives: This study was performed to examine the measurement properties of the MCHAT-R/F using Rasch Analysis.

Methods: Rasch analysis was undertaken on MCHAT-R/F data derived from a community sample of 1355 children (670 girls, 685 boys) with an average age of 21.4 (SD: 2.5) months (range: 17-42) using the WINSTEPS software. Analyses was performed on the full 20 items. Tests were conducted to evaluate the overall model fit, suitability of response options, unidimensionality, targeting, and item fit.

Results: Several properties of the scale were deemed satisfactory. The response options performed adequately well, and the scale met the criterion of unidimensionality. The item separation index (10.7) and reliability (0.9) were observed to be very high, suggesting that the items could precisely discriminate ten levels of difficulty. However, person separation (0.1) and reliability (0.01) were very low, and the scale demonstrated poor targeting, indicating a mismatch between item difficulty and respondent’s abilities. Out of the twenty items, five were also identified as misfits.

Conclusions: The Rasch model showed that the 20-item MCHAT-R/F could be reduced to a 15-item instrument as this will potentially make the scale more efficient in measuring autistic traits in community infants and toddlers. Further, the present findings highlight that the inclusion of 5 misfit items in the current measure may have unintended practical consequences (e.g., misidentification). Though the MCHAT showed promise in discriminating between ability levels, the poor targeting demonstrated that it may not be effective or particularly granular in a general population or community sample.

431.103 (Poster) School & Autism – Development of a Diagnostic Tool to Assess Individual Barriers in Inclusive School in a Participatory Research Group

Background:
A learning environment fitted for each individual’s needs is the key to inclusion, especially when it comes to autistic students. Since the introduction of UN-CRPD inclusive education must be realized by schools, by providing “reasonable accommodation” (Art.24), thus focusing on the 4 A’s: availability, accessibility, acceptability and adaptability (Riedel 2010; Sauter 2013). This highlights the need to recognize individual barriers as a first step to remove them and provide equity in education.

We will present the research-project schAUT which is based in a neurodiverse understanding of autism (Walker 2014, 2015). Accordingly, autism is recognized as an altered (sensory) perception of the environment, resulting in an increased level of arousal (Marco, et al. 2011; Perrykka and Hohwy 2020), that might make autists more vulnerable to sensory and social barriers. It is thus imperative to assess individual barriers, especially for school aged children if we want to provide an inclusive environment. The aim of the project is to develop a tool to identify subjective barriers.

The project is organized as participatory research (Farin-Glattacker et al. 2014) jointly carried by Humboldt-University Berlin, Goethe-University Frankfurt and White Unicorn e.V., an association for self-advocacy of autistic people in scientific contexts.
INSAR 2023 ANNUAL MEETING ABSTRACTS

Objectives:
The main objective of the project is to develop a diagnostic instrument to assess individual barriers of autistic students in the form of a questionnaire for elementary and secondary schools, which can be filled out by students themselves to measure their sensitivity to possible barriers.

Methods:
Based on 27 Barriers, identified by White Unicorn e.V. (2016), we first conducted an open-questions online survey to find examples for each barrier in schools (n=700). For each barrier, the four most common examples were transformed into items for a second quantitative pre-test with students (n=366; av. age: 14.5). Data from this survey were used for item selection based on factor analysis, taking item-selectivity and difficulty into account. Finally, the 50 selected items were once again reviewed in a third pretest (n=618, av. age: 13).

Based on these pretests, we developed a questionnaire consisting of 50 items, testing 25 Barriers, which is currently tested in a two-phase validation setting in 19 schools (n=1094). The second phase is currently executed.

Results:
The final version of the questionnaire showed very good reliability (Cronbach α = 0.96; corrected split half-reliability = 0.97). Throughout the tests, we saw a significantly higher barrier risk for autistic in comparison to non- or maybe-autistic participants.

Further results from the current second testing phase, including statements about test-retest reliability, will be presented during the talk.

Conclusions:
As schools are required to identify individual barriers, our questionnaire can help improve inclusive education for autistic students. Our tool is thus a contribution to supporting the goals stated in UN-CRPD and might be a way to introduce new solutions for interventions, by changing the environment and making it appropriate to each individual’s needs. Ultimately, everyone - not only autistic students - will benefit from this.

431.104 (Poster) Sex Differences in the Phenotype of Children with Autism Spectrum Disorders of Known Genetic Aetiology

J. Wolstencroft, I. D. Imagine and D. H. Skuse, (1)UCL GOS Institute of Child Health, London, United Kingdom, (2)UCL GOS Institute of Child Health, UCL, London, United Kingdom, (3)Institute of Child Health, London, United Kingdom

Background:
Overall, ASD is less commonly diagnosed in girls than boys (1:3), but there have been consistent reports over many years that the sex ratio tends toward equality in children with moderate to severe intellectual disability (ID), and that observation is linked to the finding that pathogenic genetic anomalies are relatively more common among girls with ASD than boys. To date, no study has addressed the question, are the phenotypes of non-autistic symptomatology (e.g., adaptive function, co-occurring conditions) similar or different in girls with ID-associated ASD compared with boys of equivalent intellectual disability?

Objectives:
We aimed to identify the range and severity of ASD symptomatology and co-occurring psychopathology in boys and girls with ASD of genetic aetiology. They had been identified in the course of the IMAGINE-ID study, a national investigation of children with genetic anomalies that had been identified by the UK National Health Service, which were associated with intellectual disability (ID), and all had been identified with pathogenic CNV or SNV. For comparison purposes, we undertook an equivalent analysis of sex differences in terms of common co-occurring symptom clusters (e.g., ADHD, anxiety) in a sample of children with ID of genetic aetiology that was not associated with ASD traits.

Methods:
Measures included the Development and Wellbeing Assessment (DAWBA), the Strengths and Difficulties Questionnaire (SDQ) and the Adaptive Behavior Assessment Scales (ABAS). The DAWBA is a comprehensive online interview, which has been used in national UK surveys of children’s mental health. In addition, an Index of Multiple Deprivation (IMD) was obtained from postcode data.

Results:
Data were obtained on 776 participants with ASD (4 to 19 years; M=9.1, SD=3.9), (36.1% female) and 1410 participants with ID that was not associated with ASD traits (48.2% female). Among those with ASD, there were no significant sex differences on the ABAS general adaptive composite score (p=.8) or on parental estimates of mental age (p=.8). Girls with ASD were significantly more likely to have emotional difficulties (p<.001) and better prosocial abilities (p=.03) than boys. There were no sex differences on conduct or hyperactivity problems by sex. Among those with ID who lacked autistic traits, there were significant sex differences in emotional difficulties and prosocial abilities, as well as significant differences in hyperactivity and conduct problems. Sex differences in emotional difficulties and

395
prosocial ability in children with ASD remained unchanged when tested by multiple linear regression models using chronological and developmental age as co-variates.

Conclusions:

There are sex differences in terms of co-occurring conditions between males and females with ASD of genetic aetiology in terms of emotional dysregulation and prosocial behavior, both of which are significantly greater in girls. These sex differences are not exclusively found in those with ASD but can also be observed among children with equivalent degrees of ID that is not associated with ASD traits.

431.105 (Poster) Should Implicit Bias be Studied in Differential Diagnosis of ASD in Specialized Centers?

A. I. Mendez, C. Klaiman, K. Pickard, A. Klin and W. Jones, (1)Emory University, Marcus Autism Center, Atlanta, GA, (2)Emory University, Atlanta, GA, (3)Emory University School of Medicine, Marcus Autism Center, Atlanta, GA, (4)Marcus Autism Center, Emory University School of Medicine and Children's Healthcare of Atlanta, Atlanta, GA, (5)Marcus Autism Center, Atlanta, GA

Background: There is ample evidence for racial and ethnic disparities in access to early assessment of ASD (Mandell et al., 2009, for review). African American and Latino children are more likely to experience increased barriers to accessing care and delays in diagnosis. Such disparities typically lead to underdiagnosing ASD. However, it is unclear how disparities may present in specialized assessment rooms – once families have surmounted barriers to accessing services.

This study asks whether implicit bias can influence diagnostic determinations of minority children by clinicians. Implicit bias occurs when unconscious associations lead to negative evaluations based on irrelevant characteristics. Healthcare professionals are just as likely to be influenced by implicit biases as the general population, and such biases can influence diagnostic decisions (FitzGerald & Hurst, 2017). Providers working with autistics are more likely to associate positive words with typical development and negative words with ASD—which could mirror implicit biases towards minority children (Barnes-Holmes et al., 2006). Implicit biases are complex to assess and remain understudied in the context of ASD assessments.

Objectives: This study explores whether implicit bias is a factor in diagnostic determinations in specialized centers. We examined differences between Expert Clinician Diagnosis (ECD) of ASD and an objective eye-tracking-based ASD diagnostic classifier.

Methods: Secondary analyses were performed on demographic and diagnostic data for 475 16-30-month-old children enrolled in a multisite, prospective, double-blind clinical trial (NCT03469986) investigating the utility of an eye-tracking-based device for the diagnosis of ASD relative to current best-practice ECD.

Eye-tracking and clinical procedures were conducted independently. Clinical procedures included standardized assessments, parent questionnaires, and other measures which led to an ECD. Eye-tracking quantified the moment-by-moment visual scanning of social scenes relative to age-expected normative data–demonstrating hundreds of data-driven convergences of group attention to scene elements at the same moments and divergences thereof in autistic toddlers.

We compared the proportion of ECD diagnoses of ASD to the eye-tracking-based device assignment of an ASD diagnosis by race and ethnicity.

Results: Chi-squared analyses revealed statistically significant differences in diagnoses of ASD through ECD by race($p=0.0476$) and ethnicity($p<0.001$). In contrast, chi-squared analyses revealed no statistically significant differences in the assignment of an ASD via eye-tracking based on race($p=0.827$) and ethnicity($p=0.210$). While African American and Latino children were diagnosed with ASD more frequently by ECD, this bias was absent in results via the eye-tracking diagnostic classifier (Table 1).

Conclusions: The ECD of ASD is complex and influenced by numerous factors. These results show differences in the differential diagnosis of ASD by race and ethnicity between ECD and objective eye-tracking-based methods. While this study was not designed to probe whether or not implicit bias plays a role in ECD assignments, results suggest that biases based on demographic factors exist. Interestingly, the bias observed in ECD was toward a higher prevalence rate of ASD in minority children relative to the objective eye-tracking method. It is possible that the field may have overcorrected for underdiagnoses and may have shifted towards over-diagnosing ASD in minority children. Future studies should further probe these possibilities.

431.106 (Poster) Spanish Cultural Adaptation of the Autism Spectrum Quotient, Child Version (AQ-Child)

C. J. Fernandez Alvarez, J. A. Yon-Hernandez, D. Z. Wojcik, A. Huete-García, A. N. Mota Rodriguez, A. Bejarano, E. Diez Villoria, M. Posada and R. Canal-Bedia, (1)University of Salamanca, Salamanca, Spain, (2)Instituto Universitario de Integración a la Comunidad INICO-InFoAutismo, M.I.N.D. Institute, UC Davis, Salamanca, (3)InFoAutismo- Instituto Universitario de Integración a la Comunidad (INICO), Salamanca, Spain, (4)Sociology and Communication Department, University of Salamanca, Salamanca, Spain, (5)University of Salamanca, Salamanca, Spain, (6)UNIVERSITY OF SALAMANCA, Salamanca, Spain, (7)Institute of Rare Diseases Research, Instituto de
Background: The autism spectrum condition (ASC) is a lifelong, heterogeneous neurodevelopmental condition characterized by difficulties in social communication and stereotyped patterns of behaviors and interests. Considering that ASC prevalence has increased in the last three decades, research is now also focusing on studying the Broader Autism Phenotype (BAP), which refers to mild manifestations of autistic-like behaviors present in the general population. Therefore, it is important to have effective screening tools to detect ASC and the BAP in the general population. The Autism Spectrum Quotient, Child version (AQ-Child) is a 50-item parent-report questionnaire developed to assess autistic traits in children 4 to 11 years of age. This tool was designed as a parent-report questionnaire. The scores in the AQ-Child range from 0 to 150, where higher scores correspond to behaviors more characteristic of autism.

Objectives: The aim of this study was to translate and culturally adapt the AQ-Child to Spanish to use it as part of a school-based screening program in Salamanca, Castille and Leon, Spain.

Methods: The AQ-Child was translated following the guidelines of the World Health Organization (WHO), pilot tested, and then administered online through the Qualtrics platform of the Universidad de Salamanca to a school-population sample (n = 624).

Results: A total of 56 cases screened positive on the AQ-Child, Spanish version (AQ-Child-SV). From the assessed children, 33 were identified with autism spectrum condition, 4 were identified with the broader autism phenotype, and 24 with other neurodevelopmental disorders or non-ASC. For the Spanish version of the AQ-Child sensitivity was .71 and specificity .96. Positive and negative predictive values were .54 and .98 respectively.

Conclusions: The data indicates that the Spanish version of the AQ-Child appears to be a reliable instrument to screen ASC and the BAP in school-age children. Using the Spanish version of the AQ-Child in the Spanish education system may improve the identification of ASC-related behaviors in children aged 4 to 11 years, who may have gone unidentified by early detection programs and could be at a greater risk of suffering social exclusion and academic failure due to their behavioral difficulties.
sensitivity was 31% and 37% for Withdrawn scale and 23% and 30% for the DSM-PDP scale; Positive Predictive Value ranged 88% -100% and Negative Predictive Value 63%-70% for both Withdrawn and DSM-PDP scales in HR-ASD infants.

Conclusions:

Although the differences in social-emotional aspects between HR-ASD or HR-NDD infants and typically developing infants detected using the CBCL 1½-5, the weak predictive values suggested to consider the CBCL 1½-5 for monitoring HR infant neurodevelopment in association with more sensible and specific screening tools.

431.108 (Poster) The Discrepancy between Adaptive Behavior and Intelligence Is Associated with Internalizing and Externalizing Behavior Problems in Autistic Children and Youth

Background: Previous studies have demonstrated that children with autism show lower levels of adaptive behavior than their non-autistic peers. Furthermore, there seems to be a discrepancy between the level of adaptive functioning and the level of intellectual functioning in autistic individuals. Findings in autistic adults suggested that the gap between adaptive behavior and intelligence was associated with behavior problems.

Objectives: The objective of the present study was to provide increased insight in the discrepancy between adaptive behavior and intelligence in autistic children aged between 2 and 18 years. Moreover, we wanted to investigate the role of this discrepancy in behavior problems in children with autism.

Methods: Eighty-nine children (21 girls and 68 boys) with a clinical diagnosis of autism spectrum disorder participated in this cross-sectional study. The average age of the participants was 105.91 months (SD = 51.03), and the majority of them had an intelligence in the average range (total IQ estimates: M = 90.23, SD = 19.65), with 12 of them having a co-occurring intellectual disability (ID). Parents completed the Dutch translation of the third version of the Adaptive Behavior Assessment System (ABAS-3-NL; Kreemers et al., 2020) and the third version of the Children Behavior Checklist (Verhulst & Van der Ende, 2013), and intelligence was assessed using appropriate intelligence tests.

Results: The adaptive behavior of children with autism was significantly lower compared to population-based norms for all adaptive domains and for the General Adaptive Composite score, and this was also the case for the subgroup of autistic children without co-occurring ID. On average, the adaptive behavior of the autistic children was situated one standard deviation below their intelligence (M = 15.79, SD = 19.91), and this discrepancy between adaptive behavior and intelligence significantly differed from zero, t(83) = -7.27, p < .001. The gap between adaptive behavior and intelligence was even larger when focusing on the subgroup of autistic children without ID (M = -19.77, SD = 17.60). The adaptive behavior of 55% of the autistic participants was at least one standard deviation below their intelligence, and the adaptive behavior of 38% of the children with autism fell within a one standard deviation range from their intelligence, leaving 7% of the participants with an adaptive behavior score more than one standard deviation above their intelligence score. Two hierarchical linear regression analyses revealed that after controlling for age and sex, the discrepancy between adaptive behavior and intelligence was significantly predicting internalizing behavior problems, β = -.42, t(76) = -4.03, p <.001, pr² = .42, and externalizing behavior problems, β = -.24, t(76) = -2.27, p = .03, pr² = .06.

Conclusions: Using the ABAS-3-NL, our study showed lower adaptive behavior than intelligence in the majority of the 89 autistic participants aged 2-18. Adaptive behavior was associated with internalizing and externalizing behavior problems. These findings showed vulnerabilities in those with autism, beyond the diagnostic criteria. Therefore, it is warranted to examine adaptive behavior in the context of assessment and intervention, and to handle expectations based on intelligence with great care.

431.109 (Poster) The Eye of the Beholder: Sex Differences in Parent and Teacher Report of Autistic Traits on the Social Responsiveness Scale

O. C. Putnam, T. McFayden and C. Harrop, (1)Department of Allied Health Sciences, University of North Carolina - Chapel Hill, Chapel Hill, NC, (2)University of North Carolina at Chapel Hill- Carolina Institute for Developmental Disabilities, Chapel Hill, NC

Background: Identifying the needs of autistic girls and women is an increasingly urgent call from researchers and stakeholders. Achieving this goal is made more difficult by the historical “male bias” demonstrated by clinicians, educators, and research measurement that tends to overlook autistic traits in females. Numerous studies have reported that parents rate their autistic daughters’ social communication difficulties as greater than those observed by clinicians. Previous studies with predominantly male samples have found mixed levels of agreement between parents and teachers and suggest that rating and agreement on social traits in autistic youth are context- or characteristic-dependent. Disparity between reports may be greater for females, who may engage in more camouflaging behaviors in classroom settings and are at risk of being overlooked by teachers.
Objectives: The current study aims to examine potential discrepancies between parent and teacher rated autism characteristics in a large sample of males and females. Based on previous research, we predicted that the difference between parent and teacher reports would be greater for females, with teachers underreporting autism characteristics.
